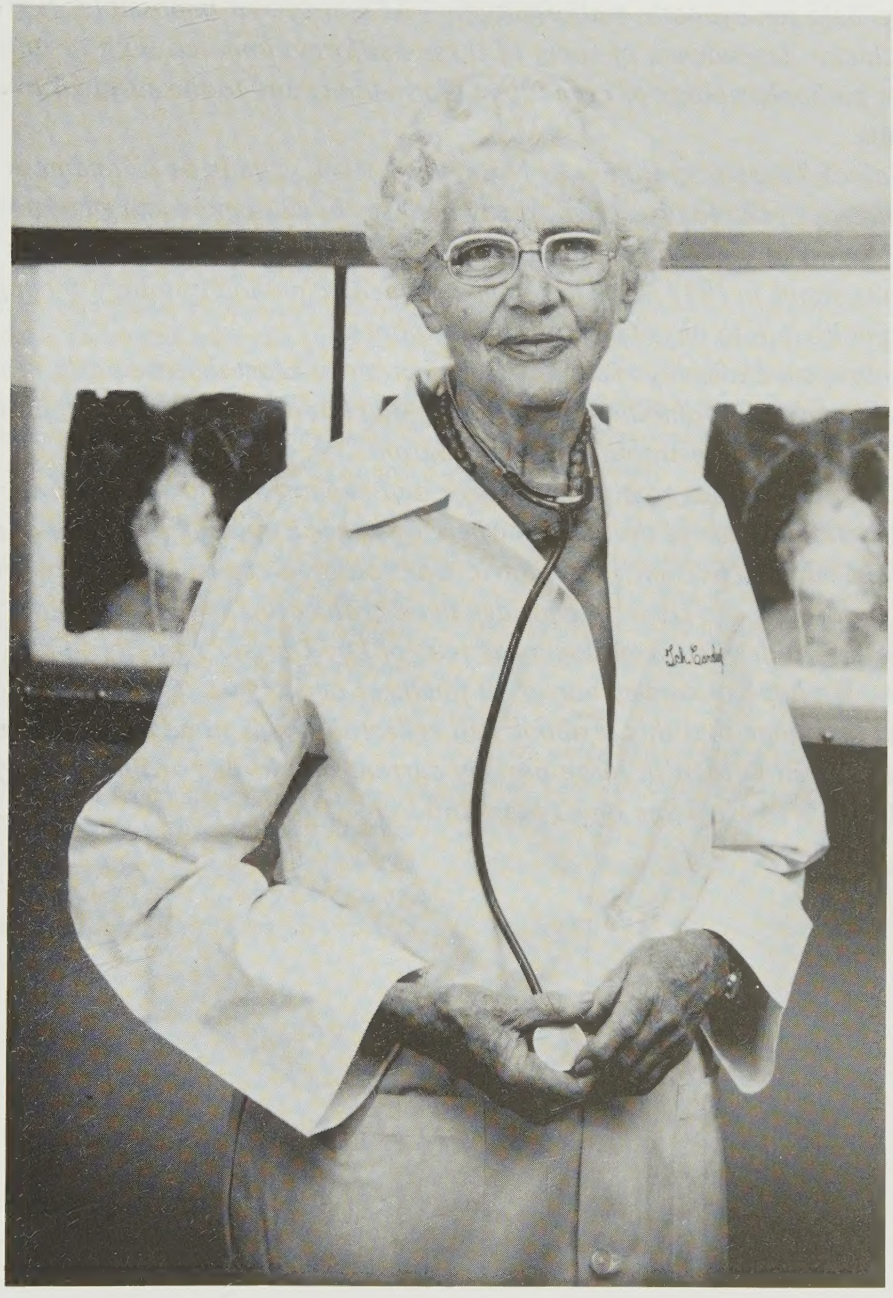
DEDICATION



Dr. Helen Brooke Taussig in the Conference Room named after her in Texas Children's Hospital.

Dr. Helen Taussig had a profound influence on the professional lives of most of the authors of this book as well as on the personal life of many of us. She visited this medical center often, lecturing, consulting on patients, and having informal conversations with the students and house staff. Because of her warm manner and directness, and her intense concern for other people, she acquired devoted friends and disciples among physicians and laymen all over the world.

We acknowledge her many contributions to science and to clinical medicine, but it is her gift to us as a marvelous human being that prompts us to dedicate this work to her.

Dr. Taussig stands as the acknowledged founder of Pediatric Cardiology. In the era when definitive help for cyanotic malformations was considered impossible, her observation of the ductal dependence of some of these malformations led both to an understanding of the pathophysiology of cyanotic malformations and to the surgical treatment of these patients.

The first Blalock-Taussig operation in November, 1944, stands as a landmark in the history of Pediatric Cardiology and led, many believe, to subsequent surgical treatment of virtually all forms of both congenital and acquired heart diseases. Publication of her clearly written textbook in 1947 made the often complicated pathophysiology of congenital heart defects intelligible to physicians of all disciplines.

Dr. Taussig proposed altering risk factors for coronary heart disease early in life for all children; an innovative if ambitious undertaking that has not yet been widely practiced, although many accept the desirability of the program.

One of her many activities was to encourage and support her former fellows. Texas Children's Hospital was one of the centers where a former trainee of Dr. Taussig's (Dan McNamara) headed the Division of Pediatric Cardiology. Because she considered her fellows her "children," she came to consider those trained by her fellows her "grandchildren." Texas Children's Cardiology was part of Dr. Taussig's family, and we miss her very much. We hope to convey our great fondness and respect for Dr. Taussig with this dedication and hope that this textbook will reflect the high standards she taught.

This book has been written in large part by current and former trainees and faculty from Baylor College of Medicine and Texas Children's Hospital.

Preface

The clinical practice of Pediatric Cardiology started in the early 1930's–1940's when pioneers in the yet unborn specialty were beginning to sort out the mysteries of congenital malformations. They started to put together those pieces of the puzzle that were available at the time, namely the electrocardiogram (limb leads only), the radiographic (especially the fluoroscopic) image of the heart, the physical examination, and with a limited yield, the "history." There was the all too inevitable opportunity to check the manifestations of the anomalies against the later autopsy findings.

The late Dr. Helen Taussig, to whom this work is dedicated, was a master at this. She remarked that, while there was no specific treatment for the patients during the early years, she sensed that these efforts at specific diagnosis were surprisingly comforting to the parents. When it became essential to distinguish one cyanotic malformation from another in order to select the correct operation, cardiac catheterization and angiocardiography became practical tools and Pediatric Cardiology developed precipitantly.

The clinical practice of Pediatric Cardiology preceded by many years the body of scientific knowledge pertinent to the field which was uncovered by research. Much of what had been learned in the clinical area was largely on the basis of deductive reasoning, but that approach had carried Pediatric Cardiology up to only a certain limit. Basic research promoted the unravelling of the scientific basis of the discipline, and this in turn advanced the clinical management of the patient.

These volumes seek to present what is known today about the preferred methods of management of the patient as well as the scientific foundation for these methods. The basic science of Pediatric Cardiology is beginning to catch up and appropriately lead the way to improved patient care and to prevention of some forms of heart disease.

The Sub-Board of Pediatric Cardiology, recognizing the needed exchange between science and practice, urges—indeed demands—that training programs include basic science courses in their curriculum, the teaching of research methods to trainees, and hands on experience in the laboratory working with an active and productive investigator. Thus, it seems timely that a text devoted to the practice and science of Pediatric Cardiology make its appearance now.

We would like to express our sincere appreciation to our assistants, Candy Liedtke, Paulette Snowden, and Steven Neish, M.D. without whom the task would have been insurmountable.

Houston, Texas

UNIT 2

NONINVASIVE DIAGNOSTIC METHODS

CHAPTER 43

History and Physical Examination of the Cardiovascular System

Desmond F Duff
Dan G McNamara

Despite major advances in noninvasive diagnosis, especially cardiac ultrasound, the history and physical examination remain important as a screening method in first the detection of heart disease in infants and children and then the evaluation of its severity.

There are a few congenital malformations in which the anatomical defect can be defined with a high degree of accuracy by physical examination alone. Usually, however, precise diagnosis requires graphic studies, ultrasound imaging, and often cardiac catheterization and angiocardiography.

Since the majority of patients who have critical congenital heart disease present during the first year and especially in the first few weeks of life, the first part of this chapter emphasizes the role of the history and physical examination in that age group.

The term "disease" is used in this chapter to indicate any departure from normal and includes congenital malformations as well as acquired or infectious or degenerative processes. "Disease" may also denote functionally benign departures from normal as well as important or life-threatening pathologic conditions.

In a prospective longterm followup study, Hoffman and Christianson[1] reported that, for subjects with congenital heart disease, the diagnosis was made in 46% by the age of 1 week and in 88.3% by the age of 1 year; 98.8% were diagnosed by 4 years of age. The diagnoses were made or confirmed at autopsy in 39 subjects (23.9%), at operation in 23 (14.1%), after cardiac catheterization in 17 (10.4%), and from clinical examination alone in 84 (51.5%). When examining a newborn infant, it is helpful to keep in mind that about one third of the infants who subsequently prove to have important congenital heart disease may be discharged as apparently well from maternity hospitals.[2]

Congenital heart disease is the single most common major congenital anomaly; it is responsible for 3 to 5% of deaths during the first week of life and up to 33% of deaths during the entire neonatal period.[3] In addition, twice as many infants die in the first month of life as die after 1 year of age from this cause.[4]

IDENTIFICATION OF FUNCTIONALLY IMPORTANT HEART DISEASE IN INFANTS AND CHILDREN

Symptoms that may be associated with congenital heart disease in a small infant include the obvious ones such as cyanosis, tachypnea, and labored breathing. In addition, such infants may have feeding difficulties, failure to gain weight adequately, sweating, irritability, or lethargy.

In childhood, the patient may be able to verbalize complaints such as shortness of breath with exercise, fatigue, dizziness, or palpitations. Delay of sexual maturation may be a sign of serious interference with cardiac output in pubertal-age patients.

Cyanosis

Cyanosis (Greek: "kuanosis" = blueness) is a blue discoloration of the skin caused by the presence of deoxygenated blood within the capillary network. Lundsgaard and Van Slyke[5] stated in 1923 that cyanosis was due to the presence of 4 to 6 g or more of reduced hemoglobin in capillary blood. Cyanosis may be either peripheral or central.

The term "cyanosis," unspecified, simply means a blue color of the skin, mucous membranes, or nailbeds. In taking a history, physicians sometime disregard the fact that there are reasons other

than arterial oxygen desaturation for a bluish appearance of the skin or mucous membranes. The parents of a healthy individual might report quite accurately that their child does turn blue at times. The history taker might automatically interpret this to indicate hypoxemia, while the mechanism could be the benign phenomenon of acrocyanosis. This can result from unusual but nevertheless physiologic prominence of diffuse veins around the eyes, nose, or lips, especially in fair or blond children. The blue color could represent the phenomenon of intermittent vasomotor changes in the skin, cutis marmorata, which is a pink, marble-like mottling of the skin that appears on exposure to a cold environment and is common in children and some adults. Cutis marmorata is presumably caused by cutaneous small arterial constriction leaving visible small cutaneous blue venules. Ordinarily, these venules are obscured by a fully filled plexus of small cutaneous arteries giving the normal pink color to the skin. This phenomenon might be brought on in certain susceptible but healthy individuals by exposure to cold ambient temperature or immersion in chilly water.

A pathologic cause of acrocyanosis is the mechanism of cutaneous arterial constriction resulting from low cardiac output. Cutaneous arterial constriction is one of the body's mechanisms to conserve blood flow for the protection of vital organs. Cretins with reduced cardiac output typically manifest this phenomenon.

Individuals with low cardiac output and pulmonary edema may exhibit cyanosis that is related to both hypoxemia caused by ventilatory insufficiency and acrocyanosis caused by lowered cardiac output.

So-called "central" cyanosis is evident when there are 3 g or more of reduced hemoglobin in the arterial blood and the blueness is noted in the mucous membranes and tongue as well as in the nailbeds of the extremities, which are usually warm (rather than cold as in acrocyanosis).[6] Central cyanosis, which implies arterial blood oxygen desaturation, is caused by an intracardiac or intrapulmonary right-to-left shunt.

Central cyanosis may be physiologic up to 20 minutes after birth; however, beyond that time, it is almost always a manifestation of serious cardiac or respiratory disease.[6,7] In order for the lips and nailbeds to appear actually blue, the arterial blood oxygen saturation must be quite low, in the range of 60 to 70%. If there is polycythemia, then blueness can be detected by physicians at a higher level of saturation. A clinically detectable abnormality in color (dark red) of the lips, nailbeds, and mucous membranes occurs when the arterial blood oxygen saturation measures 75 to 85%. The oxygen tension at which this saturation of hemoglobin occurs is 32 to 42 mm Hg in the neonate because of the character of fetal hemoglobin and 42 to 54 mm Hg in the older infant after fetal hemoglobin has disappeared.

The amount of reduced hemoglobin in the circulating blood depends upon the total concentration of hemoglobin as well as the degree of desaturation of the arterial blood, i.e., the magnitude of the right-to-left shunt. The anemic infant with arterial blood oxygen desaturation therefore may not appear as cyanotic as the baby with polycythemia with the same percentage of desaturation. As was stated by Taussig in 1947, slight cyanosis in the infant with a hemoglobin level of 10 g may be a more ominous sign than deep cyanosis in the patient with a hemoglobin of 17 g.[8] Detection of cyanosis may be masked by skin pigment and may therefore be overlooked in black infants unless the tongue, mucous membranes, and nailbeds are examined. In the infant with a systemic blood oxygen arterial saturation of 85 to 90%, clinical cyanosis is usually not evident; however, desaturation may be suspected by virtue of a dark red discoloration of the fingers and toes.[9]

The importance of recognizing cyanosis is emphasized by the findings in the New England Regional Infant Cardiac Program, in which one third of infants with potentially lethal congenital heart disease had cyanosis as their major symptom and another third had cyanosis with respiratory symptoms.[10]

Differential cyanosis indicates cyanosis that is more pronounced either in the lower extremities than the upper or vice versa. In the first case, the usual pathologic cause is reversal of blood flow through a large ductus arteriosus so that the lower half of the body receives desaturated pulmonary arterial blood and the upper half receives the more highly saturated blood coming out of the left ventricle. There must be pulmonary hypertension at the systemic level for this to occur, and a difference of about 10 to 20 percentage points between the upper and lower extremities is required for the differential to be clinically apparent. Often, reversed flow through the ductus is not suspected on visual examination because the difference in oxygen saturation is too slight. If there is an associated large ventricular septal defect with considerable mixing at the ventricular level, the difference in oxygen saturation between the brachial and the femoral artery may be measurable only by oxygen analysis.

In transposition of the great arteries with pulmonary hypertension and large ductus, with the flow through the ductus from pulmonary artery to descending aorta, the upper half of the body has a lower saturation than the lower half, but again the difference has to be very pronounced to be seen clinically.

While differential cyanosis is an interesting phenomenon when observed, it occurs so rarely that it is seldom of much practical use from a diagnostic standpoint, and there are other, more reliable means of identifying the anomalies that produce differential cyanosis. Occasionally, despite equal oxygen saturation in upper and lower extremities, one gets the impression that the finger nailbeds are decidedly more cyanotic than the toe nailbeds. The explanation for this is not clear, but it is an important fact to keep in mind, since the clinician might erroneously suspect transposition of the great arteries with pulmonary hypertension and reversed flow through a ductus.

Other causes of cyanosis also may be arterial oxygen desaturation in association with respiratory diseases, hypoventilation related to central nervous system dysfunction, and abnormalities in the pattern of the transitional circulation of the newborn, e.g., persistent fetal circulation. Methemoglobinemia causes cyanosis, producing a lowered arterial blood oxygen saturation as measured by colorimeter methods but not by Van Slyke analysis or by oxygen tension (PO_2).[6] Methemoglobinemia is a rare cause of cyanosis but should be suspected if the arterial oxygen tension is normal and the oxygen saturation is low.[6]

Paroxysmal Hypoxemic Spells

Cyanotic attacks or hypoxemic spells need to be recognized and treated as an urgent matter. Although they are well described in many texts, it is important to know that these attacks are often misdiagnosed as "colic," seizures of nervous central origin, or sometimes the antics of an irritable and spoiled baby. Hypoxemic attacks can be very difficult for parents to recognize, and unless the physician actually witnesses a spell, it may be difficult to get

a clear history. A spell may simply be described as the behavior of a cyanotic infant that cannot be comforted.

The distinctive characteristic of spells is that the infant breathes quickly and with audible and visible distress. A close look at the infant's face will convince the examiner that the victim is in distress. While the arterial oxygen saturation does fall, so does the arterial blood pressure, and the resulting pallor may be more noticeable than increased cyanosis.

Spells may occur with those cardiac defects in which there is pulmonary stenosis or atresia in combination with an intracardiac communication. These are most common in tetralogy of Fallot but may occur in tricuspid atresia or even transposition. The attacks appear to occur in the infant who has only mild to moderate arterial desaturation at rest (a so-called "pink Tet"), and they are also more common and severe in the cyanotic child who is iron deficient.[8] They may occur in early infancy or first develop at 6 to 12 months of age. Taussig[8] noted a tendency to spontaneous improvement between 18 months and 2 years. Hypoxemic spells occur more frequently in the morning and after a feeding, although episodes can occur at any time of the day. They do not start during sleep. The probable sequence of events that leads to an attack consists of an initial decrease in systemic arterial resistance with a consequent increase in the magnitude of the right-to-left ventricular shunt. As a result, the arterial oxygen saturation drops to a critically low level. This presumably leads to a further decrease in systemic vascular resistance and progression of the hypoxemia. The development of metabolic acidosis compounds the problem. The respiratory center is stimulated by the decreased oxygen tension and decreased pH leading to hyperpnea. The infant becomes restless and agitated, thereby increasing the degree of cyanosis. Rarely, a clonic seizure may occur.

Associated with these symptoms, there is an increase in heart rate and a decrease or disappearance of the systolic murmur in tetralogy of Fallot as pulmonary blood flow decreases. This state usually resolves spontaneously after 1 to 5 minutes or may last for 20 to 30 minutes. These long-duration spells may end in death. Therefore recognizing spells early and providing for emergency surgical treatment are critical.

Squatting

Children with tetralogy of Fallot who are old enough to walk may squat down to rest after exertion. The infant who is not yet walking may pull up the legs in a bent-knee position when tired. Squatting is presumably a protective response to extreme hypoxemia in blood pressure in children with an intracardiac right-to-left shunt. There is great variability in the amount of exercise that a child with tetralogy of Fallot can tolerate before wanting to squat. In some instances, it is a matter of a few steps, while other children can undertake considerable activity before resorting to the squatting position. Squatting acutely increases systemic blood pressure, which reduces the right-to-left shunt and in effect improves pulmonary blood flow. Associated with the transient increase in blood pressure, the baroreceptors are stimulated, and via the vagus nerve, the heart rate slows.

Congestive Heart Failure

Heart failure occurs in some 30% of infants and children with congenital heart defects.[11] However, in those with serious cardiac lesions, 75% have congestive cardiac failure.[12] Of infants with congenital heart disease who develop cardiac failure, 90% do so during the first year of life.[13]

The earliest manifestation of congestive failure in infants may be a change in the pattern of respiration noted initially as simply tachypnea and, most extremely (and rarely), labored respiration with grunting and intercostal retraction.

Tachypnea

Tachypnea (Greek: "tachys" = swift; "pnoia" = breath) is defined as rapid, shallow respiration with a *persistently* fast rate of 60 beats or more per minute in the fasting, quiet newborn infant. Unlabored tachypnea may be overlooked unless the rate is counted for a full minute. Most healthy newborn infants under basal conditions have a respiratory rate of 45 to 60 breaths per minute; but after being fed, if restless, or after crying hard, the infant may have a respiratory rate that transiently increases to 80 to 100 per minute (Table 43–1).

In the infant with congestive cardiac failure, the increase in rate is a reflex response to an increase in pulmonary venous pressure or volume. This results from an increase in pulmonary blood flow because of a large left-to-right shunt or an anatomic obstruction to the return of pulmonary venous blood to the left heart. Alternatively, it may result from the increased hemodynamic resistance to left ventricular filling because of left ventricular failure and raised left ventricular end-diastolic pressure. This reflex is mediated at least in part by the vagus nerve and the J-receptors in the pulmonary interstitial space.[14,15] Talner[16] reported that modest elevation of pulmonary venous pressure to 8 to 10 mm Hg in the infant and 25 to 30 mm Hg in the adult may be associated with tachypnea. Increased capillary permeability and slower lymphatic drainage have been implicated as possible factors in this age difference.

Dyspnea

With increasing pulmonary congestion, the infant may become dyspneic (Greek: "dyspnoia" = difficult breathing) with grunting (i.e., forced expiration against a partially closed glottis), flaring of the alae nasi, and intercostal, suprasternal, and subcostal retraction. Compression of bronchi by dilated, tense, high-pressure pulmonary arteries may also contribute to increasing respiratory distress. The right middle lobe, left upper lobe, and left lower lobe bronchi are especially involved. There is also pressure on the bronchi by a distended left atrium within the angle of the carina.[17] This compression may lead to stasis of secretions within the tracheobronchial tree, causing areas of atelectasis and providing a nidus for infection. Air trapping may also occur secondary to edema of the bronchial or bronchiolar mucosa. This involvement of the respiratory tract causes coughing and wheezing and predisposes the infant to respiratory tract infections. In some infants, the respiratory problems dominate the clinical picture even in the absence of other signs of congestive cardiac failure and contribute to the failure to thrive, a result of the increased work of breathing.

Physical stresses for an infant include crying, large feedings, and defecation. Inquiry should be made into the breathing pattern and color following or associated with these activities. With congestive heart failure, an increased respiratory rate is common with feeding, grunting may be provoked, and panting is not unusual, especially if the infant has constipation.

Table 43–1. Respiratory Rate: Upper Limit

Birth–6 Weeks	*6 Weeks–2 Years*	*2–6 Years*	*6–10 Years*	*Over 10 Years*
45–60/min	40/min	30/min	25/min	20/min

Feeding Difficulty and Failure to Thrive

Feeding difficulty and failure to thrive are features that are commonly elicited from parents, although parents may not recognize their significance. The tachypneic and dyspneic infant lacks the energy to suck and tires quickly. The infant has to interrupt sucking in order to breathe and may fall asleep only to awaken again shortly afterward, irritable and apparently hungry. Alternatively, the infant may be lethargic and sleep excessively. Attempts to increase the volume of the feed may precipitate vomiting. Partly because of a deficient caloric intake, weight gain is poor. The extra work of breathing likewise contributes to growth failure. Much can be learned by listening carefully to the mother's or grandmother's observations, since a parent frequently has noticed rapid breathing or an alteration in the feeding pattern before it is observed by the attending medical staff. A normal infant can drink an age-appropriate amount (3 to 4 oz in the first month; 6 to 8 oz in older infants) in 20 minutes or less. Frequently, infants with heart failure require 30 or even 45 minutes to drink lesser quantities. In addition, parents may note a decrease in urine output, which could be caused by an inadequate intake of fluid or inadequate cardiac output.

Failure to thrive in infants with congenital heart disease has multiple contributing factors. In general, infants with large left-to-right shunts and/or chronic low cardiac output have the greatest problems, whereas infants with right heart obstructive lesions such as isolated pulmonary valve stenosis may grow normally or supernormally.[18] In some infants, growth remains poor despite an apparently normal caloric intake. Infants who have persistently fast and labored breathing may fail to gain weight because of the increased muscular work of continuous tachypnea. Under resting conditions, the oxygen cost of breathing is extremely small, less than 5% of the total resting oxygen consumption. With the increased respiratory effort associated with pulmonary congestion, the oxygen cost may increase to 30%.[19] Growth failure may have a genetic basis (e.g., short parents) in patients who also happen to have a congenital heart defect of a type unassociated with pulmonary congestion or low cardiac output.

Cheek and associates[20] have demonstrated that there is a reduction in the number of striated muscle cells in children with congenital heart disease, and Baum and Stern[21] have found a similar decrease in the number of adipose tissue cells in children with cyanotic congenital heart disease. It would therefore seem that chronic tissue hypoxia may interfere with cell replication. Since it appears that the adult complement of adipose cells is established by 1 year of age, chronic tissue hypoxia should theoretically be relieved early in life if an increase in adipose tissue cell and striated muscle cell number, leading to normal growth, is to be achieved.[22] Abnormalities of intestinal absorption add to the growth failure associated with a serious cardiac anomaly.[23] There is also some evidence to suggest that skeletal maturation may be retarded. White and associates[24] noted a deficiency of cortical bone growth in children and adolescents with congenital heart disease.

Sweating and Pallor

Traditionally, we are taught that excessive sweating in the infant with congestive cardiac failure results from increased sympathetic nervous system activity, as do pallor and tachycardia. However, the increased work of breathing also contributes in a great measure to sweating. Pallor results from constriction of the skin arterioles, the body's compensatory mechanism for a reduced cardiac output, to divert the available blood pool away from nonessential areas. Physicians often mistake the pallor for evidence of anemia.

Exercise Tolerance

Many patients exhibit no noticeable symptoms despite a structurally important congenital heart defect. For example, children with pulmonary stenosis, aortic stenosis, coarctation of the aorta, or atrial septal defect frequently participate in all normal activities. Their parents deny that the child has any noticeable exercise limitation. However, inadequate cardiac output, raised pulmonary venous pressure, or severely reduced pulmonary blood flow produces fatigue, shortness of breath, syncope, or a faint feeling if the circulation is stressed. The sensation of fatigue stems directly from ischemia of exercised muscle and, in patients with inadequate cardiac output, is ascribed to oxygen debt and local deficiency in blood flow.[25] Exercise intolerance can be a difficult symptom to gauge accurately in children, since children show a great variation in degree of interest and coordination ability for physical activity. Frequently, children are not aware of exercise intolerance until their defect is repaired, and they know "normal" for the first time. Customarily, we grade exercise intolerance using the New York Heart Association grading system I to IV. This classification is useful in taking a history from adolescents who are articulate. But in younger children, the accuracy of this subjective grading system is low. The physician must depend upon the reliability of games the observers have watched the child play or exercise in comparison with presumed healthy playmates. A structured exercise stress test may be needed to accurately evaluate exercise tolerance.

In pulmonary valve stenosis, easy fatigability and dyspnea occur with only very severe obstruction, enough to initially reduce the volume of blood flow returning to the left heart. In aortic stenosis, easy fatigability, angina, or syncope occurs with very severe stenosis.[26] However, we often encounter the patient with a high grade of obstruction who denies exercise-induced fatigue, angina, or syncope. As long as the hypertrophic left ventricle can eject an adequate stroke volume, although at the expense of high left ventricular pressure, the patient may remain free of symptoms. Objective signs of myocardial ischemia may be uncovered by exercise stress tests in the asymptomatic patient.

Sudden Death

Sudden "unexpected" death may occur in association with cardiovascular disease in children. In a large cooperative international study, over half of the patients who died suddenly were inactive at the time; only 10% were engaged in active sports. A previous history of syncope occurred in only 16%. Among children who had had no previous cardiac surgery, aortic stenosis was the most

common lesion. Both obstructive and nonobstructive cardiomyopathies were present in 16%, while 25% of the patients who had had no previous surgery had either Eisenmenger's syndrome or cyanotic congenital heart disease with pulmonary stenosis.[27] A history of either dizziness or syncope, especially that which is exercise induced, should be regarded seriously and investigated further. Glew and associates have stated that death in patients with aortic stenosis is often sudden but hardly "unexpected" if one considers not only a history but also the physical examination and the resting and exercise electrocardiogram.[28] A more complete discussion of sudden death may be found in Chapter 108.

Arrhythmias

In addition to the structural cardiac defects mentioned, arrhythmias may predispose the patient to sudden death. The lethal primary arrhythmias include prolonged Q-T interval syndrome, catecholamine-sensitive ventricular tachycardias, atrial fibrillation associated with the Wolff-Parkinson-White syndrome, and congenital complete AV block. A history of resting- or exercise-induced dizziness or syncope in patients with one of these arrhythmias should be considered a warning sign.

A child 5 years of age or older may be able to answer questions about precipitating events of syncope. Was the patient exercising or frightened before the dizziness or fainting occurred? Was there chest discomfort or palpitations? Was there any particular pattern to the occurrence of the episodes? For example, a girl first developed syncope at 8 years of age at a road junction on her way to school. She was diagnosed as having epilepsy. By 11 years of age, the episodes occurred almost exclusively at this spot. She became convinced that they were going to recur and would become alarmed and frightened when approaching the junction. Ventricular tachycardia was documented in association with the Romano-Ward syndrome of prolonged Q-T interval on the electrocardiogram. A 10-year-old child wih a normal Q-T interval had recurrent episodes of polymorphic ventricular tachycardia with exercise, and multiple episodes were also precipitated while in the hospital, during blood tests.

Benign vasovagal episodes are usually unassociated with exercise but may be brought on by emotional stress or by standing for long periods of time, especially if food or fluid intake has been inadequate. A resting, an exercise, and often a 24-hour ambulatory electrocardiogram may be helpful to determine whether the syncope is associated with an arrhythmia and by taking the blood pressure supine and after standing for 10 minutes.

Chest Pain

Chest pain is a fairly common complaint in individuals who prove to be healthy and in whom no pathologic cause can be identified. Inquiry should be made about family history of angina, recent cardiac deaths, school or family stress, separation, and the like. In the vast majority of cases, the chest pain has no organic basis. Chest pain may be a conversion symptom, but it may also be a symptom associated with depression even in children.[29] It is important, however, to identify those patients in whom chest pain has a cardiac cause. Such patients can be divided into three categories: patients with structural abnormalities, e.g., left ventricular outflow tract obstructive lesions, mitral valve prolapse, or congenital coronary anomalies; patients with acquired myopericardial disease, e.g., pericarditis, coronary disease, or previous history of Kawasaki disease; and patients with arrhythmias. Organic cardiac pain is usually a pressure or squeezing sensation rather than a sharp pain. It tends to be central in location rather than apical or lateral on the chest. It is not usually affected by respiration. It may be brought on by exertion and relieved by rest, and it carries greater significance if it is associated with dyspnea or syncope and/or palpitations.

The relationship of the pain to respiration should be questioned, since pain may occur with hyperventilation. The common benign "stitch" or precordial catch is usually aggravated by a deep breath.

Any relationship of pain to meals should be documented. An esophageal or gastrointestinal cause is found in about 20% of adults presenting with chest pain, but this is a rare cause in children.[30]

Chest pain in an otherwise well child is usually benign, especially if the pain is sharp in nature, laterally located on the chest, and brief in duration. The exact cause of chest pain remains uncertain in 40 to 50% of patients even after investigation.[31] Despite this, a careful history and physical examination are a sensitive means of discriminating between organic cardiac chest pain and nonorganic causes of chest pain.[30] As with the evaluation of murmurs, it is essential that anxiety is not unwittingly created in the child or family by an inconclusive evaluation. Physicians have the responsibility to identify pathology if it is present but also to avoid creating anxiety when no disease exists.

Past Medical History

History of previous important illnesses, medications, and hospitalizations may prove to be relevant. Was there any history to suggest myocarditis in the past in an infant or child who now presents with a congestive cardiomyopathy or endocardial fibroelastosis, or was there any history of exposure to potentially cardiotoxic drugs? For example, if doxorubicin hydrochloride (Adriamycin) is administered in a dose greater than 600 mg/m^3, a congestive cardiomyopathy occurs in more than 30% of cases.[32] Disopyramide, quinidine, and propranolol are negatively inotropic and may precipitate congestive cardiac failure.[33]

In a review of children with Hodgkin's disease, Greenwood and associates found that 7% of those who received thoracic irradiation developed constrictive pericarditis.[34]

Immunizations

The immunization record should be checked, since a significant number of infants either do not receive immunization at all or are immunized well after the recommended dates. Except for the critically ill infant with heart disease, immunizations should not be delayed, since pertussis and rubeola are especially dangerous for such patients.

Development and the Central Nervous System

Inquiries should be made regarding motor and intellectual development. While the majority of children with congenital heart disease display normal development, a few have coexisting intellectual, perceptual, or motor handicaps.[18] It is especially pertinent to know whether such problems exist before an operation to avoid the suspicion that the surgery may have led to the disability. Whenever possible, details should be documented preoperatively. Neurologic complications may occur in association with cyanotic heart disease; in particular, a history of stroke should be carefully elicited. Stroke is more common in children under two years of

age. It is more likely to occur in association with iron deficiency and with a systemic arterial oxygen saturation of 50% or less.

Headaches in patients with polycythemia may result from the intravascular plethora or could be the result of bone pain in older children and adolescents with marked polycythemia. Persistent severe headaches in the child who has coarctation of the aorta are a possible, but rare, manifestation of cerebral arterial aneurysm.

Pyrexia

A presenting complaint or prior history of an inflammatory illness in the patient with cardiac findings prompts investigation for Kawasaki disease, rheumatic fever, myocarditis, or endocarditis. In the infant under 2 years of age, Kawasaki disease is the most likely. Physicians in the 1980s are familiar with the manifestations of what appears to be a newly recognized disease (Chapter 89). Similarly for rheumatic fever, the major and minor Jones criteria should be sought by careful inquiry (Chapter 86).

A history of headache, vomiting, and undue somnolence with fever in the cyanotic child should lead one to suspect brain abscess.

While an identifiable cause for a bacteremia preceding endocarditis is obtainable in only about one third of cases, it is important to ask about the state of dental health, dental therapy, or other procedure that might have led to a bacteremia. Unrecognized dental abscess is an important cause. If a procedure was performed, it is important to determine whether antibiotic prophylaxis was given, its form, and the time sequence of administration.

History of the Pregnancy, Especially the First Three Months

It is important to take a detailed history to ascertain drug exposure or viral infection during the first 3 months of pregnancy, even though only 2% of congenital heart disease is considered to have an environmental etiology.[35] Table 43–2 lists some of the known teratogens.[36–45] In many cases, exposure to one of these agents has devastating effects on the developing fetus. Rubella causes not only cardiac anomalies (pulmonary branch stenosis and patent ductus arteriosus) but also blindness, deafness, and microcephaly with associated profound developmental delay.[36] It is tragic to see infants with the maternal rubella syndrome when it is so readily preventable. Similarly, the fetal alcohol syndrome and some of the other drug-related disturbances in morphogenesis can be prevented.[37] In some instances, the observation of drug exposure may require a modification of therapy during pregnancy rather than withdrawal of treatment as, for example, in the epileptic mother.[38,39] While there is strong evidence to implicate the causative factors outlined in Table 43–2, there is also some evidence to suggest that the amphetamines and sex hormones and perhaps infection with cytomegalovirus and coxsackievirus in early pregnancy may cause cardiac anomalies.[45]

Table 43–2. Teratogens

Causative Factor	*Risk of CHD*	*Defect*
Infection		
Rubella (1941)	50–80%	PDA, PBS, VSD
Drugs		
Diphenylhydantoin		
Fetal hydantoin syndrome (1975)	10%	PS, AS
Trimethadione		
Fetal trimethadione syndrome (1975)	50%	VSD, TF
Thalidomide (1962)	20%	TF, TA
Lithium (1974)	10%	Ebstein's anomaly
Alcohol		
Fetal alcohol syndrome (1973)	30–40%	VSD, ASD
Maternal Diseases		
Diabetes	3–4%	VSD, TGA, cardiomyopathy
Lupus erythematosus	?	complete AV block

Date (■) = when association first published.
PDA = patent ductus arteriosus.
PBS = pulmonary branch stenosis.
VSD = ventricular septal defect.
TGA = transposition of the great arteries.
PS = pulmonary stenosis.
AS = aortic stenosis.
TF = tetralogy of Fallot.
TA = truncus arteriosus.
ASD = atrial septal defect.

The Mother's Health

If the mother has diabetes, the fetus has a risk of congenital heart disease that is three to four times greater than that in the general population.[44] Ventricular septal defect and transposition of the great arteries are particularly common. In addition, there is a specific cardiomyopathy in the infant of the diabetic mother that is closely analogous to the hypertrophic cardiomyopathy of older children and adults but that regresses spontaneously in the majority.

In 1966, Hull and associates noted an interesting association between congenital complete AV block in the fetus and the presence of lupus erythematosus in the mother.[46] Since then, many studies have indicated that congenital AV block in the infant may precede the overt clinical manifestations of systemic lupus erythematosus in the mother by months or even years.[47]

In the latter part of pregnancy, particularly in the week or so prior to delivery, a coxsackievirus infection in the mother may cause acute myocarditis in the newborn infant. This can be a fulminant disorder associated with a high mortality. The illness in the mother may be a simple respiratory infection with or without pleurodynia.[48] The rubella virus may also cause myocardial cell injury and necrosis.[49]

Family History

Details of the family history should be explored because of the potential genetic implications. Inquiries should be made as to whether either parent has or had a congenital heart defect, and details of all siblings should also be clearly documented. The number of stillbirths and spontaneous abortions should be recorded, though it appears from studies by Warburton and Fraser that the incidence of these events in mothers who have children with congenital heart disease is the same as that in the general population, i.e., 1 to 1.5% stillbirths and 14 to 15% spontaneous abortions.[50]

If one parent is affected or if a previous sibling had a congenital heart defect, the risk of a recurrence is 1 to 5% depending on the type of defect previously documented. Recurrence is higher with

the more common defects; the risk is on the order of 4 to 5% if a first-degree relative has a ventricular septal defect. If there are two affected first-degree relatives, the risk is tripled. In the unlikely event of three affected first-degree relatives, a family would have to be considered a type C family in Nora's classification and therefore have a high recurrence risk on the order of 60 to 100%, i.e., significantly greater than that of a mendelian dominant lesion.[35]

In the New England Regional Cardiac Program, approximately one third of patients with congenital heart disease were found to have a positive family history of a congenital cardiac anomaly. There was also a concordance of defect in approximately 50% of cases.[10,51]

With increased survival following the successful management of infants and children with congenital heart disease, more people with congenital heart disease are reaching child-bearing age and therefore potentially increasing the risk of structural heart defects in their offspring. Recent data imply approximately a 10 to 15% risk of congenital heart disease in the offspring of mothers with congenital heart disease.

Careful inquiry should also be made about syndromes in the parents or in their immediate relatives that have dominant inheritance, e.g., Marfan and Holt-Oram syndromes or a recessive inheritance trait such as Friedreich's ataxia, cutis laxa, or pseudoxanthoma elasticum. About 8% of congenital heart defects have a genetic or chromosomal basis.[35]

One of the benefits of taking a history from the parents is that it gives the physician an opportunity to assess the family structure and the interaction between the parents, as well as between the parents and child. It also allows an initial assessment of the parents' capacity to comprehend an explanation of a cardiac lesion and of their ability to cope if their infant or child is going to require intensive investigations and perhaps surgical treatment.

Birth History

Details about the progress of labor, the method of delivery, and the Apgar score should be recorded. The importance of ascertaining these facts relates primarily to the differential diagnosis of infants with congenital heart disease. Asphyxia during labor or in association with delivery may be associated with persistence of the fetal circulation. This may manifest clinically as a very cyanotic infant with persistent pulmonary hypertension, transient myocardial ischemia, myocardial dysfunction, and congestive cardiac failure or simply as transient tachypnea.[52] The distinction from structural cardiac defects may require detailed investigations such as echocardiography or, rarely, cardiac catheterization. In addition, the stressed newborn infant may suffer from hypoglycemia and hypocalcemia, which may be associated with heart failure. Delay in clamping the umbilical cord or fetal-to-fetal transfusion in the case of twins may give rise to significant polycythemia, volume overload, and congestive cardiac failure.

Birth Weight

In the New England Regional Infant Cardiac Program, the birth weight of 2178 infants with 21 different cardiac diagnoses demonstrated that in all diagnostic categories except for d-transposition, pulmonary stenosis, and hypoplastic left heart, there was an abnormally low birth weight distribution.[53] This distribution was not affected significantly by major extracardiac anomalies. However, Noonan and Ehmke have noted that among infants with multiple extracardiac anomalies and congenital heart disease, over 60% are in the low-birth-weight group.[54] It is also clear from studies of Fyler and associates that infants of low birth weight have a poorer survival rate than do infants of normal birth weight and comparable heart defects.[51]

The premature infant has an increased incidence of ventricular septal defect and, of course, patent ductus arteriosus,[55] the latter usually in association with pulmonary disease.

At the other end of the spectrum, the baby that is large for gestational age, e.g., the infant of the diabetic mother, has three to four times the risk of congenital heart disease than does the general population. The infant with Beckwith-Wiedemann syndrome has a 50% incidence of congenital heart disease.[56,57]

Sex

Coarctation of the aorta, aortic valve stenosis and transposition of the great arteries are more common in male infants than in female infants. In female infants, two anomalies are more common than in males: septal defect and patent ductus arteriosus.

Review of Other Systems

A review of the other systems is a very important part of the clinical assessment, since extracardiac malformations are common and have been detected in about 25% of patients with congenital heart disease in clinical series and up to 45% in autopsy series.[58,59]

Abnormalities of the skeletal, gastrointestinal, genitourinary, and central nervous systems have all been described. According to Greenwood and associates, a "syndrome" of some type is present in 8.5% of infants with congenital heart disease.[58] It is therefore important that specific syndromes are recognized so that proper genetic counseling and patient management can be undertaken. Table 43–3 lists some cardiac defects that are found in association with the more common syndromes.[60] The commonest is Down syndrome, which occurs in 4% of infants with congenital heart disease. Of the children with Down syndrome, 40% have

Table 43–3. Common Syndromes and Associated Cardiac Defects

Syndrome	*Defect*
Down syndrome (1866) (trisomy 21)	atrioventricular septal defect
Edwards' syndrome (1960) (trisomy 18)	double outlet right ventricle ventricular septal defect
Patau's syndrome (1960) (trisomy 13)	ventricular septal defect
Turner's syndrome (1938) (XO)	coarctation, aortic valve stenosis
Noonan's syndrome (1968)	pulmonary stenosis hypertrophic cardiomyopathy
Williams syndrome (1961) (idiopathic hypercalcemic syndrome)	supravalvular aortic stenosis
Asymmetrical cry (1967)	ventricular septal defect tetralogy of Fallot
Carpenter's syndrome (1901)	patent ductus arteriosus ventricular septal defect

congenital heart disease, and approximately 40% of those have an endocardial cushion defect.[61]

Skeletal Abnormalities

Skeletal abnormalities represented 32.5% of the anomalies reported by Lamy and associates in association with congenital heart disease excluding Down syndrome.[62]

Vertebral anomalies are uncommon in isolated congenital heart disease and are usually present as part of a more complex syndrome, e.g., the VATER or VACTERL syndrome.[54,63] Nora and associates have noted that in the Klippel-Feil syndrome, congenital heart disease becomes more frequent with increasing degrees of cervical vertebral fusion.[64]

Scoliosis

Scoliosis is an important association and has been described in 2% of children with acyanotic congenital heart disease and 6% of those with cyanotic disorders. In most instances, scoliosis appears to be of the idiopathic variety; but in 15% of cases, there are associated vertebral anomalies.[65]

The Straight Back Syndrome

The straight back syndrome, which is caused by loss of the normal physiologic dorsal thoracic kyphosis, may have findings on cardiac examination that are suggestive of mild pulmonary valve stenosis or an atrial septal defect in the presence of a structurally normal heart. A murmur that is indicative of mild pulmonary regurgitation may be present in some cases. The anterior cardiac displacement in this entity appears to be the result of a more anterior insertion or attachment of the pericardium to the diaphragm rather than simply due to the narrow anteroposterior diameter of the chest.[66]

Identification of certain abnormalities of the hand and forearm may aid in the recognition of syndromes and therefore alert the physician to the possibility of a specific type of cardiac abnormality.[67,68] Table 43–4 outlines some of these diagnostic features and indicates the more common cardiac defects found with specific syndromes.

Palmar Creases

Single palmar creases, while present unilaterally in 4% and bilaterally in 1% of the normal Caucasian population, are frequently found in children with Down, trisomy 13, cri du chat, and de Lange's syndromes.[60]

Polydactyly

Polydactyly is present in the syndromes outlined in Table 43–4, and associated cardiac defects are found in 80% of infants with trisomy 13 syndrome and in more than 50% of those with Ellis-van Creveld syndrome. Cardiac lesions are less commonly diagnosed in Carpenter's syndrome and rarely with the Laurence-Moon-Beidl syndrome. Excluding trisomy 13 syndrome, the other three disorders are recessively inherited.[60]

Thumb Abnormalities with or without Anomalies of the Radius

Abnormalities of the thumb and radius can vary from hypoplasia to aplasia. In the Holt-Oram syndrome, the thumb may be absent or resemble a finger and be triphalangeal.[69] The Holt-Oram syndrome is a dominantly inherited disorder, while Fanconi's syndrome and radial aplasia with thrombocythemia are recessively inherited.[70,71]

Unilateral absence of the thumb or radius may also be part of a multiple anomaly syndrome such as the VATER syndrome.[63] In addition, Noonan has noted that hypoplasia of the thumb or radius when not part of a multiple anomaly syndrome is usually associated with a ventricular septal defect and severe pulmonary hypertension.[61] The term ventriculoradial dysplasia has been used to describe this association.[72] Gross abnormality of the upper limb, e.g., phocomelia, was seen following maternal exposure to tha-

Table 43–4. Abnormalities of the Hand and Forearm in the Detection of Disorders with Associated Congenital Heart Disease

Single Palmar Crease	
Down syndrome[67] (1866)	AV canal, VSD, PDA, TF
Patau's syndrome[67] (1960)	VSD, PDA
Cri du chat syndrome[67] (1963)	VSD, TA
De Lange's syndrome[67] (1933)	VSD
Polydactyly	
Ellis-van Creveld syndrome[67] (1940)	single atrium
Patau's syndrome[67] (1960)	VSD, PDA
Laurence-Moon-Biedl syndrome[67] (1865)	PDA, TGA, PS
Carpenter's syndrome[67] (1901)	VSD, ASD
Thumb Abnormalities and Abnormality of Radius	
Holt-Oram syndrome[69] (1960)	ASD
Fanconi's syndrome[70] (1967)	PDA
Thrombocytopenia-absent radius syndrome[71] (1969)	TF
Ventriculoradial dysplasia[72] (1966)	VSD
VATER syndrome[63] (1972)	VSD
Rubinstein-Taybi syndrome[67] (1963)	PDA
Phocomelia	
Thalidomide[40] (1962)	TF, VSD
De Lange's syndrome[67] (1933)	VSD
Arachnodactyly	
Marfan syndrome[67] (1896)	MVP, MR, AI, aneurysm
Homocystinuria[67] (1963)	thrombosis of medium-sized arteries
Hypoplastic Dysplastic Nail	
Turner's syndrome[67] (1938)	coarctation, AS
Fetal hydantoin syndrome[38] (1975)	PS
Ellis-van Creveld syndrome	single atrium
Trisomy 13 syndrome (Patau)	VSD
Trisomy 18 syndrome (Edwards')	DORV, VSD

Date (■) = when syndrome first described.
AV Canal = atrioventricular canal.
VSD = ventricular septal defect.
PDA = patent ductus arteriosus.
TF = tetralogy of Fallot.
TA = truncus arteriosus.
ASD = atrial septal defect.
MVP = mitral valve prolapse.
MR = mitral regurgitation.
AI = aortic insufficiency.
AS = aortic stenosis.
PS = pulmonary stenosis.
DORV = double-outlet right ventricle.
TGA = transposition of the great arteries.

lidomide, but these defects may also occur in association with de Lange's syndrome.[40,41,60] Broad thumbs are characteristically present in Rubinstein-Taybi syndrome.[60] Cardiac defects are only occasionally seen in association with Rubinstein-Taybi syndrome.[60]

Arachnodactyly

Arachnodactyly is a characteristic finding in Marfan syndrome, a dominantly inherited disorder, in which mitral valve prolapse, mitral regurgitation, aortic aneurysm, and aortic insufficiency are common and progressive abnormalities.[60]

Other abnormalities of the hands that may give diagnostic information include hypoplastic or dysplastic nails seen in association with Ellis-van Creveld syndrome, Turner's syndrome, and both trisomy 13 and trisomy 18. In trisomy 18, there is also a characteristic clenched fist with overlapping fingers, the index finger over the third and the fifth over the fourth. Lymphedema may be present in neonatal Turner's syndrome. Congenital heart disease is present in approximately 25% of infants with Turner's syndrome, and 70% of these have coarctation of the aorta.[60]

Gastrointestinal Tract

In studies on infants with various gastrointestinal abnormalities such as tracheoesophageal fistula, omphalocele, imperforate anus, and diaphragmatic hernia, Greenwood and associates have documented an incidence of congenital heart disease that varies between 12 and 23%.[73–76] The prognosis is significantly altered by the presence of the congenital heart defect, which is therefore important to recognize for the proper management of infants with these abnormalities. Boesen and associates noted that there was an increased incidence of tetralogy of Fallot in children with gastrointestinal anomalies, whereas ventricular septal defects were more common in association with bone and joint abnormalities.[77]

Genitourinary Anomalies

Mehrizi reported a 4 to 15% incidence of renal anomalies in autopsy studies on patients with congenital heart disease.[78] The renal anomalies are often clinically silent; and unless the coexistence with congenital heart disease is remembered, significant abnormalities may be overlooked.

PHYSICAL EXAMINATION

In general, the traditional examination format of inspection, palpation, percussion, and auscultation should be followed, but the subject must be reasonably quiet for each step. The small infant up to nine months of age is generally easily distracted and enjoys eye and social contact. The infant at this age may also be quieted with a pacifier or can be fed during part of the examination. Infants from nine months to two years of age may be apprehensive. The examiner should allow a few minutes for the infant to become accustomed to the physician's presence before beginning the examination. Have toys available that can be used to distract the infant. Sometimes allowing the patient to hold the head of the stethoscope gives reassurance. Examination of the toddler is often best performed with the child on the parent's lap; complete evaluation in both the supine and erect postures can be carried out without difficulty. The child from three years of age upward usually cooperates for the cardiac examination.

The weight and height are measured and compared to the range of normal on a growth chart. In infants, it is usually preferable to leave these measurements and the measurement of the blood pressure until the end of the examination, since they may upset the infant. The most important initial step is to assess whether the infant or child is acutely or potentially stressed and therefore in need of urgent investigation and management. Second, is the infant cyanotic or acyanotic? Third, is the infant or child outwardly well within minimal symptoms or asymptomatic?

The infant with initial cardiac disease has either resting or stress-induced hypoxemia, pulmonary edema, right heart failure, reduced right or left ventricular output, or a combination of these pathophysiologic states. The sick infant often appears anxious; may have pallor, sweating, tachypnea, and dyspnea; and dislikes being handled. The hypoxemic infant also tolerates handling poorly. In both instances, the examination should be carried out gently and with as little disturbance to the infant as possible. Much useful information about cardiorespiratory function can be obtained from inspection of the infant alone. If the infant is asleep as the examiner enters the room, take the opportunity to measure the respiratory rate. This should be recorded for at least 30 seconds and preferably a full minute.

Is there skin pallor to suggest low cardiac output? Is the infant cyanotic or acyanotic? Is there evidence of clubbing? Any dysmorphic features should be noted carefully.

The analysis of the clinical evaluation should be critical, and definitive diagnostic conclusions should not be made about the crying or upset infant or child. This applies to the assessment of pulses, blood pressure, heart sounds, and murmurs.

Clubbing

Clubbing was recognized by Hippocrates[79] as a sign of empyema. Today, pediatricians first think of clubbing as a manifestation of cyanotic congenital heart disease. Clubbing due to cyanotic heart disease is not present at birth and is rare before three months of age. It is caused by thickening of the tissues at the base of the nail, which is secondary to capillary engorgement in association with chronic hypoxemia and polycythemia. As a result of this, the angle between the base of the nail and the adjacent skin of the finger or toe is obliterated. The skin becomes shiny, and there is increased compressibility of the nailbed. With progression, the nail loses its longitudinal ridges and becomes convex. In extreme cases, the terminal segment of the finger and/or toe is bulbous, like the end of a drumstick.

While clubbing is usually easy to recognize, there are times when the changes are mild. The measurement of the depth (from nail to palmar surface) of the index finger at the base of the nail divided by the depth at the distal interphalangeal joint may clarify the issue. A ratio that is greater than 1 is abnormal and indicates clubbing. This relationship is independent of age, sex, and race.[80]

Mild clubbing may be present when the systemic arterial blood oxygen saturation is 85 to 90%, a level at which cyanosis may not be clinically apparent. In this circumstance, the fingers and toes may have a dark red appearance.

Taussig observed that clubbing may regress in the presence of anemia.[8] It also resolves when the chronic hypoxemic stimulus has been removed by corrective cardiac surgery. Cyanosis without clubbing after the age of two years indicates that the cyanosis has been of short duration and may indicate reversal of a shunt caused by increasing pulmonary vascular resistance.[8]

Pulses

Pulses are assessed for rate, rhythm, volume, and character. The pulse character is an approximate indicator of the cardiac output unless isolated anomalies of the aortic arch vessels or the aorta damp the arterial pulse.

The criterion for tachycardia during physical examination is a heart rate of 150 beats or more per minute in the resting infant and 120 beats or more per minute in the child (Table 43–5). A phasic variation in the heart rate during respiration (faster with inspiration) indicates physiologic sinus arrhythmia. It is usually not obvious in healthy infants, since at a fast heart rate, sinus arrhythmia is not ordinarily detected clinically. A pulse deficit (i.e., a difference in the heart rate counted with the peripheral pulse compared to that determined by auscultation at the cardiac apex) is commonly appreciated in the presence of ectopic beats.

A sinus tachycardia may be an attempt on the part of the infant to increase cardiac output in the presence of increased tissue needs for oxygen or an inadequate delivery of oxygen for whatever reason.[81] Pallor and sweating are frequently evident in association with tachycardia. A heart rate of greater than 220 beats per minute would suggest paroxysmal supraventricular tachycardia.

Pulse Volume

It may be helpful when assessing the volume of the pulse and especially when comparing the brachial and femoral pulses to compress the pulse to the point of obliteration and then slowly release the pressure while assessing the comparative volume of each pulse. A difference in volume may be more readily detectable and also more sensitive in the diagnosis of coarctation of the aorta than trying to appreciate a delay in the peak of the pulse in a small infant with a heart rate of 150 to 180 beats per minute. To assess the pulses accurately, the infant must be relaxed and quiet. Many times in the tense infant, a femoral pulse will seem to be absent only to appear to be of normal volume when the infant relaxes. It is also of value to feel the pedal pulses if the femorals are difficult to palpate or as an initial step when an infant is sitting on the parent's lap before being placed supine. It should be remembered that the dorsalis pedis pulse is congenitally absent in about 10% of the population.[82]

An increase in pulse volume is most commonly associated with pyrexia, with anemia, following exercise, and with thyrotoxicosis. A marked increase in the pulse volume with a pulse pressure greater than 30 mm Hg in the infant and 50 mm Hg in the child gives rise to a bounding pulse. The presence of a bounding pulse in an infant or young child is most commonly caused by a moderate or large ductus arteriosus. It may also occur in the presence of aortic insufficiency or with truncus arteriosus when there is either a rapid runoff into the lungs or truncal valve insufficiency. An increased pulse volume is found with an arteriovenous fistula irrespective of site.

A diminution in pulse volume occurs in the presence of low cardiac output from any cause. The frequent structural causes of diffuse diminution in pulse volume are left heart obstructive lesions and particularly aortic valve atresia or stenosis. In the early phase of congestive cardiac failure due to hypoplastic left heart syndrome, aortic valve atresia or critical stenosis may be clinically suspected when the right arm pulse has a lower volume than the left arm or femoral pulse. As the ductus closes and the clinical condition deteriorates, all pulses become nonpalpable. Children with aortic stenosis may have a pulse of normal volume and character; but with careful attention to the upstroke of the pulse, a delay or slurring may be appreciated even when the volume of the pulse appears to be normal.

Table 43–5. Normal Average Pulse Rate at Different Ages

1 week	*1 year*	*6 years*	*Puberty*
140/min	120/min	100/min	80/min

In supravalvular aortic stenosis, there may be a discrepancy in the pulse volume between the right and left arms. The right arm pulse is stronger because of the Coanda effect, i.e., a tendency for a fluid jet to adhere to a wall.[83] In supravalvular aortic stenosis, there is an increased proportion of the ejected volume from the left ventricle deviated toward the innominate artery and therefore the right arm.

The right arm pulse is also stronger than the left in the presence of coarctation when the left subclavian artery is involved in the coarctation. On rare occasions, the left subclavian artery may be involved in the coarctation, and the right subclavian artery may arise from the descending aorta distal to the coarctation and travel in a retroesophageal manner to the right arm, giving rise to four-limb diminution in pulses. The carotid pulses in this circumstance have increased volume. An increased carotid pulsation is also evident with patent ductus arteriosus, with aortic insufficiency, and in the rare anomaly cerebral arteriovenous malformation. Unilateral prominent neck pulsation can be found in the presence of a cervical aortic arch, and transient compression of this pulsation causes obliteration of the femoral pulse.[84]

Prompt distension and a quick, visible collapse of the carotid arteries were described by Dominic Corrigan in 1832. In addition, the palpable findings of the arterial pulse were described in Corrigan's classic paper on physical findings in aortic regurgitation. The finding of a sudden palpable shock when the artery rapidly fills was likened to the water hammer, a Victorian toy with a small amount of fluid in a vacuum tube, by Watson in 1843. The alternation of flushing and pallor of the skin with systole and diastole (the capillary pulse) was described by Quincke in 1868. This capillary pulse may be seen with partial compression of the tip of the fingernail or with a glass slide pressed against the earlobe. Corrigan's pulses, water hammer pulses, and Quincke's pulses are all characteristic of severe aortic regurgitation but may be found in other settings with a marked diastolic runoff (such as a case of truncus arteriosus or a large ductus arteriosus with low pulmonary vascular resistance).

Pulsus Paradoxus

Pulsus paradoxus, which is an exaggeration of the normal inspiratory and expiratory variation in blood pressure, may be found in association with constrictive pericarditis, cardiac tamponade, cardiac failure, or severe respiratory distress, such as asthma. This variation may be appreciated on palpation of the pulse but is more accurately assessed while taking the blood pressure. If there is a difference of 10 mm Hg or greater between the recorded systolic pressure during expiration and that recorded during inspiration, then a significant degree of paradox is present.[85] Pulsus paradoxus was considered "paradoxical" because in the setting of tamponade, the venous pressure was noted to rise (Kussmaul's sign)

during inspiration while the arterial pressure dropped during inspiration.

Pulsus Alternans

Pulsus alternans (Traube's sign), an alternating strong and weak pulse, is a rare and late but reliable sign of severe left ventricular failure and can be appreciated on palpation of the pulse and also while recording the blood pressure.[85]

Pulsus Bisferiens

Pulsus bisferiens is a pulse with a double peak, i.e., a prominent percussion and tidal wave separated by a midsystolic cleft, which may be found in lesions with a large left ventricular stroke output such as a patent ductus arteriosus or aortic regurgitation.[85] In hypertrophic cardiomyopathy with obstruction, the pulse characteristically has a very rapid upstroke; this is followed by an extended plateau. This pulse abnormality may be minimal or absent at rest but can be exaggerated by Valsalva's maneuver or by inhalation of amyl nitrite.[85]

Blood Pressure

After assessment of the pulse contour, the next logical step is to take the blood pressure. However, as was stated earlier, it is best to leave this part of the examination until the end in children under three years of age, since the sensation of pressure on the arm is uncomfortable and may provoke crying. The recording of blood pressure in children should be part of every cardiovascular examination and is not difficult in a child. Obtaining an accurate blood pressure in infants is one of the most technically difficult parts of the examination to perform. There is no point in recording blood pressures obtained in the crying or restless infant or child. Maximum distraction is required during this evaluation to try to prevent the infant from becoming restless or agitated. In children and adults, the systolic pressure in the lower limb is some 10 mm Hg (or even up to 20 mm Hg) higher than in the upper limbs using the same-sized blood pressure cuff. In infants, the systolic pressures are the same, but at no age should the pressure in the lower limb be less than that in the upper limbs. A higher pressure in the upper limbs with a pressure difference of 10 mm Hg or greater between the upper and the lower limbs indicates coarctation of the aorta.

The methods available for obtaining blood pressure are discussed in detail in Chapter 30 and are summarized in Table 43–6. To record an accurate blood pressure, use a cuff size in which the inflatable rubber bag covers two thirds of the upper arm or the width of the bag rather than the cloth cover, which is equal to half the circumference of the upper arm. This means in practice using a cuff that covers the upper arm just leaving the antecubital fossa available for auscultation or palpation. When applied, the inflatable bag should completely encircle the arm so that uniform compression may be obtained. Too short a bag may lead to erroneously elevated blood pressure readings from the mercury manometer. A similar problem may arise if the width of the cuff is too narrow; this is one of the commonest causes of apparent hypertension. If an ideal cuff is not available, then use one that is a little too big rather than one that is too small; this reduces the margin of error. Elevated blood pressure readings may also be obtained if the cuff is not applied evenly and snugly. A loose-fitting cuff needs a higher pressure within it to occlude the artery, and therefore higher readings are recorded on the mercury manometer.

Table 43–6. Clinical Methods of Recording Blood Pressure

Palpation
Auscultation
Ultrasound Doppler
Oscillometric
Flush

Palpation

A palpated blood pressure allows a quick assessment of the systolic pressure in a small infant and should be recorded initially, since attempts at measuring the blood pressure by auscultation are occasionally frustrated by the sometimes poor transmission of Korotkoff sounds in the infant and young child and by lack of cooperation. The disadvantage of the palpated pressure is that the palpated systolic figure is about 10 mm Hg lower than the intra-arterial pressure or auscultated pressure, and diastolic pressure is not obtainable.[86] Also, the diagnostically important pulse pressure is not obtainable except by manual estimation, as already described.

Auscultation

To obtain auscultatory blood pressure in a small child, use the small pediatric head, either bell or diaphragm, of the stethoscope. Excessive pressure damps the Korotkoff sounds and is a common error in recording blood pressure of the infant or child. The systolic pressure is recorded as the first audible Korotkoff sound, while the diastolic pressure should be recorded both when the Korotkoff sounds become muffled and when they disappear. While muffling may be the most accurate point of documenting diastolic pressure, it is often difficult to appreciate in a small infant.

The principles of cuff application and cuff size also apply to the lower limb for the recording of blood pressure. Therefore the cuff should cover two thirds of the thigh, leaving the popliteal fossa available for palpation, asucultation, or the positioning of a Doppler ultrasound transducer. It is ideal to place the subject in the prone position for leg blood pressure, but infants may not tolerate this.

Doppler Method

The Doppler ultrasound technique has been used effectively for almost 15 years, and the accuracy of the values obtained have been substantiated in many clinical studies, particularly by Steinfeld and colleagues.[87] With the transducer placed over the artery, arterial wall oscillations are transformed into an audible signal at the moment the intrabladder pressure drops below the peak intravascular pressure. The sound terminates when the intrabladder pressure dips below the end-diastolic pressure. The systolic pressure recorded in this manner is very accurate; however, the diastolic pressure is not as reliable.

Oscillometric Method

More recently, oscillometric methods have been developed.[88] Special cuffs are available to complement the system, which has many advantages, in particular in the small infant. Systolic, diastolic, and mean arterial pressures as well as heart rate are digitally

displayed. Recordings can be automatically repeated at frequent intervals if required. Examiners should be wary of technical artifacts with this method. The mean is the most accurate; systolic and diastolic are calculated.

Flush Technique

While the flush technique is rarely used currently, it still has a place and can be very valuable as a means of obtaining blood pressure in the infant with suspected coarctation of the aorta. Many times, both auscultated and palpated pressures are not obtainable in the lower limb in the presence of coarctation, and more sophisticated equipment may not be available. The pressure reading obtained by using the flush technique is closer to the mean arterial pressure than to peak systolic pressure. It does, however, allow a comparison between upper and lower limbs. The principle of the technique is similar to that already described for cuff application. Thereafter the limb is elevated, and an elastic bandage is applied from the fingertips or toes proximally to eliminate blood from the skin capillaries and veins and to blanch the distal forearm and hand or lower leg and foot. With the bandage still applied, the blood pressure cuff is inflated at least 20 or 30 mm Hg above the expected systolic pressure; and with the cuff inflated, the bandage is removed. The distal limb should now be white. The pressure in the cuff is decreased by 2 to 3 mm Hg per second, and the pressure at which the first blush appears in the limb is recorded as the blood pressure. The reading may be 10 to 30 mm Hg lower than that obtained by the auscultatory method.

Jugular Venous Pressures

Elevation of the jugular venous pressure indicates elevated right atrial pressure or increased right ventricular preload. Patience and experience are required to obtain maximum information from the venous pulse wave. In the small infant, the liver size is a more reliable indicator of systemic venous congestion. The jugular venous pressure is difficult to assess in the young infant because of the short neck. Also, there appears to be a greater compliance to the venous system in infants, so even in the presence of congestive cardiac failure, the right atrial pressure may not be significantly elevated and then only as a terminal event.[89] Venous pulsation in the neck is recognized and differentiated from the arterial pulsation in the following ways:

(1) the venous pulse has a multiple wave form with A, C, and V waves and with X and Y descents;
(2) height of the venous pressure varies with respiration, decreasing during inspiration;
(3) the venous pulse is easily obliterated by light pressure just above the clavicle;
(4) the pulsation is usually not palpable; and
(5) the level of pulsation changes with variation in posture.

The timing of the venous pulse waves can be facilitated by palpating the apex beat or auscultating the heart sounds.

The A wave is due to atrial contraction and is therefore presystolic. The C wave occurs at the onset of ventricular systole and is related in part to conduction of the carotid pulse and also to a wave initiated by displacement of the tricuspid valve during the onset of ventricular systole. The V wave marks the end of ventricular systole and occurs approximately with the dicrotic notch on a carotid pulse tracing. The X descent occurs during ventricular systole as the right atrioventricular valve is drawn from the right atrial cavity, reducing the right atrial pressure in the process. The Y descent occurs during rapid ventricular filling.[89]

It is not easy to evaluate the jugular venous pulse in an infant or child, and it takes practice to perfect the skill. To assess the jugular venous pressure, place or hold the subject upright at 45° to 90°; if venous pulsation is visible in the external jugular vein at or above the level of the suprasternal notch, then there is elevated right atrial pressure.[89] To analyze the venous pulse in more detail, the patient should be positioned in such a way that the maximum amplitude of the pulse can be visualized. This may be at 30°, 45°, 60°, etc. The height of the jugular venous pressure is measured as the vertical height above the sternal angle, or Louis' angle.[89]

Prominent A waves related to atrial contraction will be evident in tricuspid atresia or stenosis and indeed in any lesion causing elevation of right ventricular end diastolic pressure, e.g., severe pulmonary valve stenosis. A regurgitant wave or prominent V wave seen during ventricular systole may be caused by tricuspid insufficiency. Differentiating a prominent A wave from a V wave or regurgitant wave can be very difficult to do accurately in the infant or in any patient with tachycardia. Another easily identifiable pattern is that associated with complete AV block in which there are variable A waves and intermittent cannon waves. The cannon wave, a sudden and transient increase in jugular venous pressure, occurs when right atrial contraction takes place during ventricular systole and therefore against a closed right atrioventricular valve.

Marked distension of the jugular veins may be noted in the presence of constrictive pericarditis, and the pressure may increase rather than decrease during inspiration (Kussmaul's sign). Another cause of very prominent venous pulsation in the neck and sometimes an associated thrill is a large cranial arteriovenous malformation. Unilateral distension may be associated with a localized arteriovenous fistula. Distended nonpulsatile jugular veins may be a sign of superior vena caval obstruction, e.g., following intraatrial repair of transposition of the great arteries.

Edema

Edema (Greek: "oideo" = swell) of the extremities, which is a frequent feature of systemic venous congestion in adults and older children, is rarely seen in infants. When present, periorbital swelling may be evident. Rarely, puffiness of the hands and feet is also seen. If there is marked edema of the hands and feet, then a renal cause should be sought and hypoalbuminemia excluded. Nonpitting edema or lymphedema is found in the neonate with Turner's syndrome.

In the absence of obvious edema, an inappropriate increase in weight may indicate fluid retention in the small infant.

Hepatomegaly

The hallmark of systemic venous congestion in the infant is hepatomegaly. The abdomen should be examined with warm hands and with a gentle technique. The normal liver in the infant is soft and may be palpable 2 to 3 cm below the right costal margin. This decreases with age to approximately 2 cm at 1 year of age and 1 cm by 4 or 5 years. The position, the size, and the consistency of the liver should be noted. A liver in the right hypochondrium indicates normal visceral situs, while a left-sided liver suggests visceral inversion. In stating the size of the liver, it should be understood that the measurement is taken at the midclavicular

line where it crosses the ninth costal cartilage. When the liver is midline, situs ambiguous is present, and the assessment of size is measured from the subxiphoid position.

In the presence of right heart congestive failure or a generalized increase in circulating blood volume, the liver is not only enlarged, and therefore palpable more than 2 to 3 cm below the right costal margin, but it is also firm, with a rounded contour to the upper surface, which may make the edge more difficult to define. However, the edge can be defined by gentle backward pressure while allowing the descent of the diaphragm to press the edge against the examining fingers or thumb. Using the medial border of the thumb to feel the liver edge in a small infant is a useful and acceptable technique. Remember that the enlarged liver may also be tender, and undue pressure may distress the infant. Many beginners in medicine exert excessive pressure in attempting to palpate the liver. A pulsatile liver suggests tricuspid regurgitation or another reason for increased right atrial pressure (e.g., tricuspid atresia with small foramen ovale). In assessing the liver and spleen, therefore, not only should the size be noted but also the texture and the consistency. A hard liver of 2 cm may be more indicative of serious pathology than a soft liver that is palpated 4 cm below the right costal margin.

The span of the liver can be further confirmed by percussion. The upper margin may be depressed from the normal fourth intercostal space by hyperinflation of the lungs, creating the false impression of hepatomegaly when the abdomen is palpated. Percussion in the infant and child should be gentle and light. A heavy percussion technique not only gives less information but may also cause discomfort or pain to the infant, especially if the liver is enlarged and tender.

The spleen tip is frequently palpable under the left costal margin in the normal newborn. It is important to document this, since it excludes asplenia. On the other hand, if the spleen is significantly enlarged, this may suggest an intrauterine viral infection such as rubella as the cause of the cardiac lesion. In the older child with a congenital heart defect and a febrile illness, splenomegaly suggests possible endocarditis. It is uncommon to have significant enlargement of the spleen in isolated congestive cardiac failure.

In palpating the spleen, it should be remembered that the small infant's spleen may enlarge toward the left iliac fossa and therefore is more laterally positioned than in the older child.

In the presence of severe congestive cardiac failure, ascites may also be present and can be detected by dull flanks, shifting dullness, and a fluid thrill.

Pulmonary Congestion

In most cases, infants with congestive failure have no auscultatory findings in the lungs. In older children, fine rales may occur. Coarse rales at any age suggest pneumonia.

EXAMINATION OF THE HEART

Observe the shape of the chest for any asymmetry. Is the left precordial area bulging, suggesting a dilated right ventricle? Is Harrison's groove present, indicating a chronic decrease in pulmonary compliance? Harrison's groove is a depression along the sixth and seventh costal cartilages at the site of attachment of the anterior part of the diaphragm.[90]

Is there an increased anteroposterior diameter of the chest, perhaps related to chronic air trapping and hyperinflation of the lungs? Is there scoliosis, which may significantly alter the position of the standard landmarks on the anterior chest such as the apex beat?

The Apex Beat

The character as well as the position of the apex beat should be noted consistently, since this observation helps to assess ventricular hypertrophy and/or dilatation. In a young infant or a child up to four years of age, the apex beat is normally in the fourth intercostal space either at or inside the midclavicular line. A forceful apex beat in the normal location indicates either increased cardiac output or left ventricular hypertrophy without ventricular dilatation. When the left ventricle is dilated, the apex beat is displaced downward and inferiorly and is hyperactive.

An indistinct apex is found in association with right ventricular hypertrophy. In the presence of pronounced right ventricular dilatation, the precordium heaves, but the apex beat may be difficult to feel or localize.

Palpation

To get the most out of palpation of the anterior chest, use the most sensitive portion of the hand. For some, this is the palmar surface of the heads of the metacarpals, while for others it is the fingertips. Generally, the right ventricular impulse can be felt best with the hand resting on the precordium. In the young child with a thin chest wall, a slight impulse can be felt along the left sternal edge. A hypertrophied (but not dilated) right ventricle produces a distinct parasternal tap, while a dilated right ventricle (with or without associated hypertrophy) produces a parasternal lift.

The examiner identifies the apex impulse best with the fingertips. If the subject is old enough, search for the apex impulse in the upright position or, better yet, the standing position. A thin chest wall facilitates evaluation of the apex. Many physicians use the ambiguous term "point of maximum impulse" (PMI) to indicate the apex impulse. It is less confusing simply to use the term "apex impulse" if that is what one means. If the parasternal impulse is the stronger, one should so indicate. Most examiners locate the apex beat's interspace and relation to midclavicular or anterior axillary line. This is of course important, but the character of the apex beat also gives much valuable information. A very strong apex impulse, though normally formed, is associated with either of two cardiovascular conditions: increased cardiac output (the tachycardia of high fever, severe infection, anemia, anxiety, or immediately after exercise) or left ventricular hypertrophy. If the overactive apex beat is also displaced both downward and to the left, dilatation of the left ventricle (with or without hypertrophy) can be assumed.

Thrill

Very few physicians carrying out a cardiovascular physical examination overlook the search for a precordial, suprasternal, or carotid artery thrill. A thrill simply indicates a loud murmur. Some beginning examiners report a precordial thrill but only a faint grade 1 to 2 murmur. If the murmur is of low intensity, the examiner has probably felt a pulsation and not a thrill. It is interesting to identify a thrill, but an examiner who intends to listen over the heart and the carotid arteries will likely identify a prominent murmur. Missing a thrill during palpation is not critical to a correct evaluation of cardiac function and structure.

A thrill associated with aortic stenosis and pulmonary stenosis usually signifies an important obstruction, but so does a loud murmur. There is no such correlation with ventricular septal defect, since an easily palpable thrill may be present with either a small or a large defect. Sometimes the location of a thrill may be misleading. A thrill in the suprasternal notch to most examiners suggests aortic stenosis, but a thrill in that location may be transmitted to the aorta from a prominent thrill in the pulmonary trunk due to pulmonary valve stenosis or a large patent ductus.

Palpation of Heart Sounds

By palpation, an accentuated heart sound also may be felt, especially in the infant or young child in whom the chest wall is thin. The second heart sound in the pulmonary valve area can usually be felt if there is pulmonary diastolic hypertension. It can also often be felt in transposition (either dextro, i.e., true, transposition, or levo, so-called corrected, transposition), since the aortic valve in both types of transposition lies anterior to the pulmonary valve. A palpable first heart sound can often be felt in the presence of a hyperdynamic heart from any cause, including exercise or fever.

While it is interesting for the examiner to palpate heart sounds before listening to the heart sounds with a stethoscope, the loud sound or click is going to be heard, so overlooking a palpable sound, just as overlooking a thrill, is not critical to the functional and structural evaluation of the cardiovascular system.

Percussion

In the infant, percussion of the cardiac borders has very limited value. It is probably the relative increase in anteroposterior diameter of the chest or perhaps the often increased amount of fat tissue in the newborn's chest that damps the percussed difference between heart border and lung. It would be risky in the infant to depend upon percussion of cardiac borders to detect either cardiac dilatation or massive pericardial effusion. It really requires the combination of chest radiograph and ultrasound to be certain about it. In older children, if the left cardiac border by percussion extends beyond the apex beat, a pericardial effusion is suspected.

Percussion of the lungs, however, forms an important part of the examination and can be successfully carried out in the quiet infant. In the infant (as in older patients), chest percussion has to be carried out with the subject upright. Examiners often try to percuss the posterior chest with the infant prone on the examining table, but this does not work. Have the parent or nurse hold the infant upright both for percussion and for auscultation of the lungs.

Auscultation of the Heart

Expert auscultation of the heart first has to be learned, over a period of weeks to months, studying under an experienced instructor and having available a sizable number of subjects (patients) with a variety of normal and abnormal heart sounds and murmurs. Once mastered, the technique of hearing and correctly interpreting the auditory variants missing from the normal and abnormal heart must be practiced often for an examiner to remain skillful (Table 43–7).

When possible, every infant and child should be examined in both the supine and the standing posture. The older child should also be evaluated following light exercise, such as running in place. A subtle ejection click can be exaggerated, and a short diastolic murmur that may be difficult or impossible to hear at rest often becomes clearly apparent in one position and not in another. This is particularly true of the diastolic rumble in the tricuspid area in a child with an atrial septal defect (best heard supine) or the high-pitched decrescendo diastolic murmur of aortic regurgitation (best heard in the upright position).

Table 43–7. Components of Auscultation of the Cardiovascular System

Stethoscope
Use in each site:
Bell
Diaphragm
Short tubing (16–18 in.)
Use familiar (personal) and comfortable instrument
Auditory Conditions
Insist on quiet:
Patient
Parents
Attendants
Examining room
Adjacent areas
Areas to Examine Routinely
Primary aortic (2nd intercostal space, right sternal edge)
Pulmonary (2nd intercostal space, left sternal edge)
Tricuspid/2nd aortic area (4th intercostal space, left sternal edge)
Mitral/apex (5th intercostal space, midclavicular line or at apex if displaced)
Right and left infraclavicular area
Right and left axillae
Right and left interscapular areas (especially if pulmonary or aortic collaterals are suspected)
Right and left carotids (especially if thrill present)
Cranium (right and left temporal areas) (especially in newborn with heart failure)
Right and left lumbar region (especially if high blood pressure)
Abdominal aorta (especially if abdominal coarctation or aneurysm suspected)
Right and left femoral arteries (especially if evaluating wide pulse pressure)
Patient Position
Examine each valve area with patient:
Supine
Sitting
Standing (brings out click of mitral leaflet prolapse)
Squatting (to reduce murmur of aortic stenosis with hypertrophic cardiomyopathy and exaggerating or eliciting murmur of mitral regurgitation)
Effect of Respiration During Basal Conditions
Quiet, deep, unforced, continuous respiratory excursion
Deep-held inspiration, then expiration
Effect of Varying Cardiac Output
Basal (or quiet, resting) state
During increased cardiac output (exaggerates most murmurs and elicits some)
After exercise
After a large feeding in an infant

Conditions for Auscultation

Auscultation of sick infants in an intensive care unit can be difficult with so much extraneous noise in the environment such as the bleeps from monitors, the hum of the incubator, and the continuous sound of airflow in infants on continuous positive air-

ways pressure. It is therefore necessary to try to achieve as quiet an environment as possible.

It is very easy to be distracted by a loud murmur and ignore the quality and characteristics of the first and second heart sounds. As a consequence, valuable diagnostic information can be lost.

Table 43–8 outlines some causes and clinical significance of variation in the quality and timing of the first and second heart sounds.

The first heart sound was considered by Leatham to be produced by closure of the mitral and tricuspid valves.[91] In recent years, other investigators have demonstrated that the components of the first heart sound are produced by acceleration and deceleration phenomena within the left ventricle and that tricuspid leaflet apposition plays little part in the generation of the first sound.[92] Despite this, the traditional concept can be helpful in conceptualizing and teaching heart sounds.

While multiple components of the first heart sound are recordable by sensitive phonocardiograph equipment, only a single sound is audible at the apex and at the lower left sternal border in most healthy individuals. However, in many children and adolescents, when the heart rate is slow enough, two components are clearly heard. This physiologic splitting is heard better at the tricuspid area at the lower left sternal border than the apex, a result suggesting that there is indeed a tricuspid valve contribution to the first sound. If a split first sound is heard better at the apex, it may be that one component of the sound is an aortic ejection click, a manifestation of bicuspid aortic valve or noncalcific aortic stenosis.

The intensity of the first sound depends on the velocity of "leaflet closure" (more precisely, acceleration and deceleration of blood flow near the atrioventricular valves) and therefore on the rate of rise of the ventricular systolic pressure and the stroke volume. Any factor that increases the cardiac output, such as exercise, pyrexia, or anemia, will exaggerate the intensity of the first heart sound.

Mitral stenosis is the archetypical cause of a pathologic loud first heart sound. The sound is loud because the high left atrial filling pressure produces a greater acceleration of blood flow from atrium to ventricle, and with the onset of ventricular pressure, a very rapid deceleration of blood flow across the mitral valve occurs.

Congenital mitral stenosis for some reason lacks the characteristically loud first heart sound noted in acquired rheumatic mitral stenosis.

A decreased intensity of the first heart sound may indicate a prolonged PR interval, significant mitral regurgitation, reduced rate of rise of ventricular pressure, and reduced ventricular stroke volume from any cause.

Second Heart Sound

In infants and young children, the importance of an increased intensity of second heart sound in the evaluation of cardiac misfunction is often misinterpreted. The second heart sound is split in two thirds of infants by 16 hours of age and in 80% by the age of 48 hours.[52] But at a heart rate of over 100 beats per minute, physiologic splitting is hard to detect by auscultation; often, the closely split heart sound may be audible as a single sound.

Splitting of the second heart sound is audible when the aortic and pulmonary components are separated by 20 ms or more. In the normal individual, splitting is best detected in the second left intercostal space at the left sternal edge. Respiratory variation of splitting should be assessed during quiet ventilation.

Splitting of the second heart sound depends upon a different impedance in the systemic and pulmonary vascular beds.

Curtis and associates have demonstrated that physiologic splitting with delayed closure of the pulmonary valve is primarily the result of a fall in pulmonary vascular impedance during inspira-

Table 43–8. Heart Sounds

Sound	*Variation*	*Example*
S_1	decreased	depressed ventricular ejection rate and volume, e.g., prolonged PR interval
S_1	increased	increased cardiac output, e.g., exercise, fever, excitement, mitral stenosis
S_2	single, increased	transposition tetralogy of Fallot with marked overriding of aorta pulmonary hypertension truncus arteriosus
S_2	single, decreased	typical tetralogy of Fallot
S_1 and S_2	decreased	decreased ventricular ejection rate and volume (low cardiac output) large pericardial effusion
S_2	splitting, wide and usually "fixed"	atrial septal defect right bundle branch block
S_2	splitting, wide but moves with respiration	pulmonary stenosis ventricular septal defect or patent ductus arteriosus with large shunt idiopathic dilatation of pulmonary artery
S_2	splitting, reversed	Wolff-Parkinson-White syndrome (some cases) left bundle branch block left ventricular failure

tion.[93] There is only a minor contribution from an increase in the duration of right ventricular systole and earlier aortic valve closure during inspiration. The aortic and pulmonary closure sounds occur at the incisurae of their respective pressure curves. These incisurae are separated from a corresponding point on the ventricular pressure trace by an interval denoted as "hangout." In the normal systemic circulation, this interval is less than 20 ms, while the duration of this interval in the normal pulmonary circulation is considerably wider, varying from 33 to 89 ms. The fall in pulmonary vascular impedance with inspiration increases this hangout interval.

In normal children lying supine, slight splitting of the second heart sound may persist during expiration. In the upright position, however, the normal second heart sound usually becomes single. Persistent expiratory wide splitting of the second heart sound in the upright position rarely occurs normally; it is a common sign of atrial septal defect, complete right bundle branch block, or Wolff-Parkinson-White syndrome.

In the small infant and in many patients with a rapid heart rate, it is more important and feasible to recognize that wide splitting is present than to attempt to hear respiratory variation in S_2. Splitting theoretically indicates that there are two functioning semilunar valves; however, one may inexplicably hear splitting in truncus, or even after tetralogy of Fallot repair in which the pulmonary valve has been totally excised.

The second sound is single and increased in intensity in transposition of the great arteries of tetralogy of Fallot. In transposition, the aorta is anteriorly placed, and the pulmonary valve closure sound is inaudible in its posterior position. In the type of tetralogy of Fallot in which there is extreme overriding of the aorta, the aortic valve closure is loud. A single loud second heart sound may be found in association with pulmonary artery diastolic hypertension, especially when pulmonary vascular resistance is at systemic level.

A loud pulmonary valve closure sound indicating pulmonary hypertension should always be interpreted in relation to the physiologic mechanisms that create elevated pressure (P), i.e., increased blood flow (F) or increased vascular resistance (R), ($P = F \times R$). Simply stating that a patient has pulmonary hypertension is incomplete. The same intensity of pulmonary valve closure may be heard with low pulmonary vascular resistance, a large left-to-right shunt, and therefore a potentially correctable defect as is heard in the child with reduced blood flow, high pulmonary vascular resistance, and an uncorrectable anomaly. In the latter type of child, the murmur becomes short and of low intensity and provides the clue to fixed pulmonary vascular obstructive disease.

In infants and children with mild pulmonary valve stenosis, there is exaggerated splitting of the second heart sound. A normal pulmonary valve closure sound in the presence of other findings indicative of pulmonary valve stenosis suggests that the degree of obstruciton is mild, while an inaudible or very diminished pulmonary sound usually indicates severe obstruction.[26]

Fixed splitting of the second heart sound, i.e., a less than 20-ms variation in splitting during the respiratory cycle, is a characteristic finding in atrial septal defects and is of great diagnostic importance in children with these defects. With a large defect and a large left-to-right shunt, fixed splitting persists in both supine and sitting positions. The cause of fixed splitting in association with an atrial septal defect was once considered to be prolongation of right ventricular systole, which caused a delay in closure of the pulmonary valve. However, studies by Shaver and colleagues demonstrated that prolongation of right ventricular systole contributes only a minor component of the overall duration of the splitting. The major contribution is related to an increase in the capacitance of the pulmonary vascular bed and therefore a fall in pulmonary vascular impedance.[94] The fall in pulmonary vascular impedance causes a prolongation of the hangout interval before pulmonary valve closure. There is no significant change in the hangout interval in the systemic circulation. In this setting, the respiratory changes in right heart volume do not alter the hemodynamics, and therefore fixed splitting occurs.[95]

Expiratory splitting of the aortic and pulmonary components is also found in idiopathic dilatation of the pulmonary artery and in patients with mild pulmonary stenosis.[96] In both instances, the dilated pulmonary arteries increase the capacitance of the pulmonary vascular bed, delaying pulmonary valve closure (or cessation of forward pulmonary blood flow) significantly beyond the end of right ventricular systole.

As the capacitance of the pulmonary vascular bed decreases from any cause, the degree of splitting lessens. This is noted in normal people with age; 45% of subjects over 40 years of age have inspiratory splitting of the second sound of only 20 ms or less, rendering the second sound single.[93] A decrease in the capacitance also occurs in association with an increase in pulmonary vascular resistance, giving rise to a single second heart sound in the pulmonary area. In the newborn, this is a constant feature with persistent fetal circulation. Also in infants and children with a large ventricular septal defect or patent ductus arteriosus, as pulmonary resistance increases and the degree of left-to-right shunting is diminished, the splitting of the second heart sound becomes less and ultimately single as the process progresses toward Eisenmenger's syndrome.

Splitting of the second heart sound therefore needs to be considered in terms of the pulmonary vascular resistance, the capacitance of the pulmonary vascular bed, and the right ventricular function.

Reversed splitting of the second heart sound in children is rare but may occur in association with left bundle branch block, Wolff-Parkinson-White syndrome, or left ventricular failure.[96]

Third Heart Sound

Third heart sound is a low-frequency transient sound of 20 to 70 cycles per second that occurs during rapid filling of the ventricles during early diastole. While the third heart sound can be recorded by sensitive phonocardiography, trained and experienced examiners can hear this physiologic sound in healthy children. The intensity of the sound can be exaggerated by exercise or any factor that increases cardiac output. However, a very rapid rate may obscure it. The third sound is audible and prolonged, producing a diastolic flow murmur in patients with increased volume of blood flow from atrium to ventricle. In the left ventricle, it occurs in ductus arteriosus, ventricular septal defect, or mitral regurgitation. Over the tricuspid area, an exaggerated third heart sound or diastolic flow murmur can be heard in atrial septal defect in which the pulmonary blood flow is at least twice the systemic flow.

The exaggerated third heart sound or middiastolic flow murmur is a difficult one to learn how to hear. It is short and low-pitched,

and even experienced examiners must make a special effort to listen for it. But it is highly important in estimating the volume of a left-to-right shunt or the severity of mitral regurgitation.

This murmur produces a gallop rhythm and resembles something like "Ken-tuck'-y." It is sometimes mistaken for the gallop of heart failure. However, the so-called heart failure gallop is an audible fourth sound, the result of raised ventricular end-diastolic pressure.

Fourth Heart Sound

An audible fourth heart sound (a low-frequency transient sound of 20 to 50 cycles per second), as distinct from the third heart sound, is nearly always pathologic and indicative of altered ventricular compliance. This sound follows atrial contraction and, like the third heart sound, is caused by vibrations within the ventricular myocardium. A fourth sound is uncommonly heard in children with heart disease but may be noted in those with hypertrophic cardiomyopathy. A fourth heart sound may also be noted in children with severe systemic hypertension or in those with a congestive cardiomyopathy, particularly in association with endocardial fibroelastosis.

Ejection Sounds

The ejection click is a snappy high-frequency sound and therefore best heard with the diaphragm of the stethoscope. It occurs during the early ejection phase of ventricular systole. Typically, it is associated with pulmonary or aortic valvular obstruction, but it may also be generated within a dilated aortic root or pulmonary trunk. An aortic ejection click occurs in truncus arteriosus and may be generated either by a degree of thickening and doming of the valve leaflets or by vibrations within the dilated truncal root. It can similarly be heard in pulmonary trunk atresia with ventricular septal defect. The ejection click is often mistaken for a loud first heart sound. An ejection click in association with pulmonary valve stenosis is heard in the pulmonary area and along the left sternal border. In mild pulmonary stenosis, the click is brought out by exercise. It is louder during quiet inspiration and may reduce or disappear during expiration. The ejection sound, while usually present in association with severe pulmonary valve stenosis, may be difficult to hear, since it moves earlier in systole and may appear to fuse with the first heart sound.

Probably the high rate of rise of elevated right ventricular pressure (RVDP/DT) forces the stenotic valve leaflets up so rapidly that a snap or click becomes audible like the pop of a sail when the wind suddenly balloons it out. The click usually disappears in severe valve pulmonary stenosis with decompensation when the rate of pressure rise has decreased.

Aortic ejection clicks are best heard at the apex and in the secondary aortic area left lower sternal border at the fourth space rather than in the so-called primary aortic area at the right second intercostal space. An isolated aortic ejection click suggests a bicuspid aortic valve, which occurs in approximately 1% of the population. The aortic click varies less with respiration than the pulmonary click. An aortic ejection click typically occurs with noncalcified aortic valve stenosis but not in subvalve or supravalve aortic stenosis.

Midsystolic Click and Mitral Leaflet Prolapse

The midsystolic click of mitral leaflet prolapse is best heard at the apex or, in triscuspid leaflet prolapse, at the left lower sternal border, fourth space. This sound may be heard in either the supine or the standing position or both, but sometimes only with the patient standing. A late crescendo mitral valve murmur may or may not accompany the click. Squatting exaggerates the murmur, but this position has a variable effect on the click.

Click Associated with an Aneurysm of the Ventricular Septum

Many infants with ventricular septal defects form a wind sock of tissue or aneurysm that develops in the process of spontaneous closure or reduction in size of ventricular septal defect. During ventricular systole, this aneurysm bulges into the right ventricle, producing an early systolic click. This click is best heard at the mid-left sternal border in the third left intercostal space and with the infant or child sitting at approximately 45°.[97] It is indistinct, however, and a difficult sound to learn how to hear.

Murmur

A murmur is the most frequent reason for referral of a patient for cardiac evaluation. However, reliance on hearing a murmur is not a very sensitive or specific screening method for case detection, especially in infants. Either benign or serious heart disease, including congenital and acquired types, often occurs in the absence of a murmur. In addition, anomalies that create a characteristically loud distinct murmur such as aortic valve stenosis may, in the infant with congestive failure, produce no murmur.

Too great a reliance on the detection of a murmur has been the cause of significant delays in recognizing congenital heart disease even when the other signs and symptoms of congestive cardiac failure are already evident.[8] Two of the most frequently missed diagnoses during childhood are atrial septal defect and coarctation of the aorta. The diagnosis of the former depends more on the wide splitting of S_2 than on the variable murmur, which may be too faint to attract the unsuspecting examiner's attention. Coarctation may be missed in infancy and early childhood if one is examining only for heart murmurs to detect heart disease. While the adolescent patient with coarctation usually has a well-developed murmur, the younger patient often does not. A murmur is nevertheless an important physical sign and helps the physician to suspect heart disease and sometimes to make an anatomical diagnosis and even to assess severity. It is of interest, if not diagnostically important, to learn the age of the patient when a physician first heard a murmur. The murmur of small ventricular septal defect may be heard at birth, but this is not the case with large nonrestrictive ventricular septal defect, since the murmur in this instance first appears after pulmonary vascular resistance falls at 2 to 6 weeks of age. In the normal full-term newborn, pulmonary resistance starts to fall promptly within the first few breaths; presumably, this occurs also in small interventricular communication. In fact, the infant with a ventricular septal defect is often discharged from neonatal care with an apparently normal heart only to present at 1 month of age with a typical pansystolic harsh murmur at the lower left sternal border, often with signs of pulmonary congestion and dilated heart.

The age of first appearance of a murmur to a physician was recorded in 166 patients, each of whom ultimately developed a murmur by the time of referral to the cardiac clinic at Texas Children's Hospital. In approximately 26%, the murmur was first heard in the first two weeks of life; but in more than one third of

the patients, the murmur was not heard until after the infant was three months of age. The author suggested that the frequent late appearance of the murmur no doubt accounted for some of the difficulty in the early diagnosis of congenital heart disease.[98] If a child has been examined by a pediatrician during the first two years of life and a murmur is heard for the first time after that age, the probability is that the murmur is innocent.

There are 11 ways to describe a murmur (Tables 43–9 and 43–10). Murmurs are usually graded on the basis of their intensity. Every junior medical student knows the grading system from I through VI, and it is unnecessary to repeat it in this work. Intensity grading is not precise, but no harm is done if one examiner calls the murmur a Grade III and the next a Grade II. But trained examiners seldom differ by more than one grade. The point is to give an approximate indication of how loud a murmur is, and this has practical value. In some malformations, the murmur changes in loudness from one time to the next. For example, in tetralogy of Fallot, patients may on some days inexplicably develop a reduction in the volume of blood going from right ventricle to pulmonary artery with the result that a greater amount of blood traverses the ventricular septal defect into the aorta. There results a sharp reduction in the murmur intensity or even a complete disappearance. It is, of course, the pulmonary stenosis rather than the right-to-left ventricular shunt that produces the murmur in tetralogy of Fallot.

In nonrestrictive ventricular septal defect with a large left-to-right ventricular shunt, one characteristically hears a very loud Grade III, IV, or V murmur, depending upon the amount of blood turbulence from the shunt. Some infants with this defect gradually develop pulmonary vascular obstructive disease, the left-to-right shunt decreases and so does the intensity of the murmur. In fully developed Eisenmenger's syndrome, when all the ventricular shunt becomes right-to-left, the systolic murmur virtually disappears. There are many other reasons why grading the intensity of the murmur is important, but students sometimes exert too much concern over whether a murmur is Grade III or IV. Besides, a murmur can increase in grade by at least one level in the presence of a transient increase in cardiac output from fever or the like.

Attention to the approximate vibrations of a murmur in terms of approximate cycles per second helps in both the anatomic diagnosis and the hemodynamic evaluation. Examiners in training soon learn to recognize a certain defect by its characteristic sound. For example, the harsh, rough, long plateau murmur of ventricular septal defect contains a mixture of high-pitched and low-pitched sounds and is quite different from the long plateau but the pure high-frequency sound of mitral valve regurgitation. Physicians

Table 43–9. Description of a Murmur

1. Intensity (Grades I–VI)
2. Phase (systole, diastole, continuous)
3. Shape (crescendo, decrescendo, "diamond," plateau)
4. Timing (early, mid, late)
5. Length (short, medium, long, pan)
6. Pitch (low, medium, high)
7. Quality (vibratory, harsh, rumbling)
8. Location of maximum intensity
9. Radiation of murmur
10. Effect of maneuvers (inspiration, standing, squatting)
11. Eponym (Still's, Austin-Flint, Carey Coombs, Graham Steell)

Table 43–10. Several Eponyms Associated with Cardiac Murmurs

Eponym	*Description*
Austin Flint murmur	Dr. Austin Flint of New York described this finding while on the faculty of the Charity Hospital in New Orleans. This was a low-frequency diastolic "blubbering" murmur at the cardiac apex caused by vibration of the anterior mitral leaflet in cases of aortic regurgitation.*
Hodgkin's murmur	The famous Thomas Hodgkin of Guy's Hospital in London published a clinical description of aortic regurgitation several years before Corrigan. Some still refer to the diastolic decrescendo murmur of aortic regurgitation as the Hodgkin's murmur, although this eponym is rarely used in the United States.†
Carey Coombs murmur	Dr. Carey F. Coombs of Bristol was one of the first physicians to have formal training in both cardiology and pediatrics. He described a middiastolic, apical, rumbling murmur in the early phases of acute rheumatic fever in patients with mitral regurgitation.‡ He thought that this murmur was caused by edematous mitral leaflets from the rheumatic inflammation, but a similar middiastolic murmur can be heard in congenital and myxomatous mitral regurgitation cases.
Graham Steell's murmur	A high-frequency diastolic decrescendo murmur in the pulmonary area was described by Dr. Graham Steell of Manchester due to pulmonary hypertension from rheumatic mitral stenosis.§ A similar pulmonary insufficiency murmur can be found in cases of severe pulmonary hypertension from other causes, such as primary pulmonary hypertension.
Gibson murmur	The continuous roaring ("train-in-the tunnel") murmur of a large patent ductus was described by Dr. Gibson at the turn of the century.‖ The eponym is used in some older publications.
Still's murmur	This common lower left sternal border, vibratory, musical systolic murmur is described in Chapter 109 in greater detail. Dr. George Frederick Still of Great Ormond Street Children's Hospital described this murmur in the early 1900s.¶

develop an ear for the distinctive quality, pitch, shape, and duration of a certain murmur in much the same way that musicians learn to distinguish between an oboe and an English horn or naturalists learn the calls of different birds. Many new students in clinical medicine assume at first that they are tone deaf when they cannot hear, much less correctly identify, certain sounds when the problem is simply a matter of learning the sound with supervising faculty to guide them. One cannot successfully read about the quality of a murmur and then independently proceed to recognize it in a patient.

No one forgets to examine the heart with a stethoscope, but in the newborn infant with pulmonary and systemic venous congestion and a dilated heart, the physician should always listen over the cranium and the liver. A continuous murmur in these areas would suggest that the cause is arteriovenous fistula. Of course, not all cranial bruits are pathologic. Benign bruits not arising from fistulae can be heard in about 15% of normal children under 5 years of age.[99]

While the classical cause of a continuous murmur is the persistent ductus arteriosus, the typical murmur may not become evident in the full-term infant until after the newborn period or, in rare instances, much later in the first year of life. On the other hand, in the preterm infant with a functionally important patent ductus, one can hear a continuous murmur in only one third of the patients, a murmur confined to systole in approximately 60%, and absence of murmur altogether in the remaining 10%.[100]

Properly carried out, the history and physical examination can give the experienced examiner a great deal of information about the functional and sometimes the structural abnormalities of the cardiovascular system. Examiners who are convinced of the value of the history and physical examination do the examination the best. But one has to adhere to a strict protocol pertinent to each individual patient. Infants and children respond to patience and gentleness, and physicians must be prepared to take as much time and care with a clinical assessment as with evaluation of the hemodynamic and imaging data obtained at cardiac catheterization.

CHAPTER 44

Noninvasive Diagnostic Methods: Plain Radiographic Diagnosis of Congenital Heart Disease

Edward B Singleton
Mary J H Morriss

CARDIAC EVALUATION BY RADIOGRAPHY

History

Early radiologic methods of cardiac evaluation consisted of chest fluoroscopy and radiographic studies. Fluoroscopic examination of the heart was considered an indispensable part of the evaluation. Relying solely on radiographic studies was as negligent as omitting fluoroscopy in the evaluation of gastrointestinal disorders. To be examined, the child was put in either a supine or upright position (depending upon age and cooperation), and careful fluoroscopic attention was given to diaphragmatic motion, pulmonary aeration, cardiac pulsations, and the pulsations of the main pulmonary arteries in the hilar regions. Then the patient would be turned 45° into a right anterior oblique position and then into approximately 60° in the left anterior oblique position. This was done to evaluate anterior and posterior borders of the heart and to identify, if possible, the size of the pulmonic and aortic windows. This procedure would be accompanied by a swallow of flavored liquid barium or barium paste. (The addition of chocolate syrup to the barium improved its taste.) After the fluoroscopic examination, radiographs were obtained in the anteroposterior (AP) or posteroanterior (PA) position, depending on the patient's age, as well as a lateral radiograph plus right and left oblique views of approximately the same angulation as the fluoroscopic studies.[1] Each of these radiographs was made following additional barium ingestion.

The introduction of image amplification fluoroscopy enabled physicians to carry out the fluoroscopic studies in a lighted room and to observe cardiac and hilar pulsations to better advantage. Increased amplitude of pulmonary artery pulsations (hilar dance) indicative of increased pulmonary blood flow was easily seen after the introduction of image amplification fluoroscopy. Prior to image amplification fluoroscopy, radiologists had to wear red goggles or sit in the dark in order to accommodate their eyes to the peripheral vision necessary for fluoroscopy. Soon it became apparent that fluoroscopy added little additional information to that obtained by the radiographic studies and was associated with a great deal more radiation than desirable. The damaging effects of radiation, both by diagnostic methods and especially following atomic detonations, produced enormous concern in the general population as well as among medical practitioners. This concern was especially directed to infants and children. Although the introduction of the image amplifier greatly reduced the amount of fluoroscopic radiation, fluoroscopy for routine study of the heart was proven unnecessary. However, because of the intensity of its image, it provided a method for cine and video recordings of angiocardiography. Today, fluoroscopy of the heart independent of catheterization is rarely carried out. But it is still useful when evaluating diaphragmatic excursion postoperatively when phrenic nerve injury is suspected.

What's in an X Ray?

In most cases, cardiac pathology is reflected in an abnormal chest x ray result. However, many serious cardiac abnormalities are not excluded by a normal x-ray film of the chest. Chest radiographs of the infant with tetralogy of Fallot and the adult with coronary disease may be strikingly normal. Another inconsistency in the requisition is a request to determine if there is cardiac hypertrophy. A measurement of hypertrophy is determined by elec-

trocardiography or echocardiography. Cardiac dilatation must be present in order to produce cardiomegaly either generally or in regard to a specific chamber.[2,3] For example, the left atrial myocardium may quadruple in thickness without altering cardiac size, and the left ventricle may double its wall thickness without appreciably changing cardiac dimension on plain films.[4]

RADIOGRAPHIC TECHNIQUE AND AMOUNT OF RADIATION

Although many restraints are available for immobilizing infants during the x-ray examination, the simplest and most practical method is to have a parent or aide (protected with an apron) hold the infant supine. The infant's elbows must be held against the ears to maintain the head in a straight position. Any head deviation results in rotation of the chest and an unacceptable AP view. The shorter tube film distance (36 to 40 in.) of a supine film does not produce the magnification seen in larger patients, in whom a 6-foot distance is required. No effort is made to keep the infant from crying, thereby enabling the technician to make the required exposure at the peak of inspiration. Gonadal shielding is imperative in all cases. A minimum of $1/60$ of a second of exposure is necessary for an acceptable radiograph; in order to have consistently good images, exposure times of at least $1/100$ of a second are preferable to avoid motion artifacts from respiratory movement and cardiac pulsations. The diaphragm should be at the level of the posterior portion of the eighth rib (or lower) to verify that an inspiratory film was obtained. Normal variations including pectoral muscle shadows, expiratory phase with high position of the diaphragm, and crowding of vascular markings should be considered in evaluating the film quality. The ability to see the thoracic spine through the mediastinal shadow in the frontal projection indicates the desired degree of penetration. Portable radiographs using condenser discharge equipment are useful for quality portable studies in the intensive care units, as well as in postoperative recovery rooms.

The approximate entrance skin dose in a small infant receiving one chest x ray is less than 10 mR over the anterior chest wall and less than 1 mR to the pelvis area.[5,6] However, the pelvis should be protected, not only during examinations in the x-ray department, but also with portable studies. To place these doses in perspective, it is notable that the annual exposure for an individual at sea level from natural radiation sources is 100 mR. Occupational workers should not exceed 5000 mR/year to the lens of the eye.

NORMAL RADIOGRAPHIC ANATOMY OF THE HEART

Infancy

It may be very difficult to evaluate accurately heart size in young infants if the thymus is large. A large thymus may completely envelop the cardiac silhouette in the frontal projection, making accurate measurements and establishment of a cardiothoracic ratio impossible. In addition, an infant's inability to hold his/her breath voluntarily in inspiration frequently results in radiographs with the diaphragm at a high level, producing an increase in the cardiothoracic ratio and crowding of the lung markings. The infant's thoracic cage is also wider than it is deep, as compared to the opposite dimensions in an older child. An acceptable inspiratory radiograph is one in which the diaphragm is at the level of the eighth rib posteriorly, or the sixth rib anteriorly. Because of the thymus and alterations in degrees of inspiration, the "cardiothoracic" ratio may be as much as 70% in an infant with a normal heart. The cardiothoracic ratio is the ratio of the largest transverse dimension of the heart to the widest intercostal diameter of the chest. Fluoroscopy may be helpful in identifying the thymus by showing the angle of the thymus when the patient is rotated into oblique positions and by demonstrating changes in configuration of the thymus with inspiration and expiration. In addition, the thymic "wave sign" usually can be identified on AP chest radiographs.[7] This sign consists of indentations on the lateral border of the thymus by the costal cartilages.

The thymus gradually reduces in size, and during the latter part of infancy and by the end of the second year (or the beginning of the third year) of life, the cardiac configuration usually resembles that of the older child. However, thymic tissue may persist during the first few years of life and should not be mistaken for an abnormal mediastinal mass. The use of steroids to "shrink" the thymus in order to evaluate the heart configuration or size is not indicated. Repeat chest radiographs in order to obtain a better inspiratory study are also rarely necessary. If the infant has pneumonia or congestive failure, it is more difficult for an x-ray exposure to be made in expiration since the tachypnea accompanying these conditions may guarantee a low position of the diaphragm. X-ray exposures made in cardiac diastole may suggest cardiomegaly but, again, other methods of cardiac evaluation are helpful for further assessment.

Childhood

Because of the variation of the mediastinal silhouette in infants, the description of the radiographic anatomy does not become consistent until later childhood. In order to demonstrate radiographic anatomy, AP (or PA) and lateral views of the chest as well as oblique views are necessary.

In the frontal projection (Fig. 44–1), the right cardiac border is the right atrium. The lower left cardiac border is normally the left ventricle. Above this is a normal convexity, the undivided portion of the pulmonary artery. The convexity above this is the aortic arch, which displaces the trachea slightly to the right. A right aortic arch is identified on the PA view as a fullness in the right superior mediastinum with displacement of the trachea to the left. The left atrial appendage contributes to the left heart silhouette between the pulmonary artery and left ventricle. But the atrial contour blends with the left ventricle and is distinct only when the atrium is dilated.

In the right anterior oblique (RAO) view, the right side of the patient's chest is against the cassette with the left side turned 45° from the flat surface of the cassette (Fig. 44–2). This position can be recognized by seeing the cardiac contour extend to or close to the chest wall anteriorly. The anterior chamber is the right ventricle and the convexity above this is the pulmonary artery; posteriorly the inferior shadow is the right atrium and above this, the left atrium. If the esophagus is outlined with contrast material, an indentation produced by a normal left aortic arch will be identified. Below this, an indentation by the left bronchus frequently is visible. The main advantage of this view is a demonstration of left atrial enlargement. When the left atrium enlarges, it extends pos-

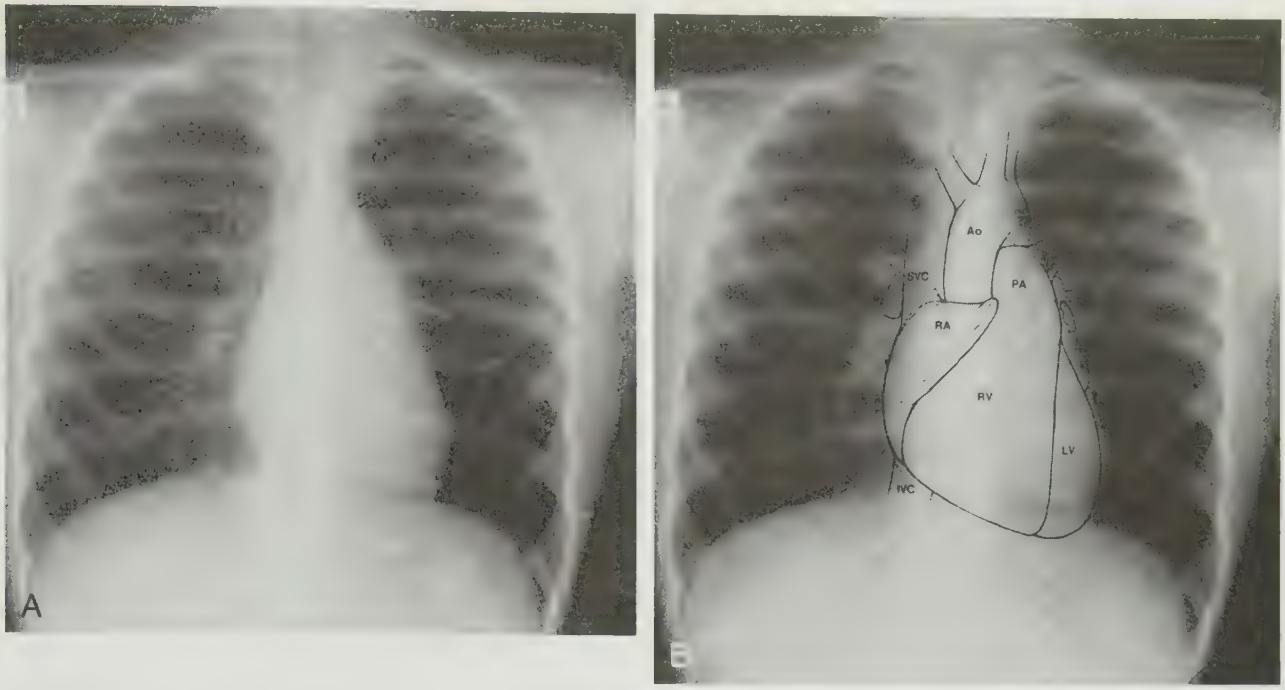

Fig. 44–1. Normal posteroanterior chest radiograph in a 10-year-old child. (A) PA view with barium in the esophagus. (B) Drawing of anatomic chambers identified in the PA view.

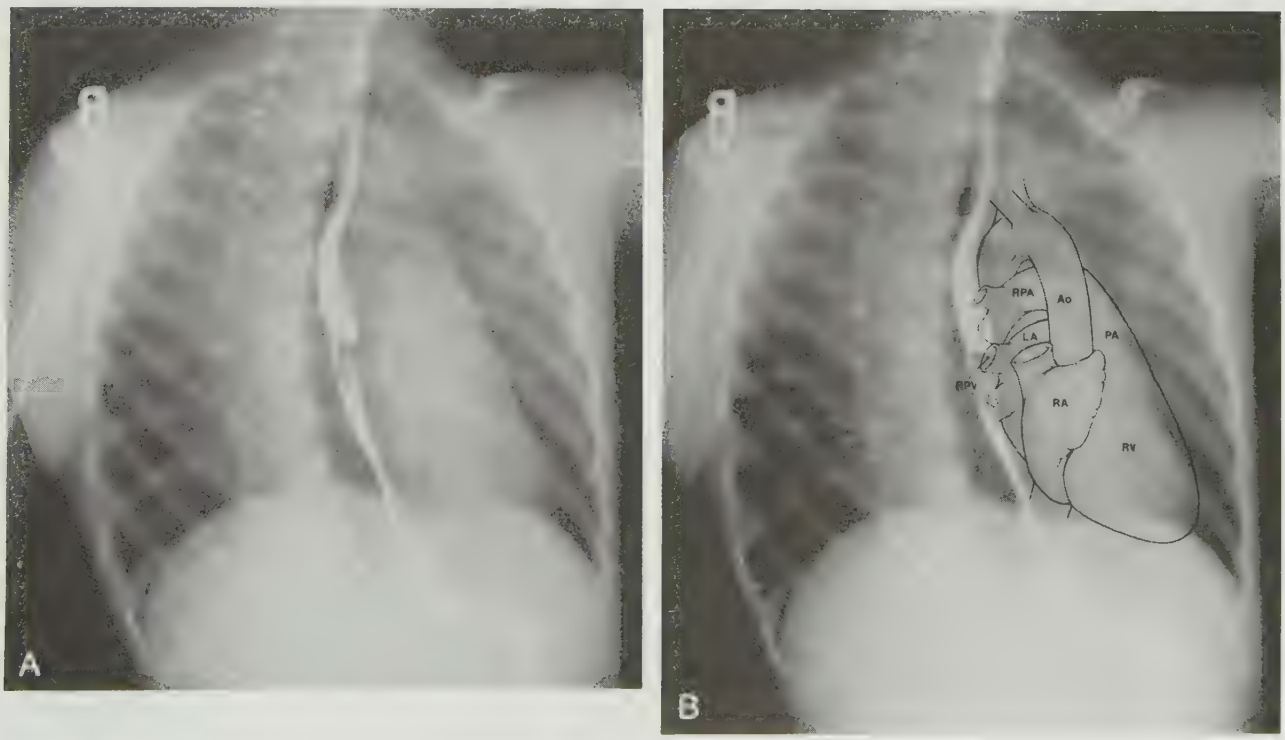

Fig. 44–2. Right anterior oblique view. (A) The concavity on the upper anterior portion of the esophagus is produced by the aortic arch. There is no posterior displacement of the left atrium. (B) Drawing of cardiac chambers in this view. Note the proximity of the left atrium to the lower third of the esophagus and the proximity of the aortic arch to the upper portion of the esophagus.

teriorly and to the right, thereby displacing the esophagus posteriorly and to the right.

In the left anterior oblique view (LAO), the left side of the chest is against the cassette with the right side approximately 60° from the flat surface of the cassette (Fig. 44–3). This position can be recognized easily because the anterior chamber that is the right ventricle does not extend to the chest wall. The posterior chamber is the left ventricle. Increased convexity, or a decrease in the distance between the anterior cardiac chamber (right ventricle) and the chest wall, suggests right ventricular dilatation. If the esophagus contains contrast media, a right aortic arch can be identified indenting the esophagus. The main advantage of this view is to evaluate right and left ventricular dilatation.

In the lateral view (Fig. 44–4), the right ventricle constitutes the lower one-half to two-thirds of the anterior cardiac border and lies behind the sternum. The upper third constitutes the right ventricular outflow tract and pulmonary artery root. The space above the origin of the pulmonary artery is occupied by the thymus; past infancy, this is a clear area of aerated lung. The upper half of the posterior cardiac border consists of the left atrium, and the lower half includes the left ventricle.

Because of the additional radiation involved in obtaining multiple views and because other modalities are available to evaluate cardiac size, the oblique views are rarely necessary and barium ingestion is now used primarily for the evaluation of a suspected vascular ring. However, posteroanterior and lateral chest radiographs are valuable in screening and are justifiably obtained as part of the initial workup of patients with suspected heart disease. All areas included on the radiograph are best observed systematically including the cervical spine, shoulder girdles, thoracic cage and chest wall, and the subdiaphragmatic areas. For example, children with Down syndrome frequently have only 11 ribs and double manubrial ossification centers. Premature fusion of sternal segments is common in many cases of cyanotic heart disease. A straight thoracic spine and decrease in the anteroposterior dimension of the chest (straight back syndrome) may be responsible for a functional murmur.[8] Pectus excavatum apparent on the lateral film may explain the AP film appearance of displacement of the heart into the left chest and exposure of the right hilar area mimicking pulmonary pathology. Kyphoscoliosis may produce marked displacement of mediastinal structures, making radiographic evaluation of the heart and lungs difficult.[9] Scoliosis is present in 6% of patients with cyanotic heart disease. A coarse and trabecular pattern with expansion of the medullary cavity of the ribs is expected in chronic anemias and cyanotic heart disease, and rib notching is an expected finding in older patients with coarctation of the aorta. Unilateral rib notching is also a common finding following a Blalock-Taussig procedure (subclavian-pulmonary artery anastomosis).[10]

The subdiaphragmatic organs such as the stomach and liver should be identified in order to recognize situs inversus. There are four major considerations regarding the recognition of abdominal viscera.[11] Situs (position) solitus (usual) is usually associated with a normal heart and normal bronchial divisions. In situs inversus, true mirror image dextrocardia is frequently present; in this condition, the aortic arch is on the right. This should not be confused

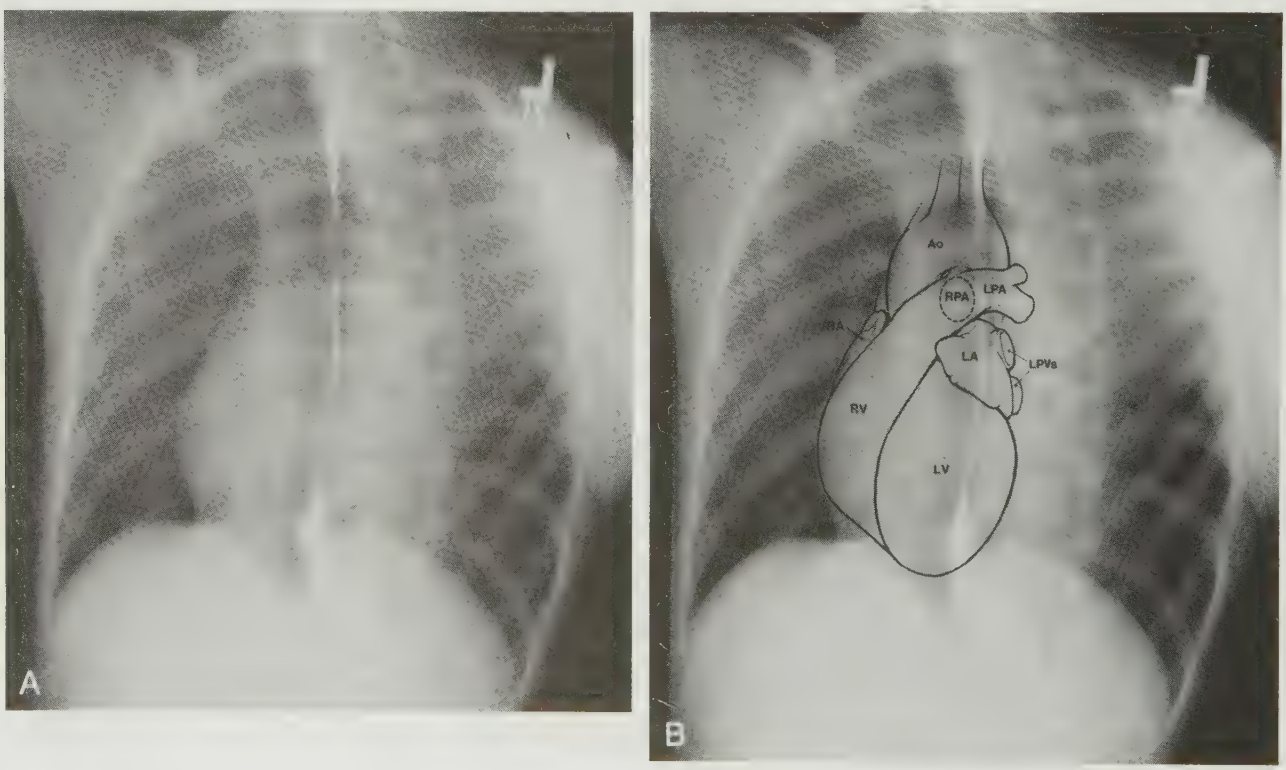

Fig. 44–3. Left anterior oblique view. (A) Note the greater distance between the anterior cardiac border (right ventricle) and the anterior chest wall compared to the right anterior oblique view (see Fig. 44–2). (B) Drawing of cardiac chambers showing most of the anterior cardiac silhouette. In this view, the right ventricle is anterior and the left ventricle is posterior.

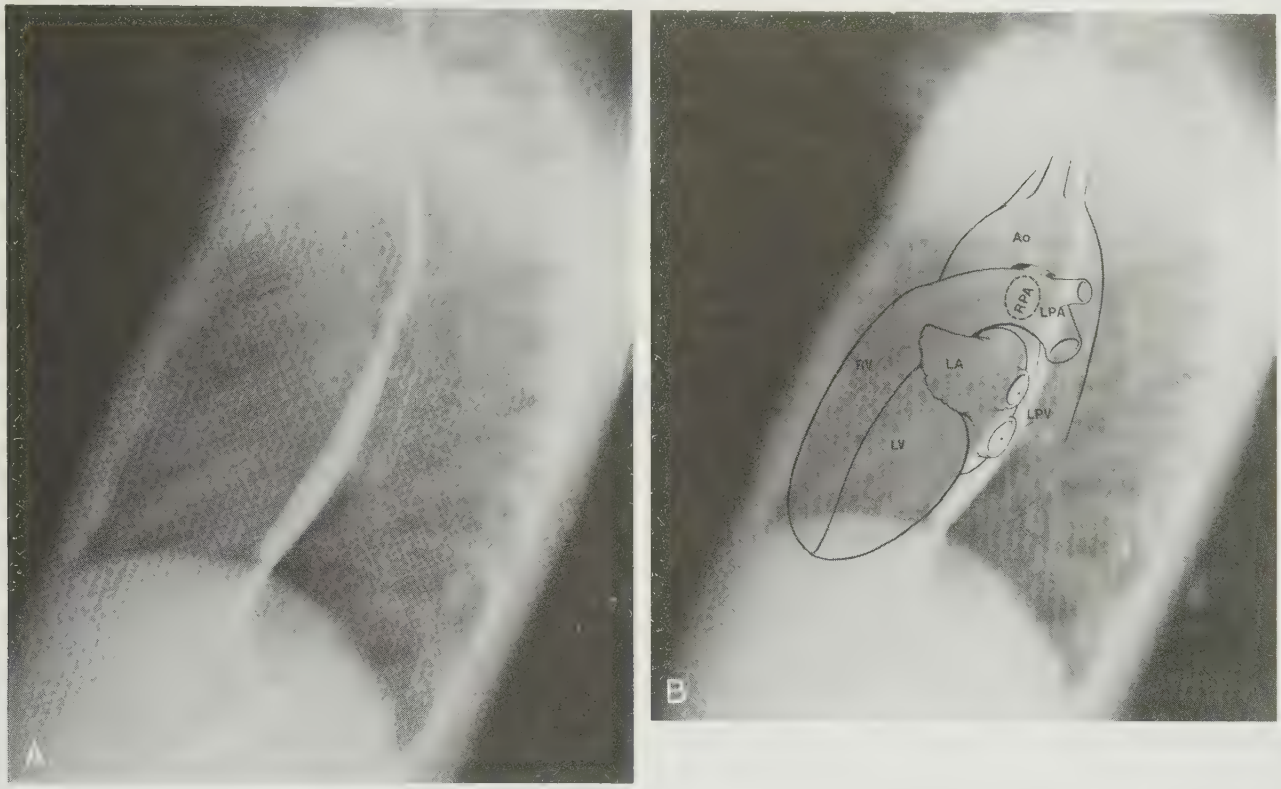

Fig. 44–4. Lateral view. (A) Radiograph shows normal configuration of the esophagus with slight indentation in the upper portion produced by the aortic arch. (B) Anatomic drawing showing the proximity of the right ventricle to the anterior chest wall.

with dextroversion, in which the aortic arch remains on the left with the configuration and position of the heart to the right of the midline of the chest similar to dextrocardia. In true situs inversus with dextrocardia, there is also inversion of the lungs.[12] In other words, the left-sided lung has three lobes and the right two. The incidence of cardiac anomalies with situs inversus may be up to twice that of situs solitus.[13] Correct labeling of the radiograph as to right and left sides is important to avoid a mistaken diagnosis of dextrocardia and situs inversus.

Thus, there are two long bronchi of equal length with a wider-than-normal midline angle. In the polysplenia syndrome, there are usually two bilobed lungs (left-sided pulmonary isomerism).[14–16] In this condition, the stomach bubble is usually in a more medial position and the liver is also in a midline location. A common feature of this syndrome is venous drainage from the abdomen through the azygous system into the right atrium (azygous continuation of the inferior vena cava). The congenital heart diseases associated with the polysplenia syndrome typically are those anomalies associated with left-to-right shunts. These include atrial and ventricular septal defects, endocardial cushion defects, double outlet right ventricle, and patent ductus arteriosus; mixed pulmonary venous return is frequent.

The asplenia syndrome (Ivemark syndrome)[17] is associated with bilateral right-sidedness. In other words, two right lungs each contain three lobes; the major bronchi are short because of the origin of a right upper lobe bronchus bilaterally. The liver is usually in the midline position. This syndrome commonly is associated with complex or severe heart disease, often cyanotic, typified by a variety of conditions including endocardial cushion defects, pulmonary atresia or stenosis, transposition of the great vessels, and double outlet right ventricle. An evaluation of the bronchial configuration as to whether there is bilateral right-sidedness or left-sidedness is determined by high 100 kilovolts radiograph utilizing a Thoraeus filter made of copper and aluminum.[18] The presence or absence of multiple spleens is easily determined by liver–spleen nuclear scans.

RADIOGRAPHY OF CONGENITAL HEART DISEASE

Newborn

Serious cardiac malformations may be present in a newborn, but clinical manifestations may not develop until several weeks later. However, one group of cardiac anomalies can be identified clinically during the first few days of life. Among the most common are complete transposition of the great vessels, hypoplastic left ventricle, and total anomalous venous return below the diaphragm. The hypoplastic left heart syndrome is the most common cause of congestive heart failure during the first few days of life; complete transposition of the great vessels is most common in the cyanotic newborn. Severe aortic stenosis, tetralogy of Fallot, and coarctation of aorta may make their presence known clinically during the newborn period, but these are less commonly detected than the other anomalies. Newborn infants with hypoplastic left ventricle usually show cardiomegaly with increased prominence of the pulmonary venous structures. The overall appearance of these infants may be similar to that of transient tachypnea of the newborn, a condition in which there is retained fetal lung fluid

with associated cardiomegaly, prominent pulmonary veins, Kerley B lines, and fluid in the interlobar fissures and pleural space. In this latter condition, the chest radiograph returns to normal after a few days, as a result of lymphatic and capillary absorption of the fluid. In the hypoplastic left heart syndrome, the changes of congestive failure increase. Total anomalous pulmonary venous return below the diaphragm should be suspected in an infant with Kerley B lines, a heart that is normal in size and configuration, and hepatomegaly. Kerley B lines are best seen above the costophrenic sulci and appear as horizontal lines of increased density.[19] They represent fluid within the interlobular septa and lymphatics and reflect an increase in pulmonary venous pressure. Cardiomegaly and congestive heart failure also may occur in acute and chronic hypoxemic conditions, intrauterine transfusion syndrome, erythroblastosis fetalis, large hemangiomas, and especially in arteriovenous malformations such as an aneurysm of the vein of Galen.

An experienced radiologist can make a diagnosis of a specific type of congenital heart disease from conventional posteroanterior and oblique views of the chest with an accuracy of approximately 70%. The probability of including the right diagnosis within a select list of differential possibilities is over 90%.

Infancy and Childhood

In the radiologic consideration of congenital heart disease, there are five primary considerations: 1) Is the heart enlarged? 2) Which chambers are dilated? 3) Are the pulmonary arterial markings increased, decreased, or normal? 4) Is the undivided portion of the pulmonary artery convex or concave? 5) Is the aortic arch large, small, or normal in size and position in the chest?

The most important of these considerations is the evaluation of the pulmonary arterial vascularity.[20,21] If the vascularity is increased, diminished, or normal, then there are entirely different groups of differential consideration that can be further defined by evaluating cardiac chamber size, size of the pulmonary artery, and size of the aortic arch.

Differentiation of the pulmonary arteries from pulmonary veins may be made with a reasonable degree of accuracy. The pulmonary veins are straight in their course and directed toward the central portion of the heart, which is the left atrium. The pulmonary arteries, on the other hand, are more tortuous, and can be seen on end, particularly in the region of the superior hilus.

One method of determining increase or decrease in the size of the pulmonary arteries is to compare an "end on" bronchus filled with air with an adjacent "end on" artery, which should be comparable in size in the middle third of the lung field. When pulmonary vessels are enlarged, the artery is larger than the bronchus.

The following classification, based on the prominence of the pulmonary arterial markings, is valuable in determining the differential diagnosis of congenital heart lesions (Table 44–1). This does not include all examples of congenital heart conditions because many forms defy description. In addition, the evaluation of congenital heart disease is not entirely a radiologic problem. Rather, it is a cooperative effort between the radiologist and the cardiologist, synthesizing the information obtained from electrocardiography, echocardiography, and cardiac catheterization.

If we can conclude that the pulmonary arterial markings are increased, we can usually assume that one of the following conditions is present: atrial septal defect, ventricular septal defect, atrioventricular canal, patent ductus arteriosus, anomalous pulmonary venous return, true truncus arteriosus, or uncomplicated transposition of the great vessels. Corrected transposition (ventricular inversion) also may be included because this is usually associated with a ventricular septal defect. In this group with increased vascular markings are further findings that are helpful in determining which further condition is present. In each of the defects in which there are increased pulmonary arterial markings, there is increased pulmonary flow. If there is associated pulmonary hypertension with increased resistance, the reliability of an evaluation based on the prominence of the arterial markings is less accurate.

Congenital cardiac defects in which there are decreased pulmonary arterial markings include tetralogy of Fallot, pseudotruncus (which is a variation of tetralogy of Fallot with pulmonary artery atresia rather than pulmonary stenosis), various types of tricuspid atresia, and Ebstein's malformation.

In a number of conditions, the pulmonary arterial markings are normal—namely, aortic stenosis, endocardial fibroelastosis, coarctation, congenital mitral stenosis, cor triatriatum, pulmonary valvular stenosis, and idiopathic dilation of the pulmonary artery. In this group, increased pulmonary venous pressure may be present with resulting increased prominence of the pulmonary venous markings and Kerley B lines. In such conditions, the accurate differentiation of pulmonary arteries from veins becomes difficult but not impossible. Also, the presence of complicating bronchopneumonia makes it more difficult to determine whether or not the arterial markings are increased, decreased, or normal. Pneumonia as a complication of congenital heart disease is much more

Table 44–1. Radiologic Considerations of Congenital Heart Disease

Increased Pulmonary Vascularity	*Decreased Pulmonary Vascularity*	*Normal Pulmonary Vascularity*
1. Atrial Septal Defect	1. Tetralogy	1. Aortic Stenosis
2. Ventricular Septal Defect	2. Pseudotruncus	2. Endocardial Fibroelastosis
3. AV Commune	3. Tricuspid Atresia	3. Coarctation
4. Ductus	4. Ebstein's Malformation	4. Congenital Mitral Stenosis
5. Partial Anomalous Venous Return	5. Pulmonary Hypertension	5. Cor Triatriatum
6. Total Anomalous Venous Return	6. Transposition with Pulmonary Stenosis	6. Pulmonary Valvular Stenosis
7. Truncus Arteriosus		7. Idiopathic Dilatation of the Pulmonary Artery
8. Transposition		
9. Corrected Transposition		

common in association with a left-to-right shunt, because of compression of the dilated pulmonary arteries on the bronchial tree with resultant obstruction. In addition, air trapping of a lobe or pulmonary segment can occur and simulate congenital lobar emphysema.[22] The common sites of compression are the left main stem bronchus and the left upper and right middle lobe bronchus.

Increased Pulmonary Arterial Markings

Atrial Septal Defect

The usual atrial septal defect of the secundum type shows radiographic evidence of increased arterial markings, slight or moderate enlargement of the heart, convexity of the undivided pulmonary artery segment with a small aorta, and no evidence of left atrial enlargement as determined by absence of esophageal displacement in the right anterior oblique view (Fig. 44–5). Partial anomalous pulmonary venous return produces an identical radiographic appearance. One type of anomalous pulmonary venous return occurs in the "scimitar sign," in which a single large pulmonary vein (usually on the right) empties into the right atrium or inferior vena cava (Fig. 44–6). Atrial septal defect of the secundum type does not typically show left atrial enlargement due to the ease with which the atrium can "decompress" in the presence of a large atrial communication. One exception is that some of the ostium primum defects will show left atrial enlargement, particularly when mitral insufficiency (common in this anomaly due to cleft mitral valve) is present. If there is no left atrial enlargement, if there is the combination of a small aortic knob, a prominent pulmonary artery segment, and increased pulmonary vascularity, the lesion is probably an atrial septal defect or partial anomalous pulmonary venous return.

Ventricular Septal Defects

There are several different anatomic locations for ventricular septal defects with radiologic expression reflecting the size and direction of the shunt. Normal radiographs commonly are present with small defects (Fig. 44–7). Pulmonary vascular markings begin to appear prominent when pulmonary to systemic flow ratios (Q_p/Q_s) are 1.7/1 or more. The pulmonary vascular markings are increased, the aortic knob is small, the pulmonary artery segment convex, and there is usually evidence of left atrial enlargement in the right anterior oblique projection (Fig. 44–8). Most of the ventricular septal defects with a significant left-to-right shunt will show left atrial enlargement. Restrictive ventricular septal defects with a small left-to-right shunt and a pulmonary artery pressure less than 50% of the systemic pressure frequently show no radiographic abnormality. Ventricular septal defects with significant pulmonary hypertension (pulmonary artery pressure 85% of or equal to the systemic pressure) and with a balanced or reversed shunt (right to left across the defect) show little or no cardiac enlargement. These defects also have decreased peripheral arterial markings, an increase in size of the right and left pulmonary arteries at the hilus, and less evidence of left atrial enlargement (Fig. 44–9).[22] Recurrent pneumonia and segmental areas of air trapping are common in large left-to-right shunts (Fig. 44–10). The segments of air trapping should not be confused with congenital lobar emphysema.

Atrioventricular Canal

The radiographic features of atrioventricular canal defects are similar to ventricular septal defects except the heart is usually larger in the canal defect. This is particularly true in young infants in whom the heart may be markedly dilated and is also more globular or rounded than it is in isolated ventricular septal defect (Fig. 44–11). This is the most common cardiac lesion associated with Down syndrome.

Patent Ductus Arteriosus

The radiographic features of patent ductus arteriosus resemble those of ventricular septal defects except for a larger aortic arch. This difference is impossible to evaluate in the infant, but in the older child or adult it is usually apparent. In older children and adults, pulmonary arterial markings are increased; the undivided portion of the pulmonary artery is prominent and the left atrium is usually dilated.

The younger the patient, the more difficult is the evaluation of radiographic findings. But with increasing age, these differentiating features become more characteristic (Fig. 44–12).

Total Anomalous Venous Return (TAPVR), Supracardiac

This represents one type of congenital heart disease in which the radiographic findings may be pathognomonic (Fig. 44–13). In the most common type, pulmonary veins drain into a common chamber that empties by way of a left vertical vein into the innominate vein, to the right superior vena cava, and into the right atrium. In such cases, there is characteristic widening of the superior mediastinum that produces a "snowman" or "figure-eight" silhouette. Distention of the right superior vena cava and left vertical vein accounts for the "snowman" configuration. The heart is enlarged with convexity of the pulmonary artery segment and increased pulmonary arterial markings.

Total Anomalous Venous Return (TAPVR) Below the Diaphragm

The heart in this condition is usually of normal size (Fig. 44–14). Pulmonary vascular markings are poorly defined, and the overall appearance is more suggestive of passive venous congestion, bronchopneumonia, or hyaline membrane disease. The heart is not dilated because of the obstruction to venous return within the liver. The radiographic identification of Kerley B lines, normal heart size, and configuration with clinical evidence of hepatomegaly strongly suggests TAPVR below the diaphragm. Other differential considerations include pulmonary vein atresia or stenosis, cor triatriatum, and congenital mitral stenosis.

In transient tachypnea of the newborn (wet lung syndrome), which results from retained fetal lung fluid, Kerley B lines may be prominent, but the cardiac enlargement and pleural effusion differentiate this condition from total anomalous venous return below the diaphragm. Severe pulmonary lymphangiectasis in the newborn may resemble TAPVR below the diaphragm, but the clinical findings, catheterization data, and angiocardiography are differentiating procedures. Pulmonary arteriograms in a patient with intradiaphragmatic TAPVR demonstrate the return of pulmonary venous blood into a common venous trunk which passes through the diaphragm into the portal vein or inferior vena cava.

True Truncus Arteriosus

The pulmonary arterial markings in patients with true truncus arteriosus are usually greatly increased (Fig. 44–15). In addition, the heart is enlarged and the pulmonary artery segment is concave.

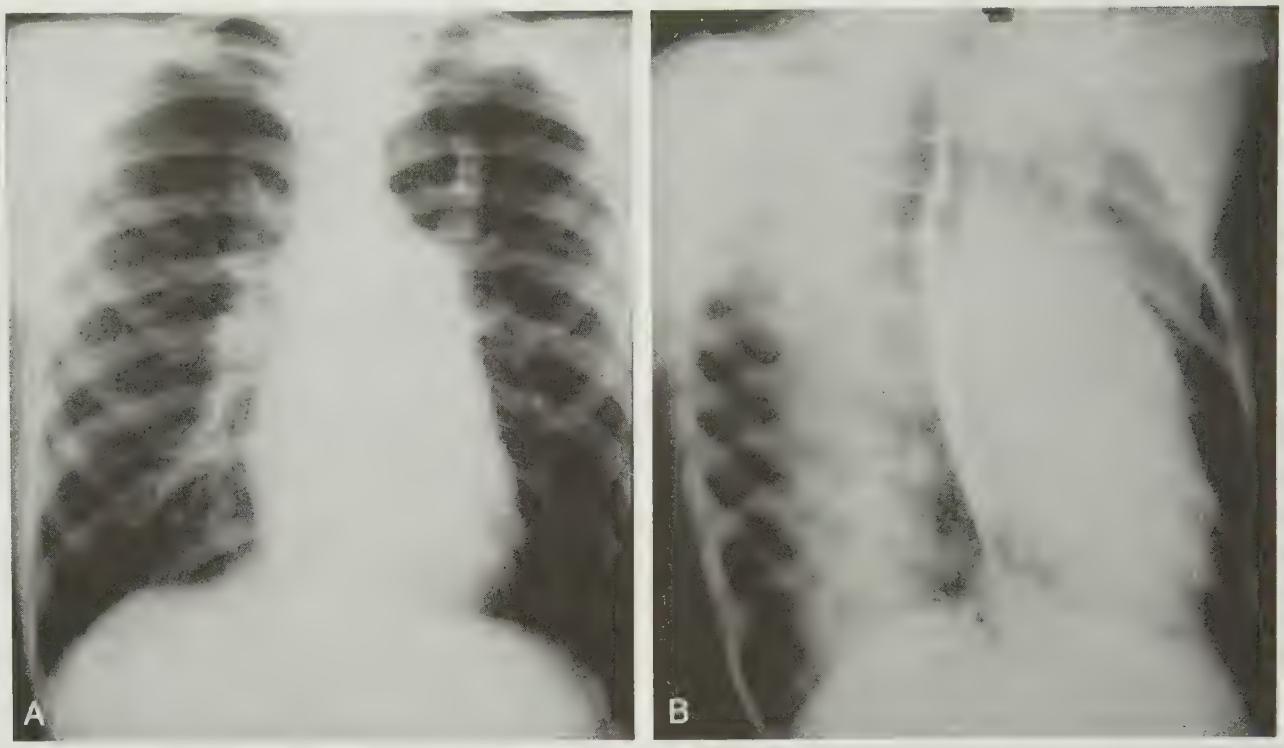

Fig. 44–5. Atrial septal defect (secundum type). (A) Posteroanterior chest radiograph shows a normal-sized heart but increased pulmonary arterial markings. The main pulmonary artery segment is convex and the aortic arch is normal (or perhaps slightly small). (B) Right anterior oblique view shows no evidence of left atrial displacement of the esophagus.

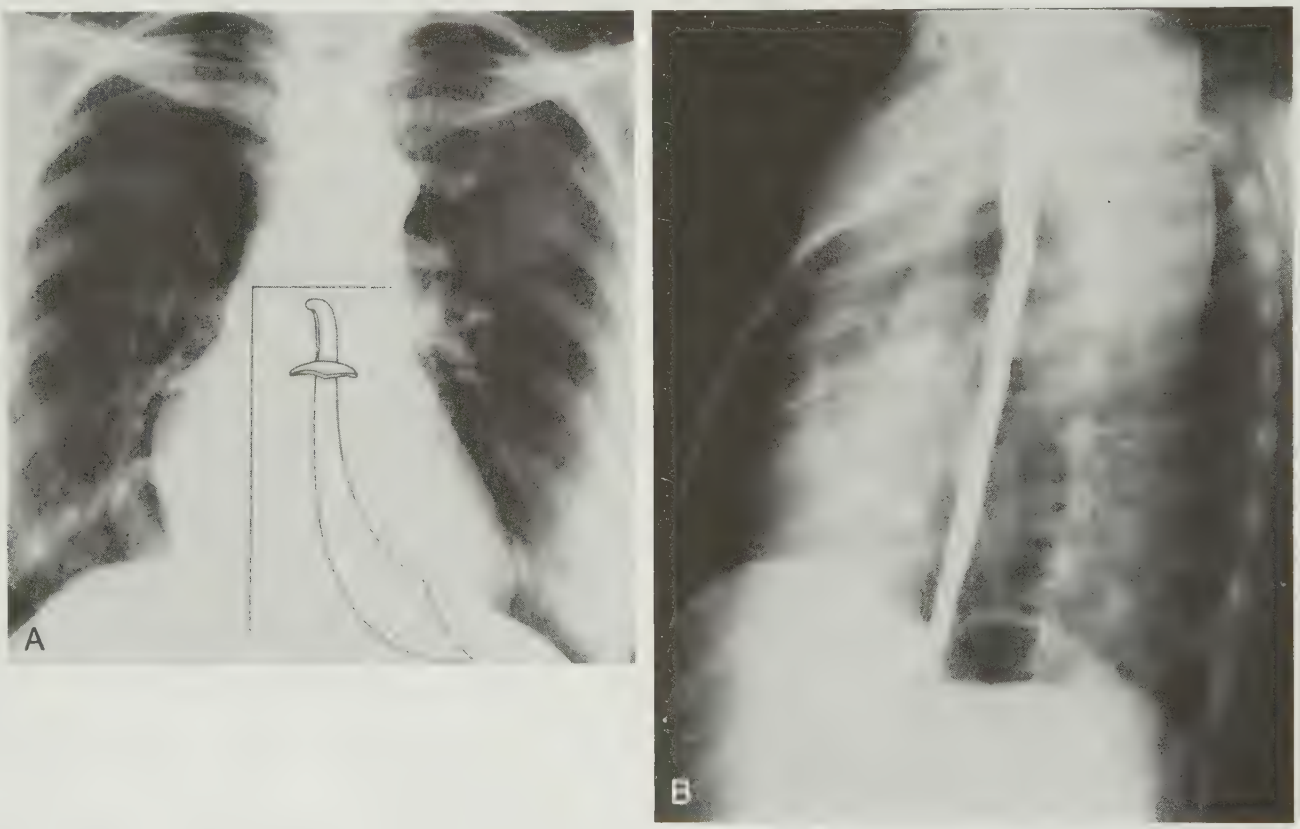

Fig. 44–6. Anomalous pulmonary venous return (scimitar sign). (A) An anomalous vein is adjacent to and parallels the right atrium. (B) Left anterior oblique view shows the anomalous vein terminating in a round area of increased density identifying its entrance to the right atrium.

Fig. 44–7. Small ventricular septal defect. The chest radiograph is normal.

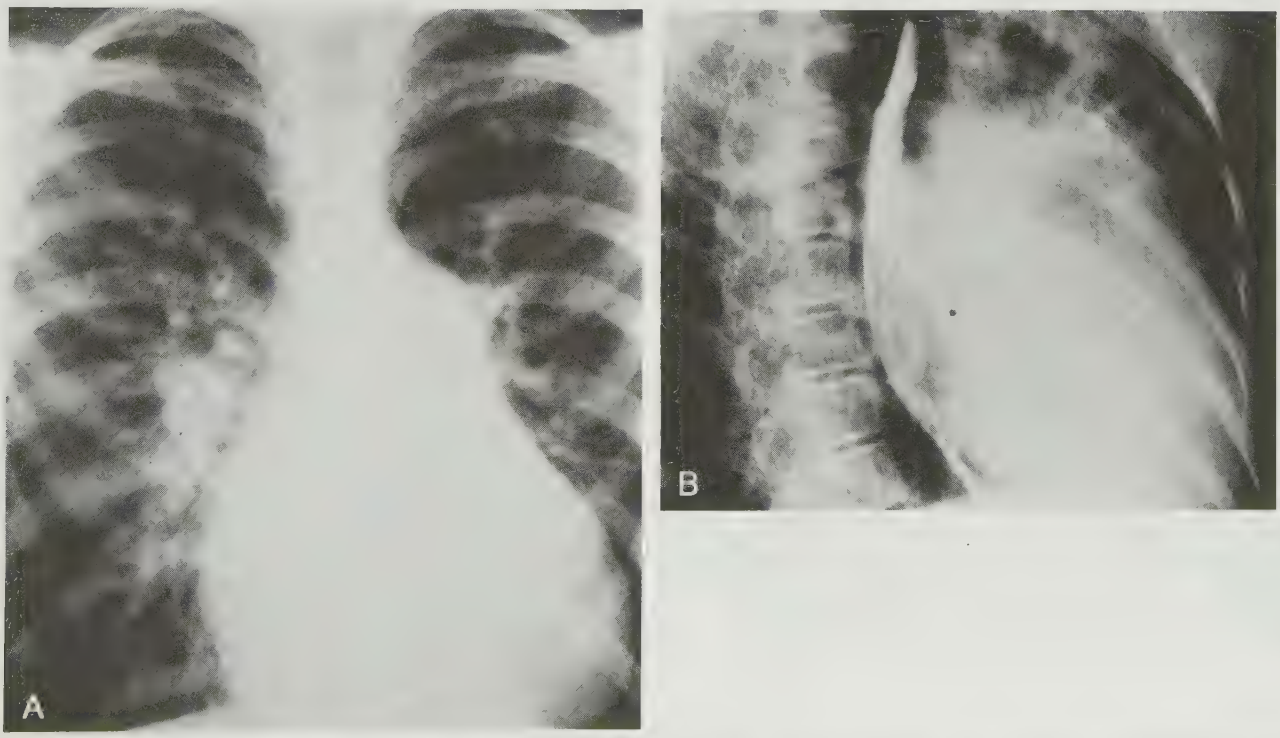

Fig. 44–8. Ventricular septal defect with large left-to-right shunt. (A) The heart is enlarged, pulmonary arterial markings are increased, the undivided portion of the pulmonary artery is abnormally convex, and the aortic arch is small. (B) Right anterior oblique view shows displacement of the esophagus by the dilated left atrium. There is minimal impression of the small aortic arch on the upper portion of the esophagus.

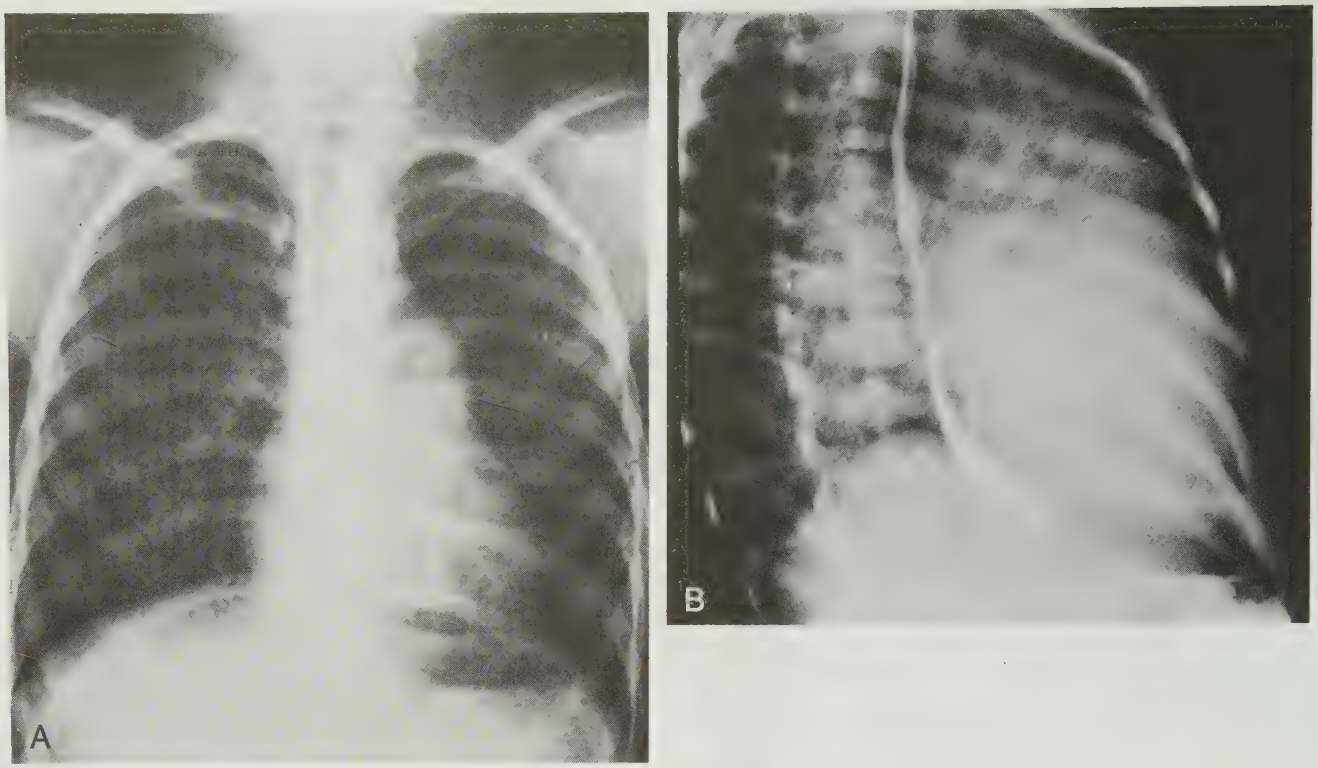

Fig. 44–9. Ventricular septal defect with pulmonary hypertension and right-to-left shunting. (A) The heart is of normal size, the main pulmonary artery is convex, the aortic arch is small, and pulmonary peripheral vessels are diminished. (B) Right anterior oblique view shows minimal posterior displacement of the esophagus by the left atrium.

Fig. 44–10. Ventricular septal defect. The heart is slightly enlarged, and pulmonary arteries are markedly increased. Perihilar pneumonia is present and the right middle lobe shows increased aeration due to air trapping.

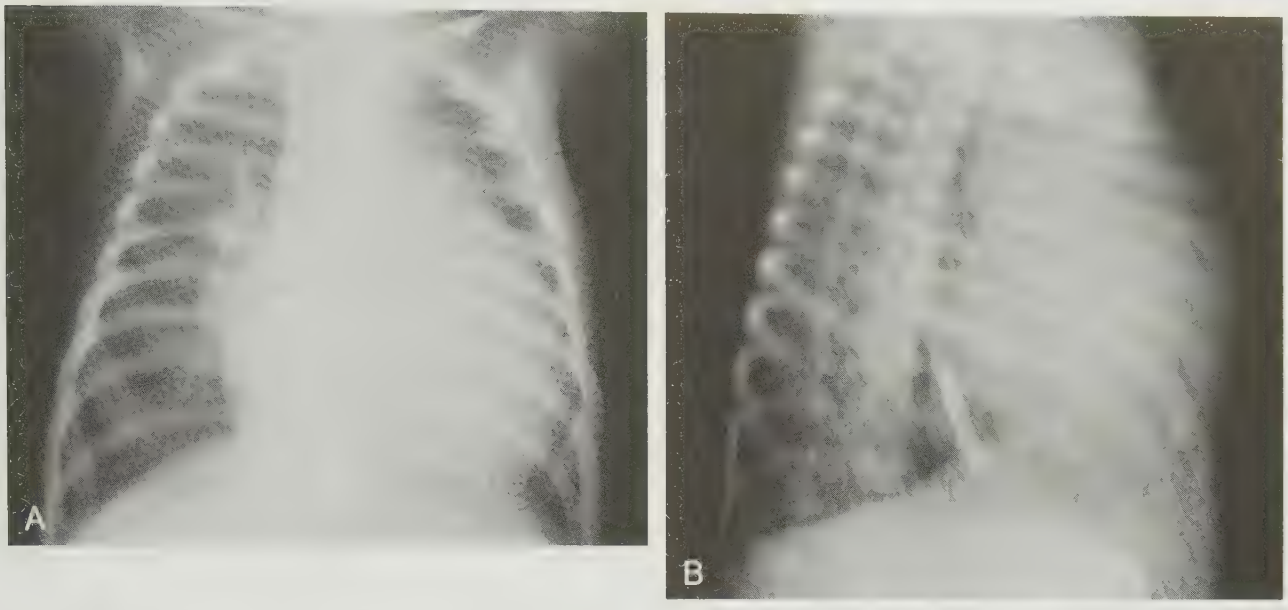

Fig. 44–11. Atrioventricularis communis. (A) The heart is enlarged and has a globular configuration. The pulmonary arterial markings are increased and the esophagus is displaced slightly to the right by the dilated left atrium. (B) Right anterior oblique view shows that all chambers are dilated with posterior displacement of the esophagus by the left atrium.

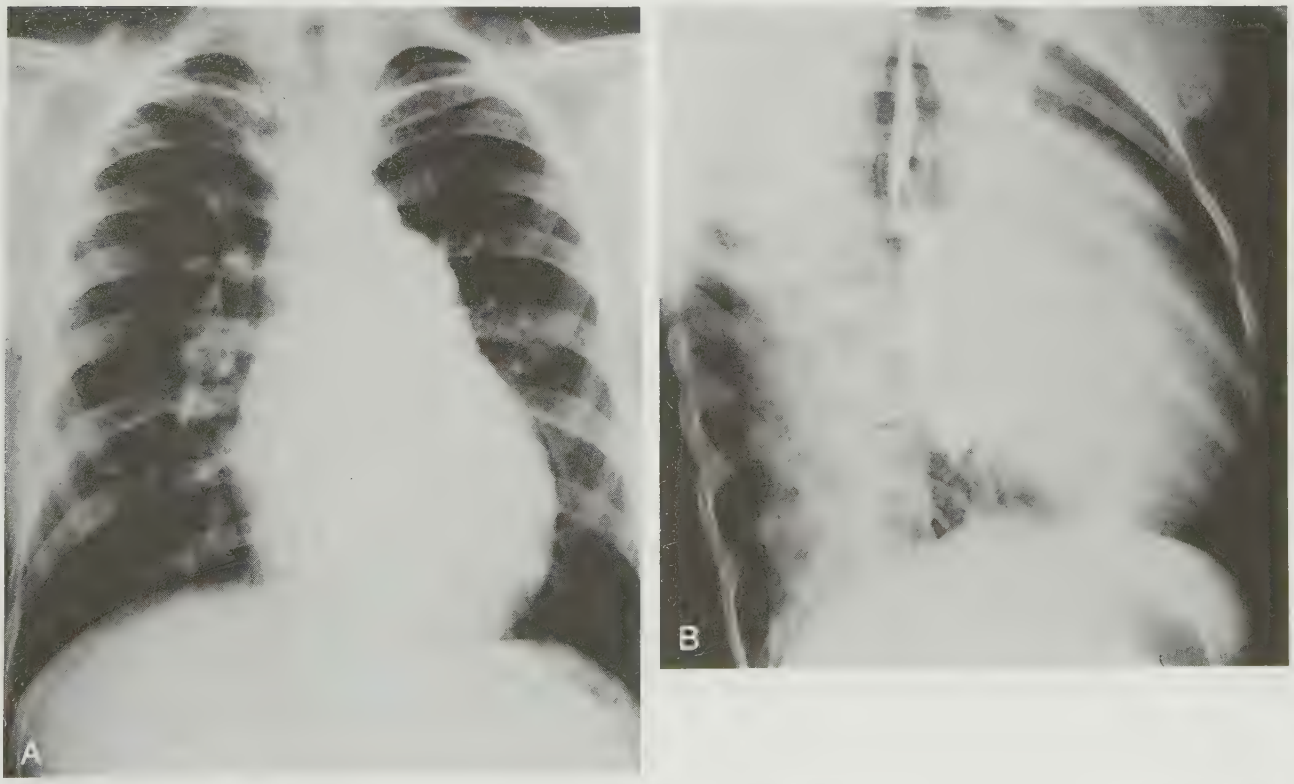

Fig. 44–12. Patent ductus arteriosus. (A) The heart is slightly enlarged, the main pulmonary artery is convex, and the aortic arch immediately above this is abnormally prominent. (B) Right anterior oblique view shows displacement of the esophagus by the dilated left atrium. Above this, the esophagus is significantly indented by the large aortic arch.

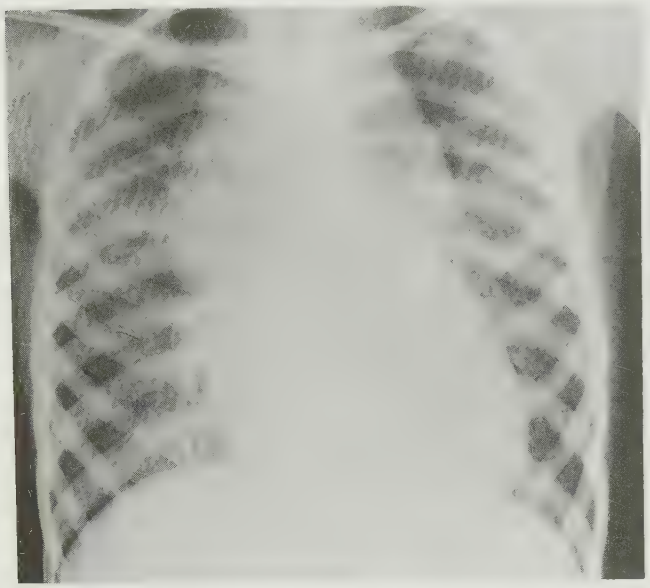

Fig. 44–13. Total anomalous venous return above the diaphragm. The heart is enlarged, pulmonary arterial markings are increased, and there is dilatation of the right and left superior venae cavae, resulting in the wide superior mediastinum.

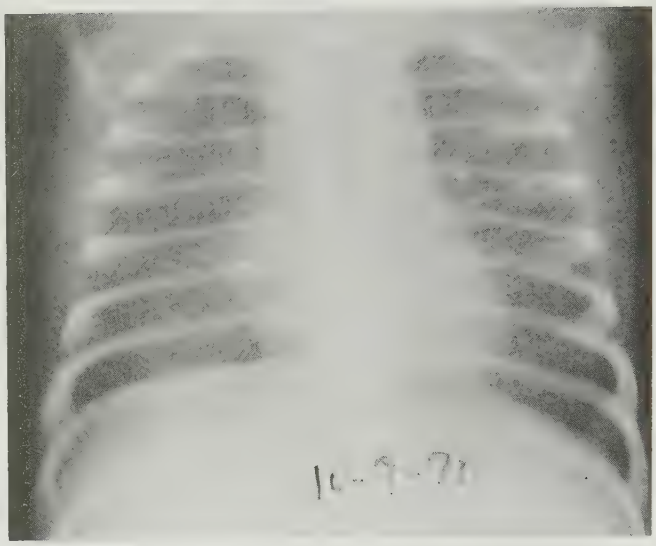

Fig. 44–14. Total anomalous venous return below the diaphragm in a newborn infant. The heart is of normal size. Pulmonary venous pattern is increased and ill-defined Kerley B lines are seen above the costophrenic sulci. On physical examination, the liver was enlarged.

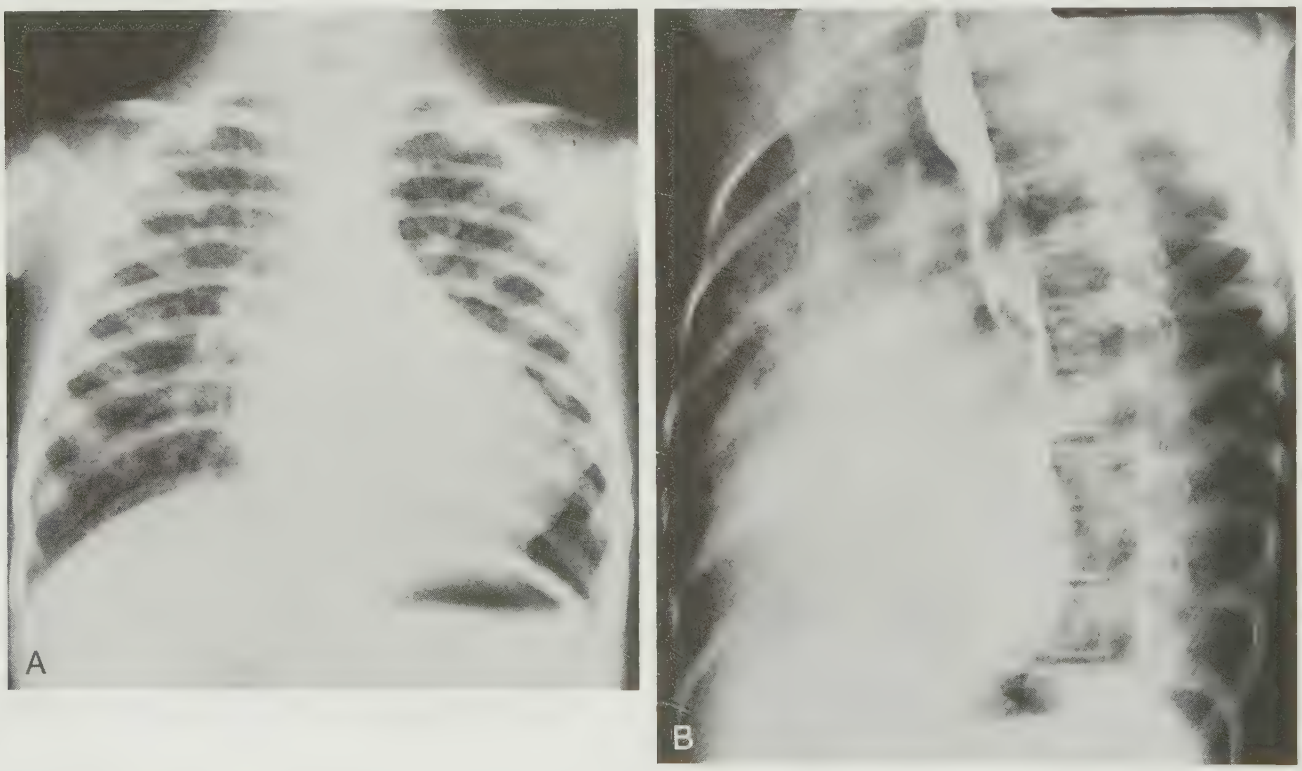

Fig. 44–15. True truncus arteriosus (Type I). (A) The heart is enlarged and pulmonary arterial markings are increased in prominence. The superior mediastinum is narrow. (B) Left anterior oblique view shows the enlargement of both right and left ventricles. Note the indentation on the anterior portion of the upper esophagus produced by a right aortic arch.

Both ventricles are prominent, and there is evidence of left atrial dilatation. A right aortic arch occurs in approximately 25% of patients with truncus arteriosus and, consequently, the combination of cardiac enlargement, increased pulmonary vascularity, and a right aortic arch, is very suggestive of this condition.

In complete transposition, the aorta arises from the right ventricle and is usually anterior to the pulmonary artery, which arises from the left ventricle. Obviously, various intra- and extracardiac communications must be present in order to sustain life.

The radiographic findings consist of cardiomegaly, increase in the pulmonary arterial markings, and a narrow superior mediastinum because of the transposed vessels (Fig. 44–16A). In the left anterior oblique view, the mediastinum may appear widened because of the transposed vessels (Fig. 44–16B). The heart frequently has an oval or egg-shaped configuration and the radiographic features may be otherwise very similar to true truncus arteriosus.

In corrected transposition of the great vessels, the great vessels are transposed, but the ventricles are also inverted with the aorta arising anteriorly from the inverted right ventricle and the pulmonary artery arising posteriorly from the inverted left ventricle. If a ventricular septal defect is present, the pulmonary arterial markings may be increased; but if a shunt is not present, pulmonary arterial markings will be normal and the heart will be of normal size.

In corrected transposition, the ascending aorta consequently is continuous with the left ventricle and produces a straight left cardiac border. Absence of the ascending aorta in its normal right mediastinal position results in a prominent right pulmonary artery that is in a seemingly higher location (Fig. 44–17).

Decreased Pulmonary Arterial Markings

Tetralogy of Fallot

The cardiac size and configuration of an infant with tetralogy of Fallot is frequently normal (Fig. 44–18). The so-called boot-shaped heart (from cor en sabot, which means wooden shoe) associated with tetralogy of Fallot results from right ventricular hypertrophy with the apex of the heart "upturned" and lifted off the diaphragm. This is seen in the older child or young adult. In the infant, the heart is usually normal in size but pulmonary vascular markings are diminished. However, if there is pulmonary atresia (pseudotruncus) rather than pulmonary stenosis, the apex may become elevated and a cor en sabot configuration may develop even in infants (Fig. 44–19). In both tetralogy of Fallot and pseudotruncus, the aortic arch is abnormally large, and is right-sided in approximately 25% of the patients (Fig. 44–20). The evaluation of ventricular hypertrophy is, as in the other conditions, more accurately determined by electrocardiogram or echocardiogram. Absence of the pulmonary valve with ventricular septal defect is characterized by an unusually large pulmonary artery with diminished peripheral vessels (Fig. 44–21).

Ebstein's Malformation of the Tricuspid Valve

In this condition, the posterior and septal leaflets of the tricuspid valve are abnormally displaced toward the right ventricular apex with resulting tricuspid reorganization. An atrial septal defect is commonly associated with Ebstein's malformation. The most striking radiographic findings in this condition are the large right atrium and the decreased pulmonary arterial markings (Fig. 44–22). The heart is usually enlarged, often massively, with most of the enlargement being due to the dilated right atrium.

A number of other conditions are associated with decreased pulmonary markings; most represent various forms of pulmonary stenosis with associated defects allowing right-to-left intracardiac shunting.

Normal Pulmonary Arterial Markings

In a number of congenital heart defects, the pulmonary markings are normal. Occasionally, this may be difficult to determine, not only because of the variability in prominence of arterial markings but also due to the association of congestive failure. Usually, distended veins are distinguishable as the result of their straight course toward the left atrium. Only with experience can a radiologist confidently discern these vascular differences.

Aortic Stenosis, Coarctation, and Endocardial Fibroelastosis

Infants with aortic stenosis usually show cardiac enlargement. The left atrium is dilated and may be very large displacing the esophagus to the right and posteriorly (Fig. 44–23). The pulmonary arterial markings are normal, but there may be distended veins secondary to passive venous congestion.

The radiographic findings are similar (often identical) in infants with coarctation of the aorta, endocardial fibroelastosis, and anomalous origin of the left coronary artery from the pulmonary artery. In each case, the left ventricle and left atrium are dilated and the pulmonary arterial markings are within normal limits of prominence (Fig. 44–24). With progressive dilation of the left ventricle and left atrium, compression of the left bronchus may produce air trapping with hyperinflation of the left upper lobe (Fig. 44–25) and later obstruction with resultant atelectasis of the left lung.

In older children with coarctation of aorta, the radiographic findings are similar to those found in the adult (Fig. 44–26). The heart may or may not be enlarged, the left atrium is usually not enlarged, and the arterial markings are normal. The esophageal displacement anteriorly and to the right, as the result of poststenotic dilation of the aorta below the coarcted segment, is particularly well displayed with a barium esophagram. The normal tapering of the aorta occurs at the aortic isthmus between the origin of the left subclavian artery and the ductus arteriosus or ligamentum. Immediately below the isthmus, the proximal descending aorta is frequently dilated (Fig. 44–27); this is the location of entry of the ductus arteriosus in fetal life. These normal variants may persist in infants and should not be confused with coarctation of the aorta. Rib notching is unusual before midchildhood but it is virtually pathognomonic of coarctation. Frequently, the silhouette of the aortic arch, the site of the coarctation, and the intra-aortic dilation produce a "figure-three" configuration. Further collateralization may be apparent on the lateral radiograph when viewing a tortuous soft tissue density lying parallel and adjacent to the posterior border of the sternum; this occurs because of the large collateral internal mammary arteries.

Congenital Mitral Atresia and Cor Triatriatum

Infants with either of these conditions usually have evident posterior displacement of the esophagus in the region of the left atrium. The left ventricle is not enlarged as is more accurately determined by the electrocardiogram. Pulmonary arterial markings

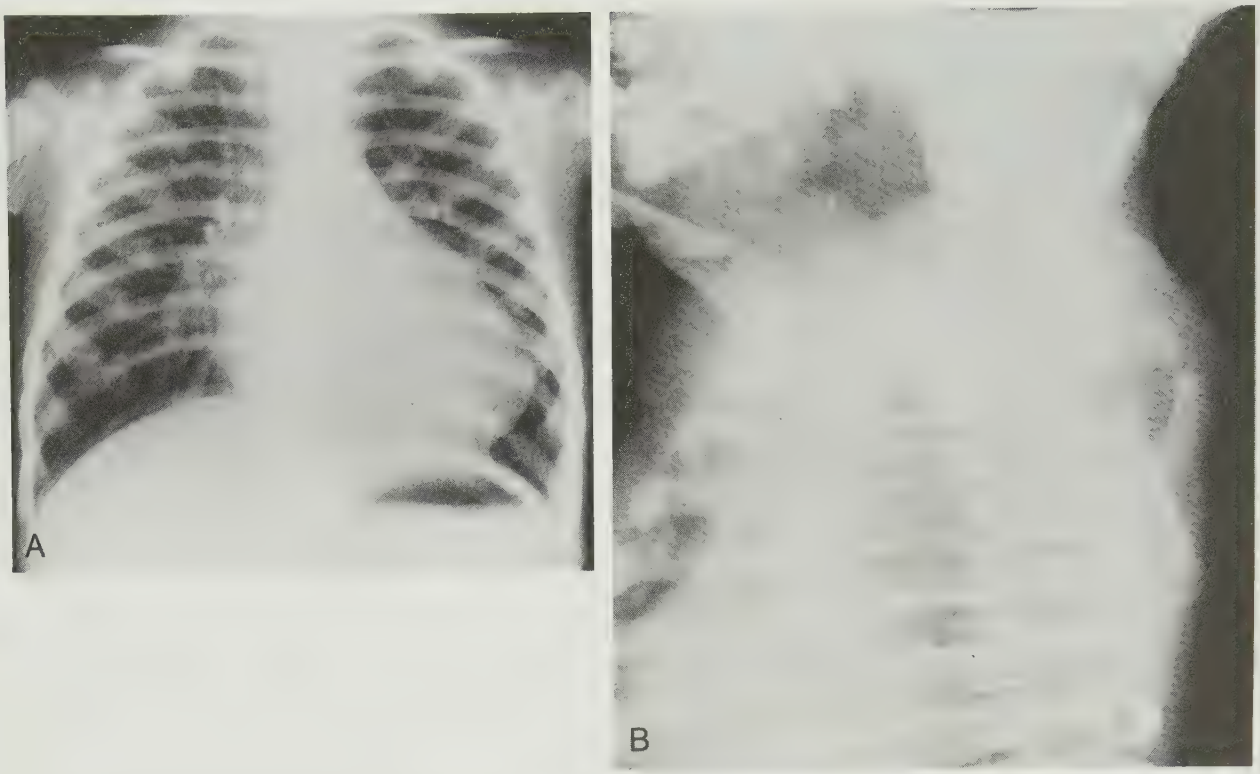

Fig. 44–16. Transposition of the great vessels. (A) The heart is enlarged and has an "egg" configuration. Pulmonary arterial markings are increased, and the superior mediastinum is narrow. (B) Left anterior oblique view shows widening of the structures in the superior mediastinum due to the anteroposterior alignment of the aorta and pulmonary artery.

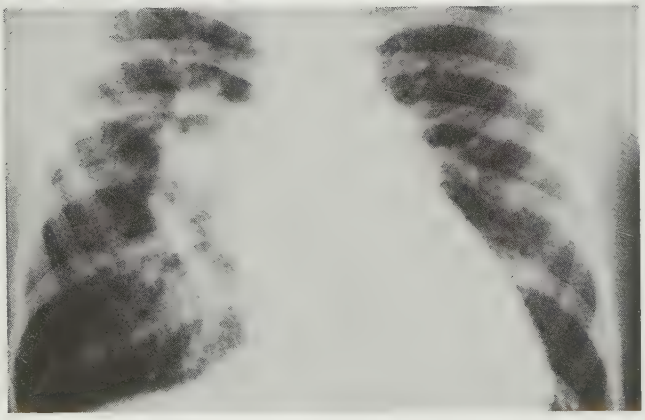

Fig. 44–17. Corrected transposition. The heart is enlarged, and pulmonary arterial markings are increased as a result of associated ventricular septal defect. The right pulmonary artery appears unusually prominent and in a high position because of the absence of the shadow of the ascending aorta usually seen in this position.

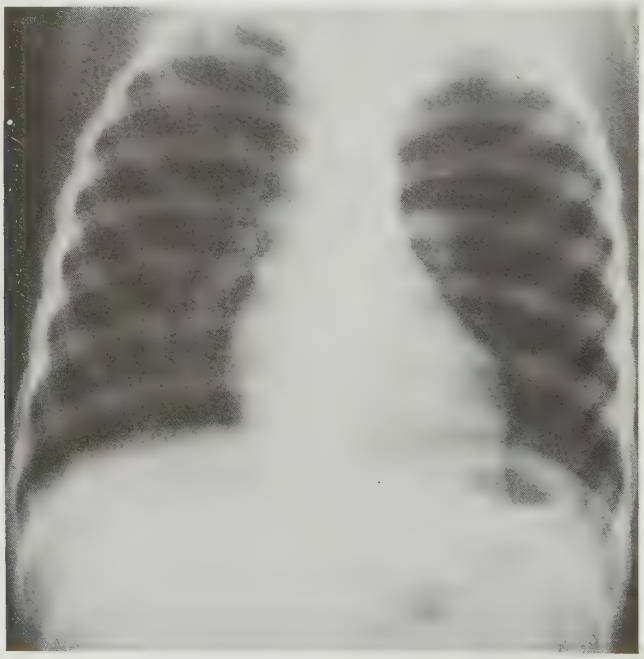

Fig. 44–18. Tetralogy of Fallot in an infant. The heart is of normal size. Aortic arch is prominent for an infant of this age, and pulmonary vascular markings are diminished.

Fig. 44–19. Pseudotruncus. Overall heart size is within normal limits. But the cardiac apex is elevated, pulmonary arterial markings are diminished, and the aortic arch is on the right.

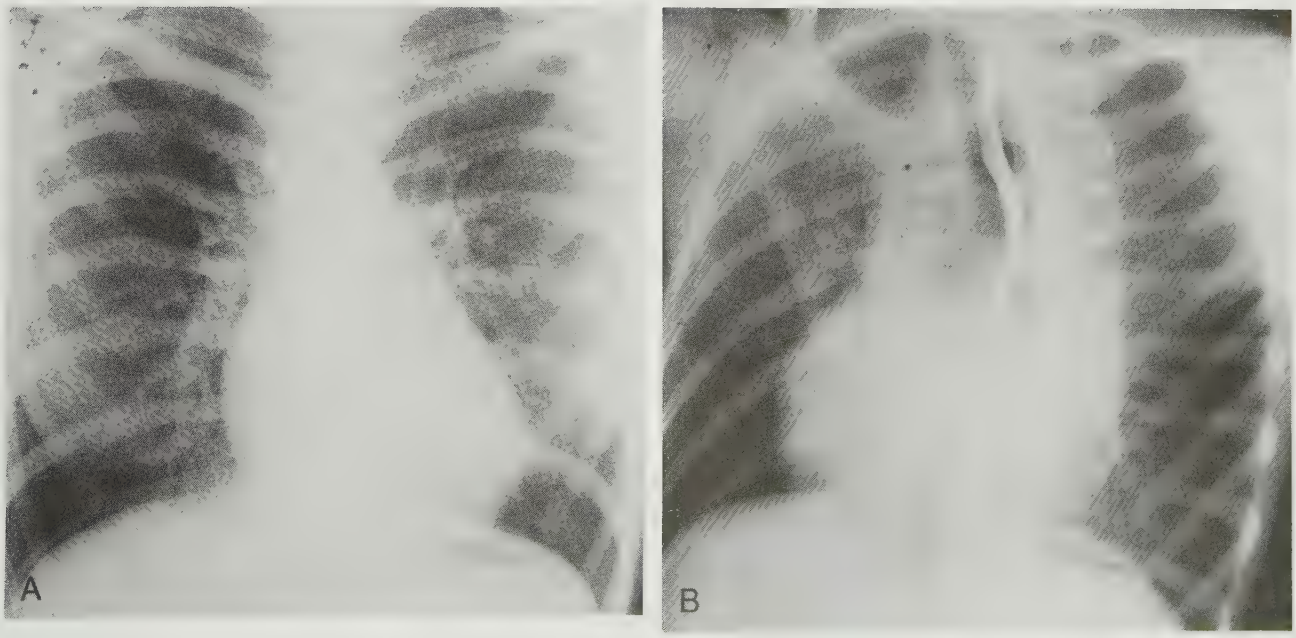

Fig. 44–20. Tetralogy of Fallot. (A) The heart is of normal size and pulmonary arterial markings are diminished. The aortic arch is on the right, displacing the esophagus to the left. (B) Left anterior oblique view showing increased convexity of the anterior chamber (right ventricle). The prominent right aortic arch displaces the esophagus posteriorly.

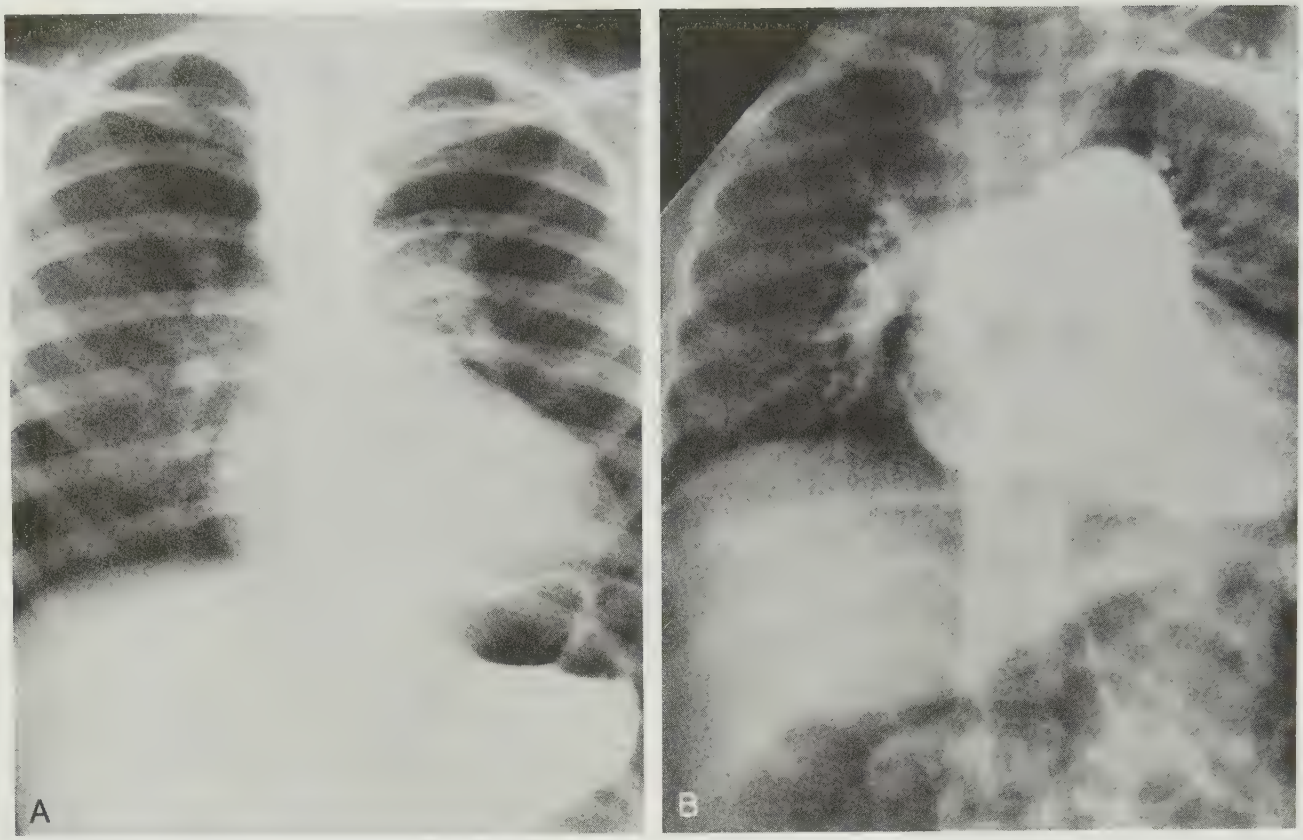

Fig. 44–21. Absence of pulmonary valve. (A) The heart size is normal, and the right and left pulmonary arteries are unusually prominent. But the peripheral vessels are diminished. (B) Angiocardiogram showing the large main pulmonary artery and right and left branches.

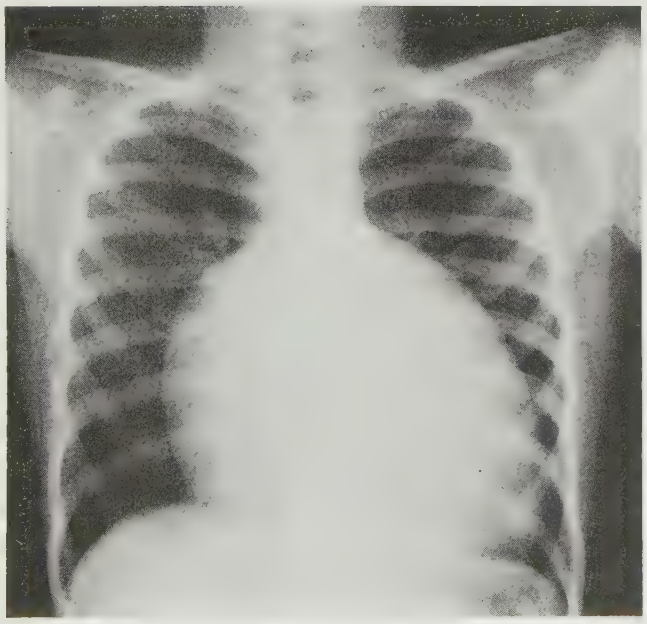

Fig. 44–22. Ebstein's malformation. The heart is enlarged with marked dilation of the right atrium and diminished pulmonary arterial markings.

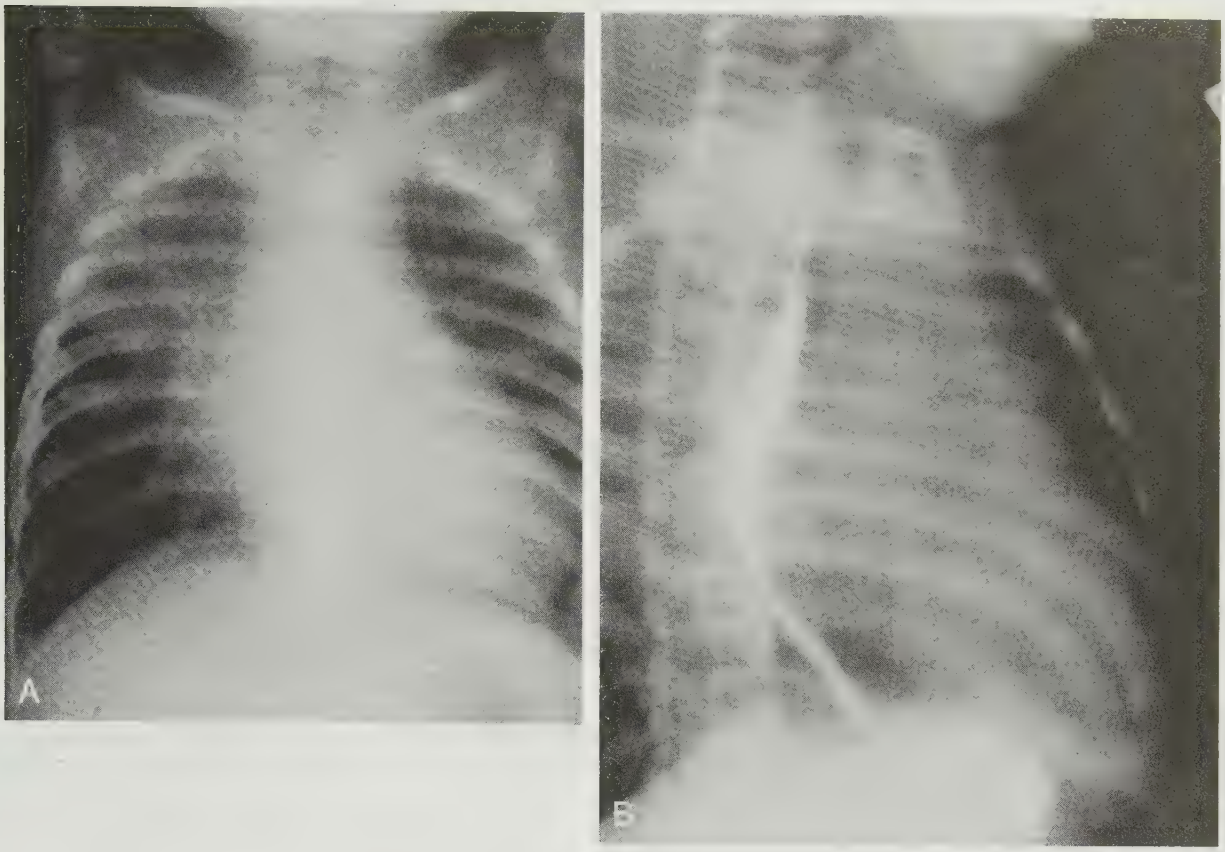

Fig. 44–23. Aortic stenosis in an infant. (A) The heart is enlarged and the left atrium displaces the esophagus to the right. Pulmonary arterial markings are normal. (B) Right anterior oblique view shows selective enlargement of the left atrium displacing the esophagus posteriorly.

are not increased, but there is evidence of passive venous congestion (Fig. 44–28).

Pulmonary Valvular Stenosis

Isolated pulmonary valvular stenosis with an intact ventricular septum usually is associated with normal pulmonary markings. Occasionally, the markings may be diminished if there is an associated atrial septal defect allowing a right-to-left shunt. The heart is normal in size or enlarged, and the pulmonary artery segment is often convex due to poststenotic dilation (Fig. 44–29). The dilated pulmonary artery is the most striking radiographic feature.

Idiopathic Dilation of the Pulmonary Artery

In this condition, the pulmonary artery is abnormally prominent resembling pulmonary valvular stenosis; but pressure studies are normal and the patients are asymptomatic. There is usually a short murmur attributed to ejection of blood into the dilated pulmonary artery, preceded by an ejection sound. The electrocardiogram should be normal with no evidence of right ventricular hypertrophy. Radiographic distinction between idiopathic dilation of the pulmonary artery and small atrial septal defect or pulmonary valve stenosis may not be possible.

Vascular Ring

There are a variety of vascular rings, most of which are responsible for inspiratory and expiratory stridor as well as more severe forms of respiratory distress. Chronic or recurrent pneumonia, particularly on the right, is commonly associated with ring anomalies. The most common vascular anomalies that encircle the trachea and esophagus are a double aortic arch (with a common descending aorta usually on the left) and a right aortic arch (with a ligamentum arteriosum or ductus arteriosus). A double arch is the type of ring most likely to cause symptoms in early infancy. In a double aortic arch as well as in a right arch with a ligamentum arteriosum or ductus arteriosus, radiographs of the esophagus show compression on the anterior portion of the trachea and on the posterior portion of the esophagus.

A retroesophageal subclavian artery is usually an incidental finding identified by an oblique defect on the posterior portion of the esophagus extending obliquely upward from left to right.

Left pulmonary artery sling anomaly is another vascular defect that may be responsible for respiratory disturbance or recurrent pneumonia. In this condition, the left pulmonary artery passes behind the trachea and in front of the esophagus. In so doing, it compresses the posterior tracheal wall or left main-stem bronchus and the adjacent anterior wall of the esophagus. These vascular anomalies are discussed in greater detail in Chapter 82.

Postoperative Radiographs

Immediately following surgical correction of the cardiac abnormality, a chest radiograph should be obtained to determine the degree of pulmonary expansion and cardiac size; the presence or

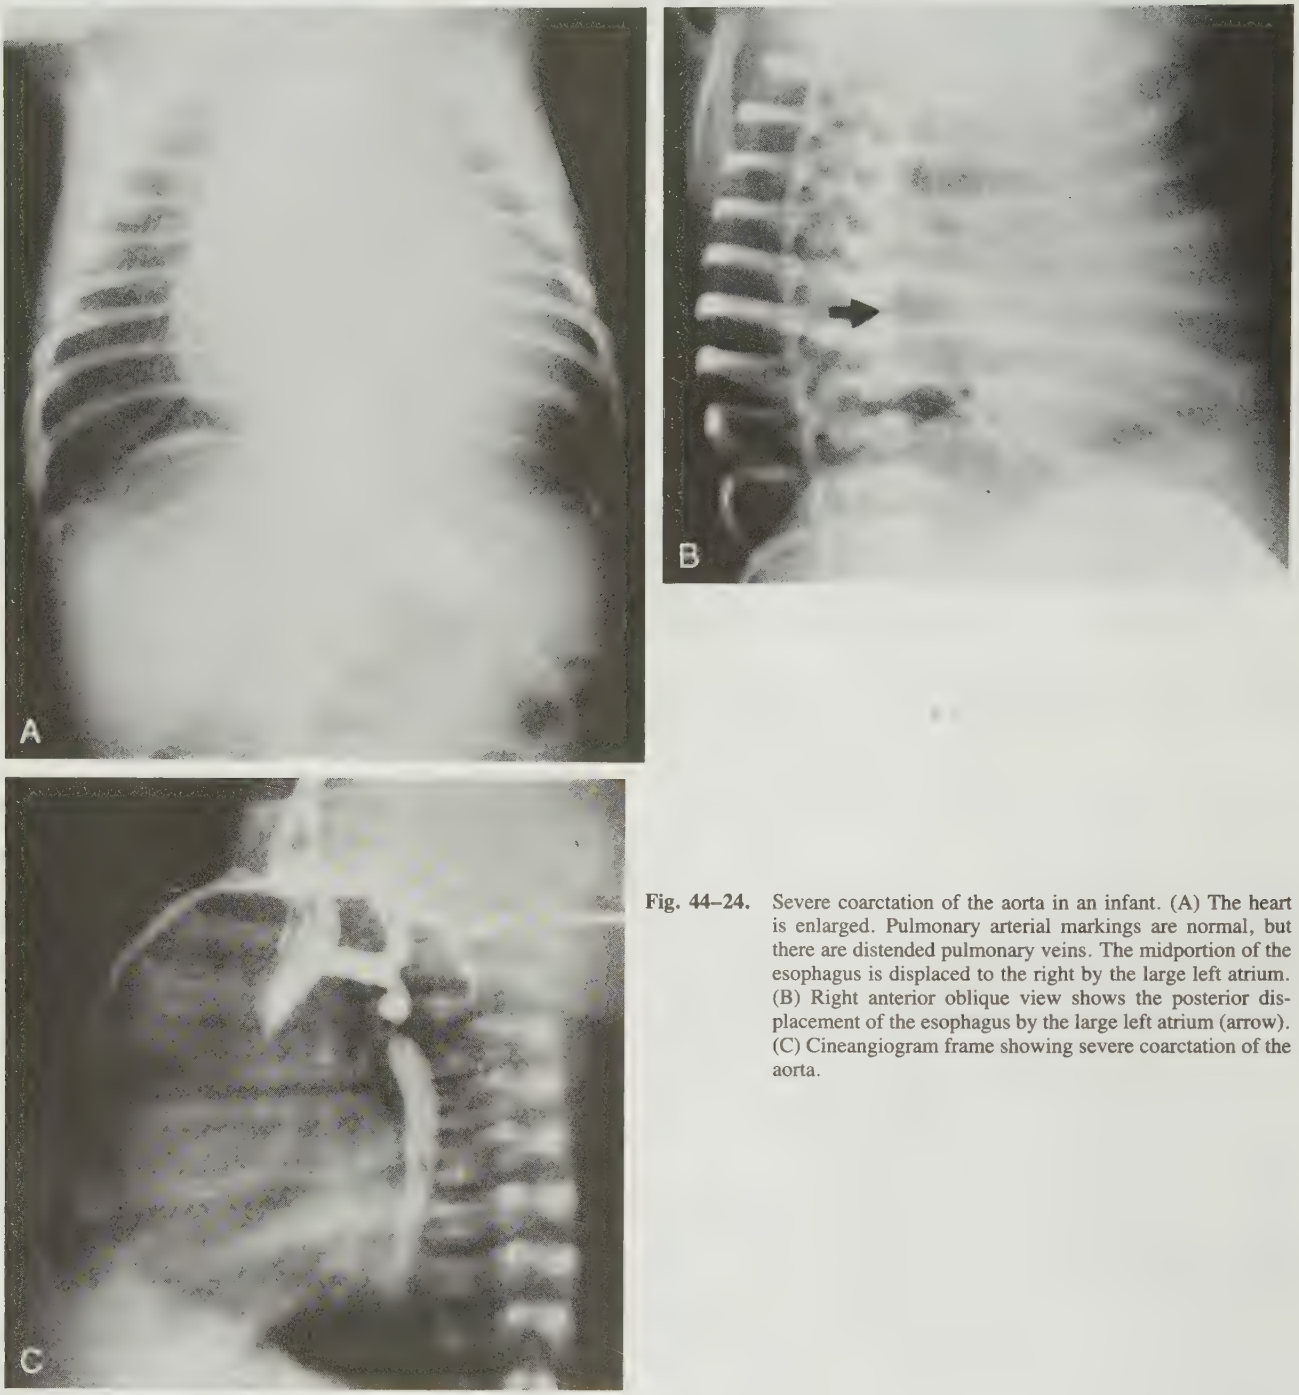

Fig. 44–24. Severe coarctation of the aorta in an infant. (A) The heart is enlarged. Pulmonary arterial markings are normal, but there are distended pulmonary veins. The midportion of the esophagus is displaced to the right by the large left atrium. (B) Right anterior oblique view shows the posterior displacement of the esophagus by the large left atrium (arrow). (C) Cineangiogram frame showing severe coarctation of the aorta.

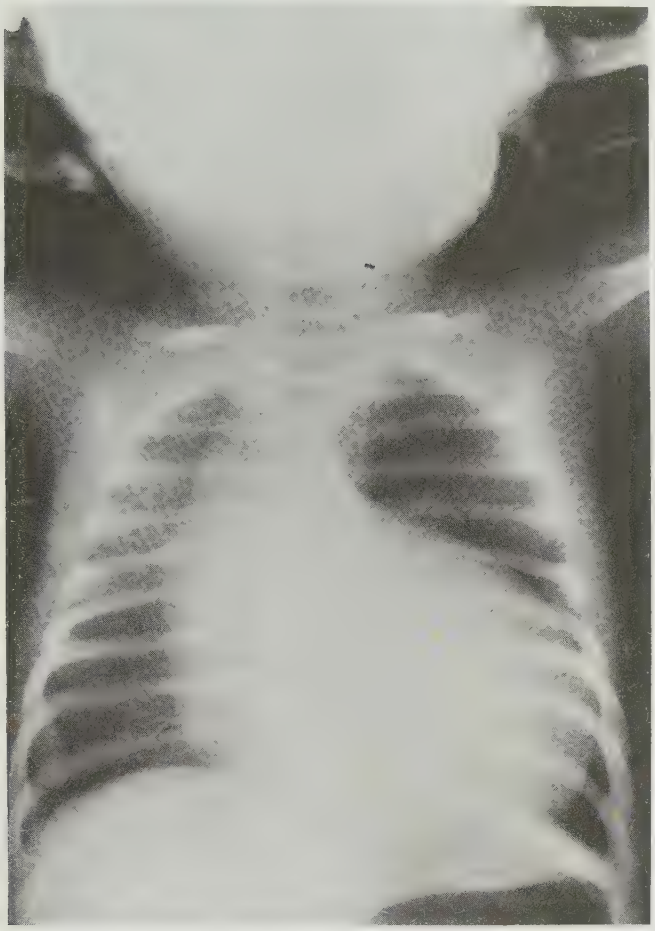

Fig. 44–25. Endocardial fibrosis in an infant. The heart is dilated and pulmonary arterial markings are within normal limits. The left upper lobe shows increased radiolucency due to air trapping.

Fig. 44–26. Coarctation of the aorta in an older child. Chest radiograph shows early rib-notching involving the posterior portions of the third, fourth, and fifth ribs bilaterally. There is a "figure-three" sign in the left upper mediastinum, as a result of the aortic arch, and the poststenotic dilation of the aorta below the coarctation.

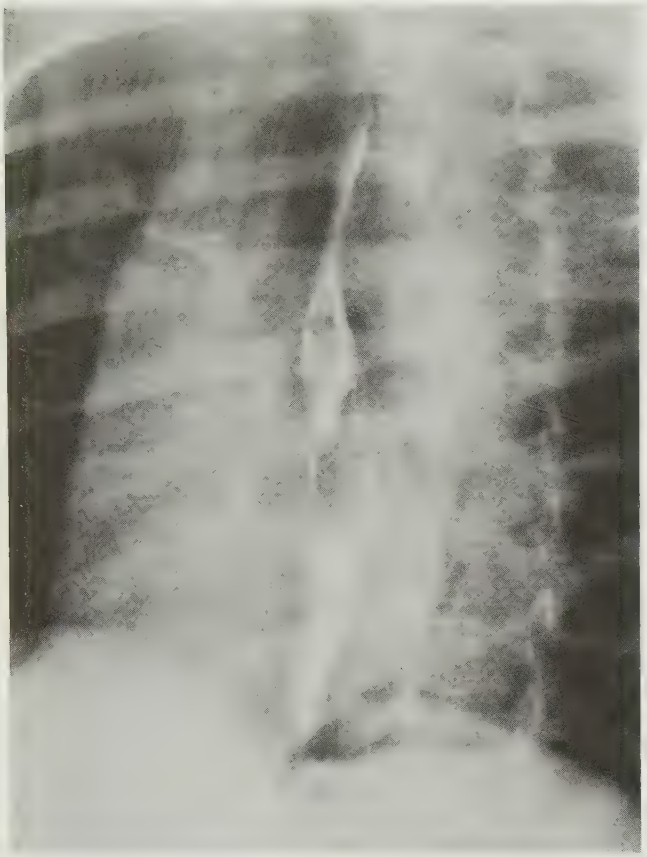

Fig. 44–27. Anterior oblique view in a normal child showing minimal indentation of the posterior portion of the esophagus by the aortic arch.

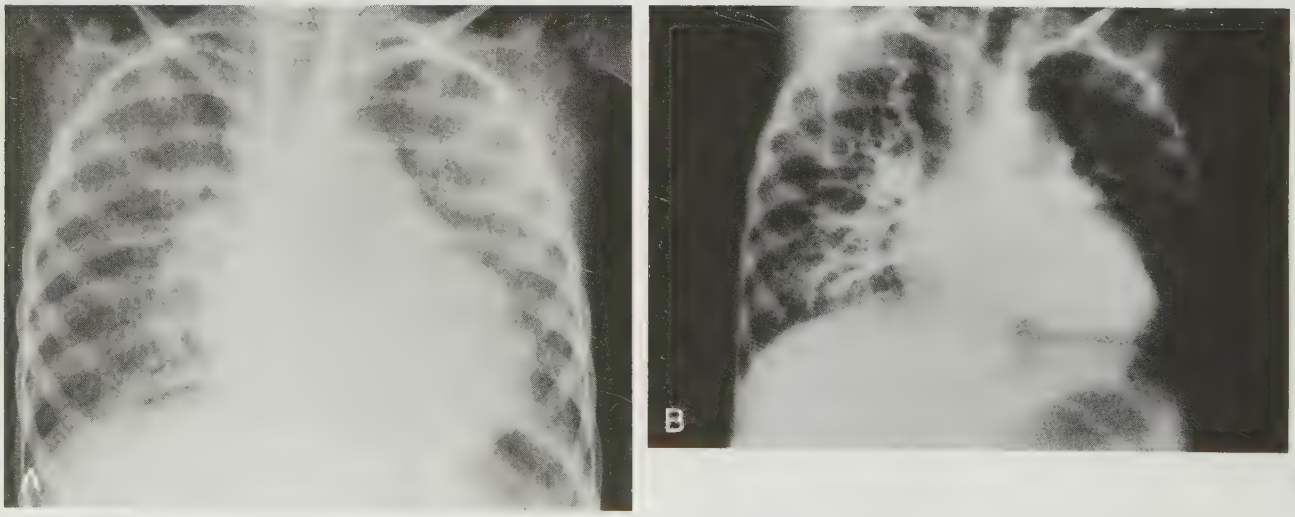

Fig. 44–28. Cor triatriatum. (A) The heart is slightly enlarged. Pulmonary arterial markings are normal, but there is an increase in the pulmonary venous pattern and faint Kerley B lines are identified above the costophrenic sulci. (B) Angiocardiogram shows the septum within the left atrium.

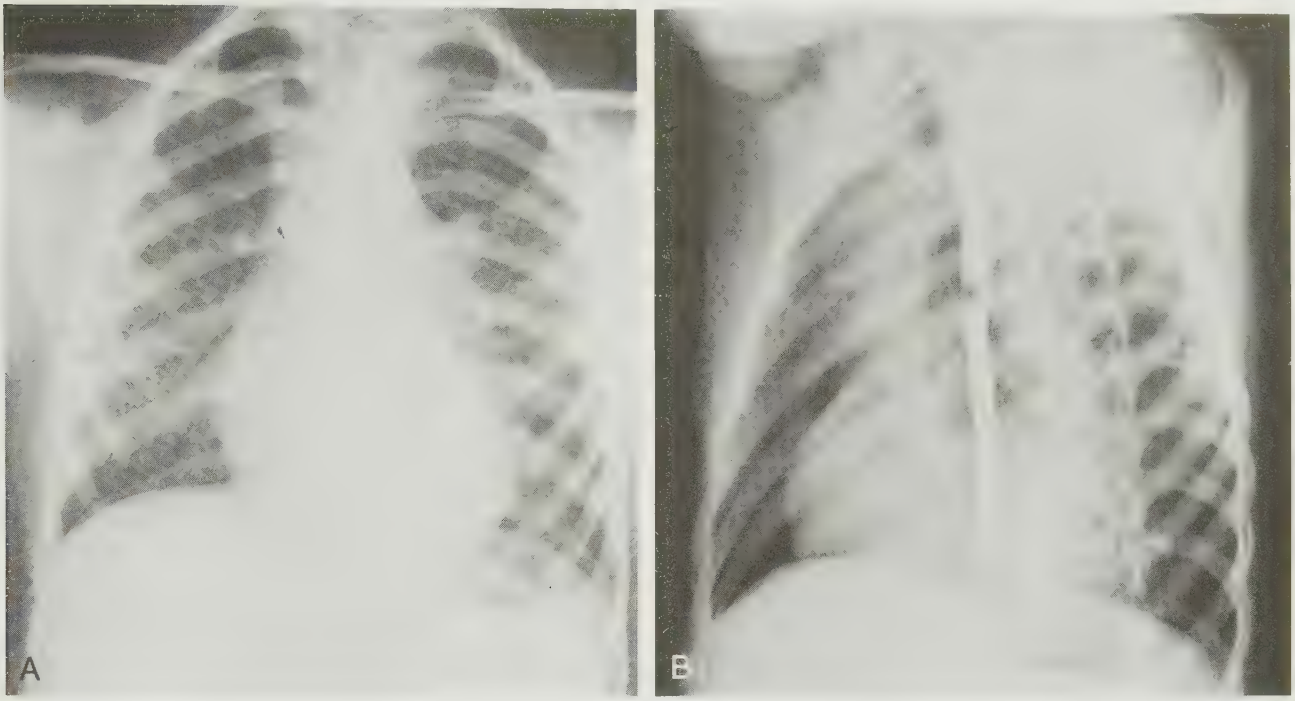

Fig. 44–29. Pure pulmonary valvular stenosis. (A) The heart is normal in size. The main pulmonary artery is abnormally convex, and the pulmonary arteries are within normal limits. (B) Left anterior oblique view shows increased convexity of the anterior chamber (right ventricle).

absence of pleural effusion and pneumothorax; and the location of the endotracheal tube, chest tubes, central lines, and pacemaker wires. Special attention also should be given to identifying any possible foreign object such as a surgical needle which may have been left inadvertently in the chest. Ideally, the endotracheal tube should be above the carina but below the thoracic inlet. An endotracheal tube that extends to or into the right main stem bronchus may produce hyperinflation of the right lung and atelectasis of the left lung. The chest tube should be inserted far enough to ensure that the holes in the tube are within the chest cavity. A central line placed in the neck should extend into the superior vena cava or into the right atrium. A Swan-Ganz catheter used for pulmonary artery pressure measurement usually passes into the right pulmonary artery where it can be advanced distally for purposes of measuring wedge pressures. It is also acceptable for the catheter to enter the left pulmonary artery. The pulmonary artery bifurcation is usually identifiable at the convexity of the main left pulmonary artery on the left cardiac border below the level of the aortic arch. However, in cases of left ventricular preponderance, the undivided segment may be in a more midline position and not be part of the left cardiac profile. The point of origin of the right and left pulmonary arteries may, consequently, be obscured. But the direction of the catheter to the right or left identifies the bifurcation.

The position of temporary pacing wires should be verified. Following removal of the endotracheal tube, another postoperative examination should be obtained—again, to evaluate cardiac size, pulmonary expansion, and the presence or absence of pleural effusion. The level of the diaphragm should be studied carefully after extubation in view of the possibility of phrenic nerve injury and diaphragmatic paralysis. Following removal of chest tubes, another portable chest radiograph is needed to ascertain that pneumothorax has not developed. A common complication of open heart surgery is the postpericardiotomy syndrome usually manifest within 1 to 3 weeks postoperatively. The radiographic findings in this condition include an increase in heart size secondary to pericardial effusion. Pleural effusion is also frequently present.

CHAPTER 45

Electrocardiography

Arthur Garson, Jr

"There are comparatively few people who are not in greater danger of having their peace and happiness destroyed by an erroneous diagnosis of cardiac abnormality based on a faulty interpretation of an electrocardiogram than of being injured or killed by an atomic bomb." Thus began Frank Wilson's introduction to Lepeschkin's *Modern Electrocardiography,* over 30 years ago.[1] The same holds true today. Because it is so important to understand the basis and range of normal, the first half of this chapter is devoted to the normal electrocardiogram, the definition and proper measurement of electrocardiographic wave forms, and finally the variations produced by malposition of the heart within the thorax. In the second half of the chapter the abnormal electrocardiogram is considered. Since electrocardiography provides both complementary and supplementary information to echocardiography and nuclear imaging in terms of cardiac chamber enlargement and hypertrophy, we will consider the continuing contribution of the electrocardiogram in this area. The specific morphology of ventricular depolarization and repolarization will be shown to provide information on conduction disturbance, myocardial ischemia, injury, and infarction. The effect of systemic alterations on the electrocardiogram will be discussed: electrolyte abnormality, drug effects, and the effect of diseases in other parts of the body on the heart. Finally, a systematic approach to the recognition of artifacts will be presented in the hope that the patient with a normal heart will not become an "electrocardiographic casualty" because of an erroneous interpretation of what is truly sinus rhythm. This chapter is a synopsis of a book on the subject by Surawicz.[2] The interested reader can find greater detail, including a discussion of arrhythmias, in that volume.

THE NORMAL ELECTROCARDIOGRAM

As the transition is made from fetus to neonate, infant, child, and adult, changes in physiology, changes in size and position of the cardiac chambers relative to one another, changes in size and position of the heart relative to the body, and changes in overall body habitus, contribute to the different patterns of normal in the pediatric electrocardiogram. The major changes in amplitudes and direction of depolarization and repolarization occur in the first year of life; thereafter changes slowly occur in the timing of cardiac events, as reflected in the electrocardiographic intervals. Since the majority of the measurements made on a neonate's electrocardiogram would be abnormal in an adult (Fig. 45–1), it is important to refer to the table of normal values (see Table 45–1), which is given by age. In the following discussion, we will consider the normal electrocardiogram from the full-term newborn through the adolescent. Discussion of the normal premature[3] and adult[4] electrocardiograms can be found elsewhere.

Normal Values

Normal values included in Table 45–1 are those collected and published by Davignon et al.[5] These are summarized here; full tables can be found elsewhere.[2,5] This population consisted of 2141 white children. Each had a normal physical examination. The total population was divided into 12 age groups, with seven age groups in the first year of life to reflect the greater changes in the electrocardiogram during this time. There are at least 100 children in each age group. The data were analyzed by computer. In addition, the electrocardiograms that fell in the upper or lower tenth per-

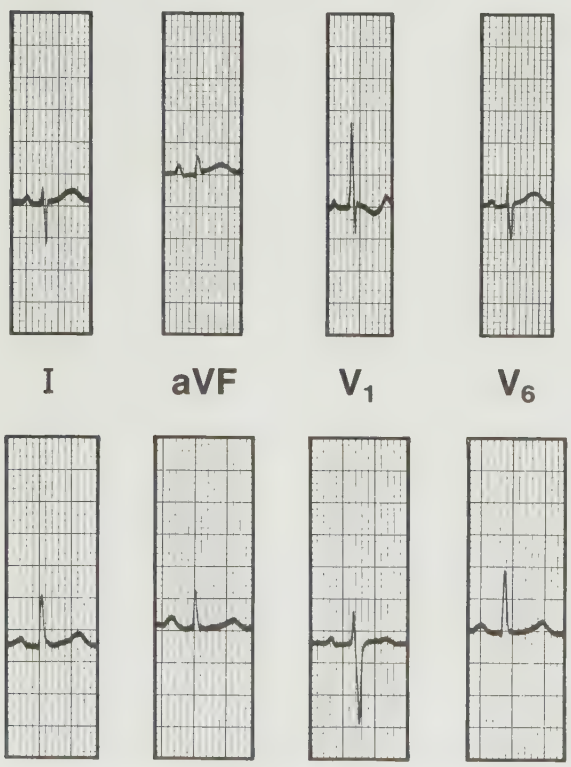

Fig. 45–1. Comparison of the normal neonatal and adolescent electrocardiogram. The neonate is shown in the top row and the adolescent in the bottom row.

centile were displayed with an electrocardiograph and were verified visually by a physician. If the computer and physician disagreed, the visually determined value by the physician was substituted in the data file. These normal values are therefore applicable to all tracings recorded from an electrocardiograph that meets American Heart Association standards. The limits of "normal" include the second and ninety-eighth percentile in each age range.

Heart Rate

In sinus rhythm, the heart rate is measured by determining the interval between successive P waves or R waves on the electrocardiogram. The onset of each deflection should be used for timing rather than the peak since a change in the shape of a complex may result in a faulty measurement if the peak occurs at a different time relative to the beginning of the complex (Fig. 45–2). The exact heart rate can be calculated by dividing the RR intervals (in seconds) into 60. For example, assume an RR interval of 0.46 sec; the heart rate is 60/0.46 or 130 beats/min. An approximation can be made by counting the number of 0.2-sec blocks (large boxes on the electrocardiogram paper) that are contained in the RR interval. If the RR interval is approximately one box (0.2 sec), the heart rate is 300 beats/min; for two boxes, it is 150 beats/min; and so on: 300, 150, 100, 75, 60, 50, 43, 38. For a more exact heart rate, it is helpful to remember that the small boxes (0.04 sec) between 100 and 150 represent 10 beats/min and those between 150 and 300 represent 30 beats/min (Fig. 45–3). This can be committed to memory.

The normal heart rate increases from the first day of life to a maximum between 1 and 2 months of age and then slowly declines (see Table 45–1). The reason for this has not been demonstrated but probably is connected to the relative immaturity of the sympathetic nervous system at birth.

P Wave

The configuration of the P wave is generally symmetric in leads I and II. The normal shape is that of a bullet, and not of a steeple

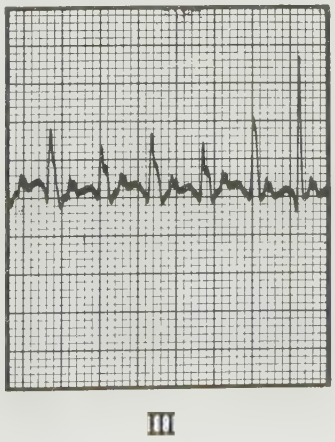

Fig. 45–2. Measurement of heart rate. In this patient with supraventricular tachycardia with varying intraventricular conduction, the QRS morphology changes sufficiently that the peak of each complex does not occur at the same time relative to the onset of each beat. Therefore in measuring heart rate, rather than measuring from peak to peak, the onset of the QRS complex should be used at all times.

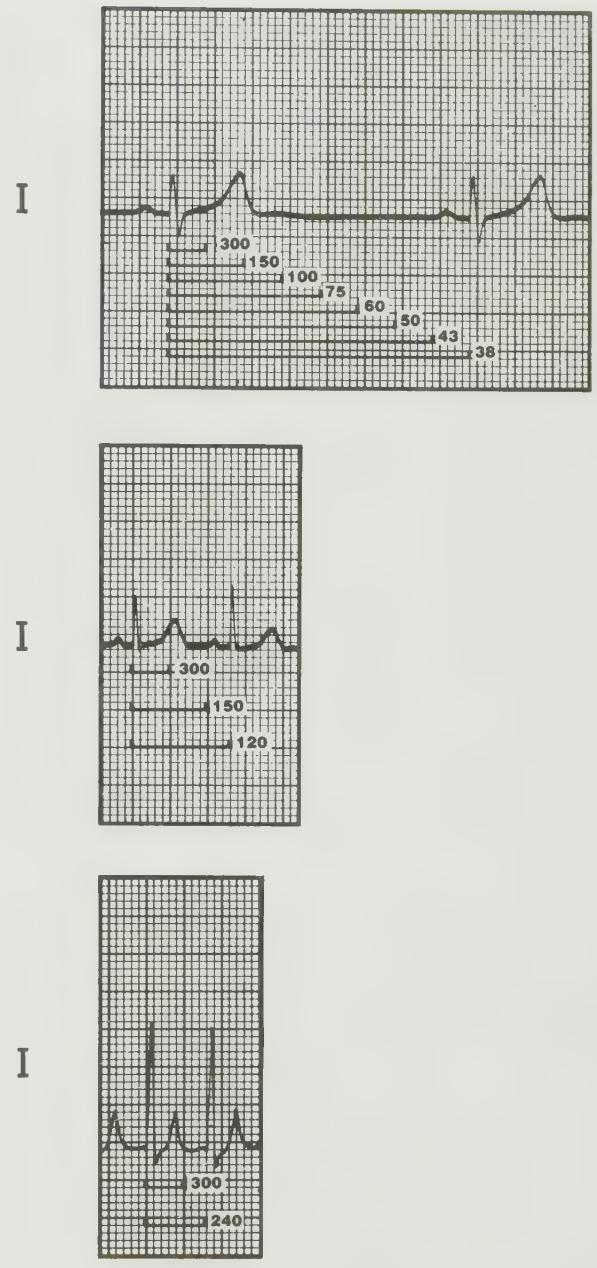

Fig. 45–3. Calculation of heart rate. Top tracing—a heart rate of 38 beats/min. This is exactly nine large boxes on the electrocardiogram. The method of counting large boxes is illustrated. Middle tracing—sinus rhythm at a rate of 120 beats/min. The QRS complexes are separated by two large boxes and three small boxes. Lower tracing—supraventricular tachycardia at 240 beats/min. The QRS complexes are separated by one large and three small boxes.

(right atrial enlargement) or a bent staple (left atrial enlargement) (Fig. 45–4). With the improved frequency response of most electrocardiographic machines, over 25% of normal children will have a notch in the middle of the P wave. Therefore notching by itself must be considered normal. In lead V_1, the P wave may normally be biphasic, but the terminal negative portion should be less than 0.04 sec in duration and less than 1 mm deep (less than one small box by one small box). The overall duration of the P wave in lead II should be between 0.03 and 0.09 sec in children 3 years old and younger; over the age of 3 years, the normal duration is between 0.05 and 0.10 sec. The normal P wave amplitude is less than 2.5 mm at all ages.

The P wave axis is directed away from the site of origin of atrial depolarization. (The more proper term for "axis" is "mean vector"—but the more popular term will be used.) While it is possible to calculate the exact P-wave axis in practice only the quadrant of the vector in the frontal plane is determined. If the P wave is isoelectric or positive in lead I and isoelectric or positive in lead aVF (P-wave mean vector between 0° and +90°), we infer that the atria begin depolarization from the high right atrium, i.e., from the sinus node (Fig. 45–5). If the P wave is negative in lead aVF and isoelectric or positive in lead I (P-wave axis between −1° and −90°), the atria begin depolarization from the low right atrium. If the P wave is negative in lead I (P-wave axis between +91° and −91°), the atria begin depolarization from the left atrium (see section on "Malposition of the Heart"). The P-wave axis in the horizontal plane is variable and is not helpful in determining the site of origin of atrial depolarization, i.e., sinus P waves can be positive, isoelectric, or negative in lead V_1.

P–R Interval

The P–R interval is measured from the beginning of the P wave to the beginning of the QRS complex. The true onset of atrial or ventricular depolarization may not be recorded in a lead because the initial forces are directed perpendicular to the lead and the initial portion of the P wave or QRS complex may therefore be isoelectric in that lead. Thus the P–R intervals measured in different leads may vary by as much as 0.04 sec (Fig. 45–6), but usually only vary by 0.02 sec or less.[4] It has been the practice to measure either the longest P–R interval or the P–R interval in lead II. Standards are available in children only for lead II (see Table 45–1). If a "delta wave" is present (see section on "Preexcitation"), the shortest "P–R interval" (actually a P–delta interval) should be sought in the diagnosis of the Wolff-Parkinson-White syndrome. With an isoelectric delta wave, the P–R interval may be normal, and only in certain leads will the truly short P–R interval be observed (Fig. 45–7). (See section on "Preexcitation" for other causes of short P–R interval.) A more common cause for a short P–R interval in a normal heart is a low right atrial pacemaker. In this instance, the P wave is negative in lead aVF and positive or isoelectric in lead I. When the impulse originates low in the atrium, the normal high to low right atrial conduction time (which accounts for up to 0.04 sec of the P–R interval) is eliminated, and therefore low right atrial pacemakers may have a P–R interval up to 0.04 sec less than normal.

The P–R interval normally increases with age and decreases with heart rate. The increase in P–R interval with decreased heart rate can be accounted for by the fact that heart rate decreases normally with age. Therefore in Table 45–1, the P–R interval is correlated with age and not heart rate.

P–R Segment

The P–R segment is measured from the end of the P wave to the beginning of the QRS complex. The length of this segment is variable and depends upon the duration of the P wave. Normal

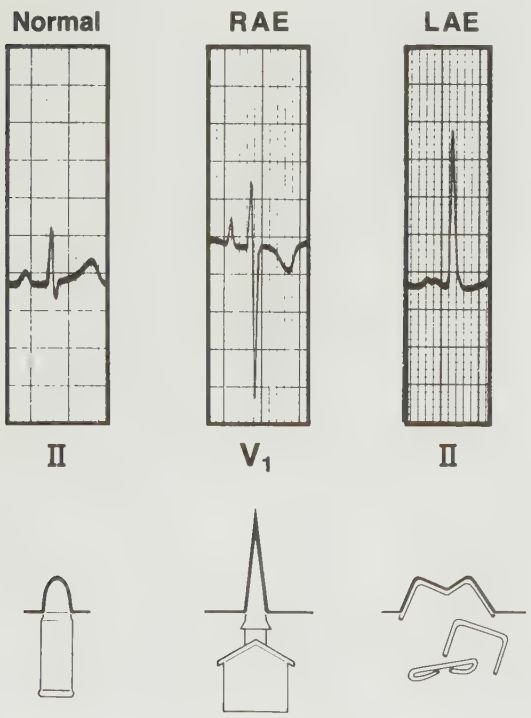

Fig. 45–4. Shape of P wave. On the left, the normal shape is shown to be similar to that of a bullet. In the middle, the P wave of right atrial enlargement (RAE) is shown. This is similar to a church steeple. On the right, the P wave of left atrial enlargement (LAE) is shown. This is similar to a bent staple.

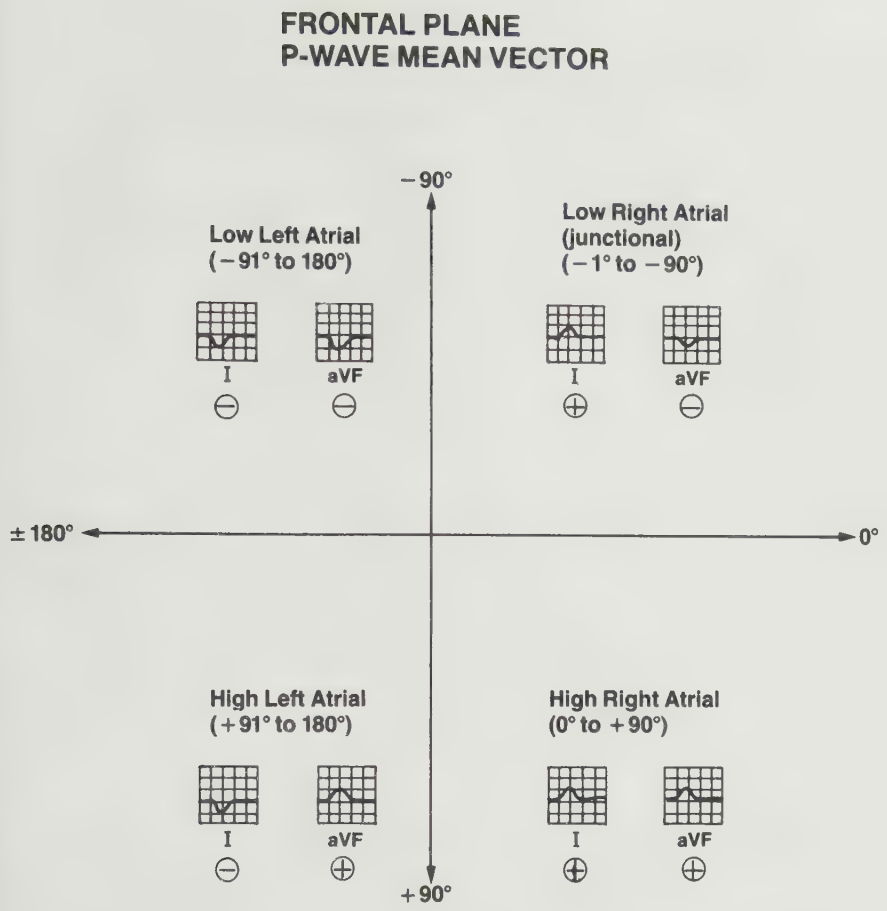

Fig. 45–5. Frontal plane P-wave mean vector (axis).

values for the duration of the P–R segment in children are not available. A short P–R segment is most often due to a long P wave with a normal P–R interval, rather than to the Wolff-Parkinson-White syndrome. The importance of the P–R segment in pediatrics is that it may provide the only estimation of the isoelectric line on the electrocardiogram.

QRS Complex

Duration

The QRS duration is measured from the beginning to the end of the ventricular depolarization complex. It should be measured in a lead with a Q wave. The precordial leads may have a QRS duration that is 0.01 to 0.02 sec longer than that measured in the limb leads.[4] For the normal values included in Table 45–1, lead V_5 was chosen to measure the duration because there usually is a Q wave and a defined termination to the QRS complex. As ventricular muscle mass increases, the QRS duration increases. Since with age, the muscle mass increases, the QRS duration tends to increase with age.

Axis

The most practical method for estimation of the axis is to determine the most isoelectric complex (Fig. 45–8). This is defined as the lead in which the sum of positive and negative deflections equals 0. The QRS mean vector is perpendicular to this lead. However, there are two possible perpendiculars. For example, if lead aVR is isoelectric, this implies that the axis is directed 90° away from (perpendicular to) lead aVR. Since lead aVR points toward −150°, the axis would be directed toward either −60° or +120°. To determine which of the two perpendiculars is the true axis, the lead with the maximum net positive deflection is examined. If lead III has the maximum net positive deflection, the frontal plane QRS axis is +120°. It is more accurate to base the calculation of the perpendicular to the isoelectric lead rather than simly on the direction of the largest deflection, because of the true difference in lengths of the lead axes. If all the QRS complexes in the frontal plane are equiphasic, the axis is termed "indeterminate" and no calculation can be made.

"Axis Deviation". If the value for the QRS axis falls outside the range of normal values for age (see Table 45–1), "axis deviation" is diagnosed. In the first month of life, "right-axis deviation" occurs when the axis is between the upper limit for age and −90° ("northwest axis"). In older children, right axis deviation occurs when the axis is between the upper limit for age and ±180°. For a 3-mo-old, right-axis deviation is between +105° and +180°. In a 10-yr-old, right-axis deviation is between +120° and +180° (Fig. 45–9). Using logic from the "method of perpendiculars," if the QRS complex is isoelectric or positive in lead aVR (and isoelectric and positive in lead aVF) in a 10-yr-old, right-axis deviation is diagnosed. The most common cause of right-axis deviation in children is right ventricular hypertrophy.

"Left-axis deviation" occurs when the axis is between the lower limit for age and −90°. Over the age of 2 mo, left-axis deviation

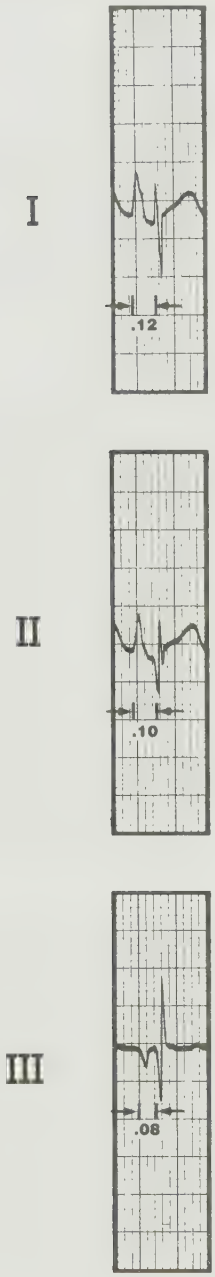

Fig. 45–6. P–R interval. Simultaneous leads I, II, and III. The P–R interval in lead I is 0.12 sec, in lead II 0.10 sec, and in lead III 0.08 sec. The reason for the seemingly short P–R interval in lead III is that the early part of the P wave is isoelectric in that lead.

is between 0° and −90° (Fig. 45–9). Using logic from the method of perpendiculars, if the QRS complex is isoelectric or negative in lead aVF (and isoelectric or positive in lead I), in a child over 2 mo of age, left-axis deviation is diagnosed. The most common causes of left-axis deviation in childhood are those due to abnormal intraventricular conduction associated with congenital heart disease: complete atrioventricular canal, ostium primum atrial septal defect, tricuspid atresia, single ventricle (see section on "Left Anterior Hemiblock"). Concentric left ventricular hypertrophy generally does not cause left-axis deviation.

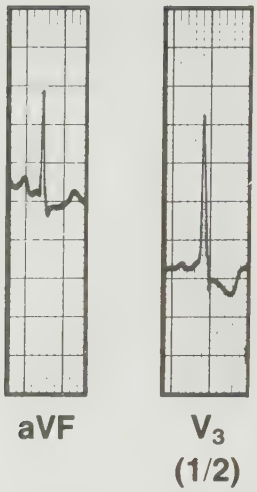

Fig. 45–7. P–R interval in Wolff-Parkinson-White syndrome. In lead aVF, the P–R interval is normal and there is no delta wave. The short P–R interval and delta wave are apparent only in lead V_3, taken from the same patient.

If the frontal plane QRS axis is between −90° and ± 180°, "northwest axis" is diagnosed (Fig. 45–9). This may be either an extreme form of right-axis or left-axis deviation. In general, in northwest axis only, if the initial QRS forces are directed at +120° (Q wave in lead I or aVL), left anterior hemiblock coexists with the northwest axis and this is a form of extreme left axis deviation. On the other hand, if the initial forces are directed at −60° (Q waves or QRS pattern in leads II, III, and aVF) this is extreme right-axis deviation.

Morphology

Depending upon the lead and orientation of the initial forces, a Q wave may or may not be present. The remainder of ventricular depolarization is written as an R wave followed by an S wave. This is true in all normal precordial leads and limb leads other than lead aVR, with the following exception. An R wave without an S wave may be present normally in lead V_1 up to 5 mo of age and in lead V_6 at any age. In approximately 7% of normal children, in the right chest leads, a second R wave or R′ may follow the S wave, giving an RSR′ pattern.[6] In these normal children, the overall QRS duration may be prolonged by 0.01 sec above the normals given in Table 45–1, but the R′ wave has a rapid deflection and has the same duration as the preceding R and S waves. In normal children, wih an RSR′ pattern, the S wave usually has a greater amplitude than either the R or R′ wave. The RSR′ pattern can be found in complete right bundle branch block and right ventricular hypertrophy. In complete right bundle branch block,

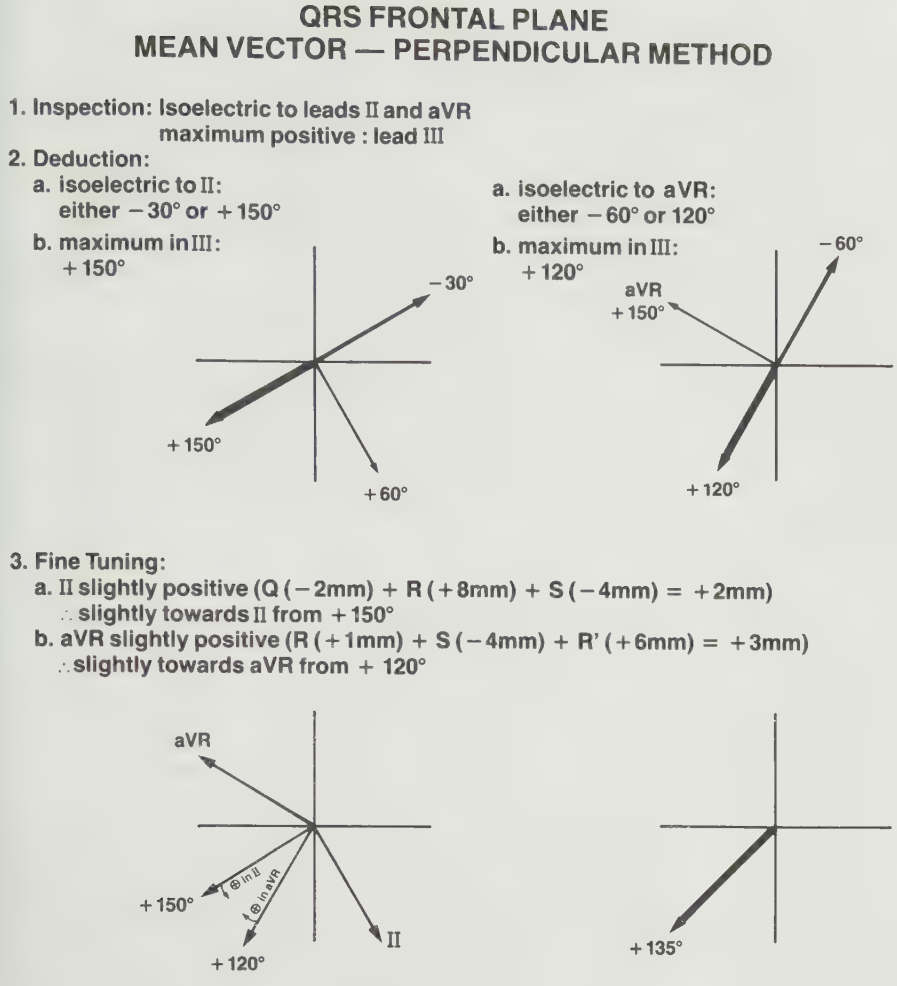

Fig. 45–8. Calculation of QRS frontal plane mean vector (axis) by the perpendicular method (see text).

the total QRS duration is increased and there is a true terminal conduction delay with an increase in the duration of the slurred R′ as compared with the normal duration of the initial R and S waves (see section on "Conduction Disturbance"). In mild to moderate right ventricular hypertrophy, the R and especially the R′ waves have a greater amplitude than the S wave. With a QRS complex of normal duration, right ventricular hypertrophy can be diagnosed by an R′ amplitude greater than 15 mm in an infant under 1 year of age or 10 mm over 1 year. In children with a QRS complex of normal duration and an RSR′ pattern with a small R′ wave, since the distinction between mild to moderate right ventricular hypertrophy, incomplete right bundle branch block, and normal is difficult, we would prefer the designation "RSR′ pattern in right chest leads" without a further attempt at diagnosis.

Amplitude

Q Wave. A normal Q wave may be present in almost any lead. A QS pattern (or initial S wave) may be normal in lead aVR at any age and in V_3R and V_4R in older children. A QR pattern (Q wave followed by an R wave) is not normal in lead aVR or the right chest leads, and if present, this usually indicates right ventricular hypertrophy (see section on "Right Ventricular Hypertrophy"). Q waves present in the midprecordial leads generally imply counterclockwise rotation of the heart (see section on "Malposition of the Heart").

The distinguishing points between normal and abnormal Q waves are the duration and the amplitude of the Q wave. A normal duration Q wave is 0.01 to 0.015 sec. Any Q wave greater than 0.03 sec is definitely abnormal.[6,7] The normal amplitude of Q waves varies with the lead and with age.[5] Normal for lead aVL is less than 2 mm; lead I less than 3 mm; and leads II and aVF less than 4 mm. At all ages leads III and V_6 are the most variable with age (see Table 45–1).[8] The implications of abnormal Q waves are further discussed in the section on "Infarction."

R and S Waves. Since in the frontal plane, the ventricles overlie each other to a great extent, the attempt at separation of right ventricular from left ventricular forces is best made in the horizontal plane. Therefore R-wave and S-wave amplitude will only be considered in the horizontal plane. In the normal heart with normally related ventricles, the right ventricular forces are directed anteriorly and to the right. The anterior forces are reflected by the height of the R wave in lead V_1 and the rightward forces by the depth of the S wave in lead V_6. Conversely, the posterior forces

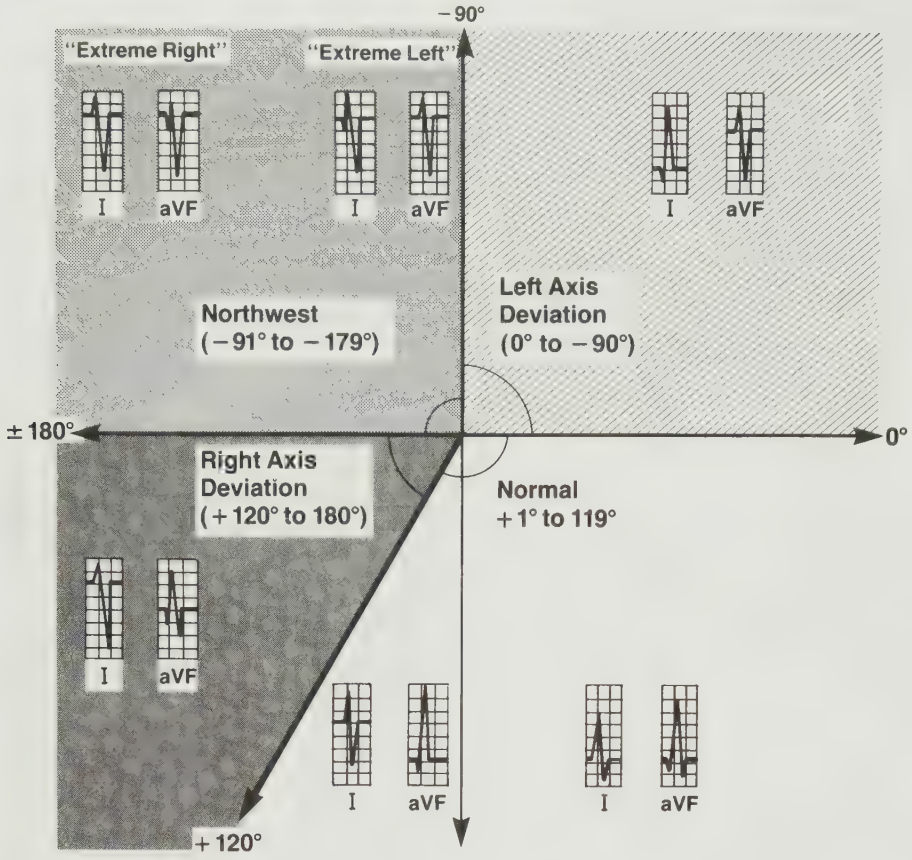

Fig. 45–9. "Axis deviation." Limits for normal and abnormal frontal plane axis in a 10-year-old child. The electocardiograms have been drawn to reflect the mean vector in each of the quadrants.

generated by the left ventricle are reflected by the depth of the S wave in lead V_1 and the leftward forces generated by the left ventricle are reflected by the height of the R wave in lead V_6. Left ventricular forces can also be represented by the sum of the posterior and leftward forces, or the sum of the depth of the S wave in lead V_1 plus the height of the R wave in lead V_6. The normal values by age for the amplitudes and ratios of R waves and S waves in leads V_1 and V_6 are given in Table 45–1.

The transition leads are the precordial leads in which the QRS complexes are approximately equiphasic (R and S waves are equal amplitude). The transition leads record activity from both ventricles and if the total amplitude of the R wave plus the S wave in the transition leads is increased, this represents biventricular hypertrophy. In Table 45–1 the normal total amplitude of R plus S in lead V_4 is given.

The mean amplitudes of the waves reflecting the right ventricle decrease with age while those reflecting the left ventricle increase with age. The variability of these amplitudes also decreases with age. During adolescence (12 to 16 years of age) sex differences in the electrocardiogram become manifest. R waves, especially in the left chest leads, are smaller in girls. This may represent breast development or the smaller cardiac size in women. With adolescence, changes in race and body habitus become more manifest. Larger midprecordial voltages are found in blacks and those with thin chests.[9]

Lower Limit of QRS Amplitude

Heretofore, we have been concerned with the upper limits for QRS amplitude. The lower limit is important because low-voltage QRS complexes are usually a sign of myocardial edema (in myocarditis, myxedema or generalized edema), loss of functioning myocardium (in congestive heart failure, tumor, or amyloid), or increased distance between the heart and chest wall (in obesity, pneumothorax, constrictive pericarditis, or pericardial or pleural effusion) (see section on "Injury due to Myocarditis"). The criterion for abnormally low voltage of QRS complexes is a total amplitude of R + S or 5 mm or less in each of the limb leads or 8 mm or less in each of the chest leads.[7]

ST Segment

The ST segment is the portion of the electrocardiogram between the end of the S wave and the beginning of the T wave. The ST segment normally gently curves into the proximal limb of the T wave and is not perfectly horizontal. To determine ST-segment deviation above or below the base line, it is best to consider the P–R segment as the base line (see section on "P–R Segment"). The ST segments should not be elevated to more than 1 mm or depressed greater than 0.5 mm in any lead in children. The exception is the "early repolarization" syndrome of adolescence, in which the ST segment can be elevated to 4 mm in the midprecordial leads (see section on "Functional T-Wave Changes").

The T Wave

The T wave is normally asymmetrical in shape with the upstroke having a more gradual slope than the downstroke (Fig. 45–10A). The T wave usually has a smooth, curved form but it may have a notch near its summit (Fig. 45–10B).

The T-wave amplitude is generally not measured in specific

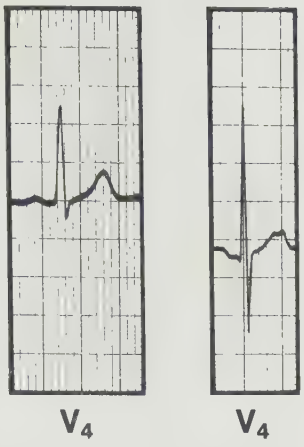

Fig. 45–10. T waves. (A) Normal smooth T wave. (B) Normal notched T wave.

leads, since it is so variable in normal children. However, low-voltage or "flattened" T waves in several leads may indicate an abnormality (see section on "Ischemia"). The T waves in leads I, II, and V_6 should be more than 2 mm in all children over 48 hr old. An abnormally tall T wave is generally defined at any age as greater than 7 mm in a limb lead or 10 mm in a precordial lead.

The T-wave axis in the frontal plane can be calculated by the same methods as for the QRS complex. However, in practice it is helpful to remember that in normal children the T waves should be upright in leads I and II (over 48 hours of age), upright in lead aVF (over 5 days of age), and inverted in lead aVR (at all ages) (Fig. 45–11). Between approximately 5 days of age and adolescence, the T waves should be inverted in leads V_1 and V_3R.[10] If they are positive, this is usually a sign of right ventricular hypertrophy. In infants less than approximately 5 days of age or in adults, the T waves in lead V_1 or V_3R are variable. The T waves in lead V_6 should be positive at all ages.

The U Wave

The normal U wave has the same polarity as the preceding T wave but the normal U wave has only 2 to 24% of the T-wave amplitude. There is a wide variation of normal; however, the normal U wave should not be more than 50% of the amplitude of the T wave (Fig. 45–12). The largest-amplitude U waves are recorded in leads V_2 to V_4. The shape of a normal U wave is different from the normal T wave. In the U wave, the upstroke is steeper than the downstroke.[7,11]

Differentiating T, U and P Waves

It is important to differentiate between T waves and normal U waves so that the U wave can be discounted in the measurement of the Q–T interval. A normal U wave is one with an amplitude no more than 50% of the preceding T wave. At slow heart rates, the T and U waves are usually separated by a distinct isoelectric line, but at rates over 90 beats/min, there may be no intervening isoelectric line and it may be difficult to determine whether the terminal portion of the deflection is a U wave or the second half of a notched T wave. If, in the same or a different lead, another wave is seen later in timing than the questionable wave, then the questionable wave is a notched T wave (Fig. 45–13). It may be possible to bring out a U wave by recording the electrocardiogram in the sitting position. This tends to decrease the T-wave and increase the U-wave amplitude in the left precordial leads.[12]

If there is a single wave in all leads, it is not possible to determine whether this represents a T wave or fusion of a T wave and U wave. If there is no notch in any lead, but the wave is smooth throughout, it should be considered a T wave (Fig. 45–14). If there is a notch in the terminal part of the wave and the amplitude is 50% or less of the peak, then the downstroke of the early portion of the wave should be extrapolated as the T wave (Fig. 45–15). If the terminal portion of the wave in any lead (usually V_4 is the clearest) is more than 50% of the amplitude of the peak, the terminal portion of the wave should be included as part of the T wave (Fig. 45–16). Whether this terminal portion should be called a T wave is semantic.[13] The important electrocardiographic ques-

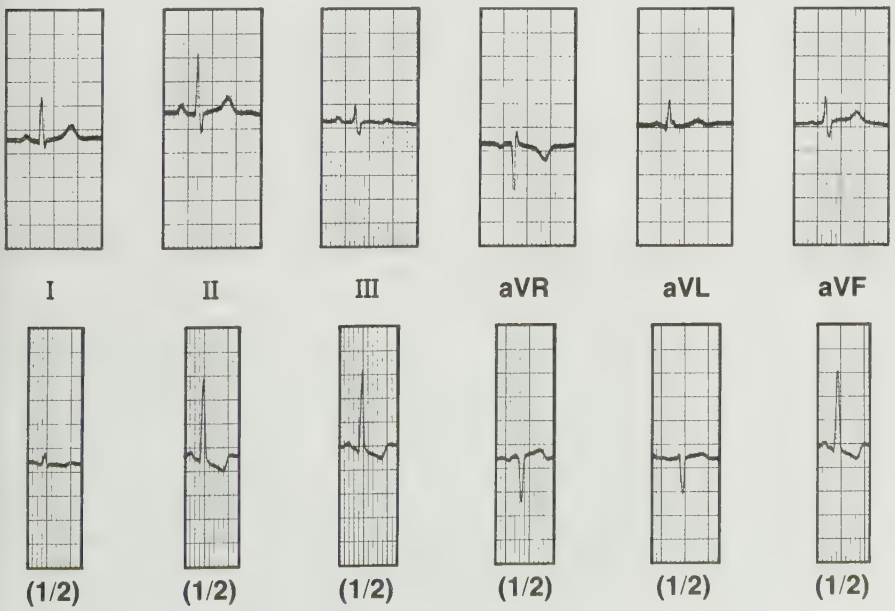

Fig. 45–11. T-wave axis. Top tracings: Normal 7-yr-old; QRS frontal plane axis +17°, T-wave axis +34°; the QRST angle is 17°. Bottom tracings: 7-yr-old with severe aortic stenosis; frontal plane QRS axis +85°, T wave axis −90°; the QRST angle is 175°.

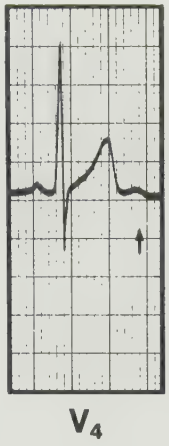

Fig. 45–12. U wave (arrow).

tion to be answered is whether there is a significant increase in the amount of late repolarization. This can be indicated either by a separate U wave with an amplitude more than 50% of the T wave, or by a single fusion wave whose terminal portion is more than 50% of the amplitude of the peak. The causes and consequences of increased late repolarization are the same. Therefore the same consideration should be given to long T waves as to excessively large U waves.

The distinction of P waves from T or U waves in sinus rhythm is simplified by examining multiple leads. P waves are most obvious in lead II and least obvious in leads V_4 to V_7. T and U waves are most obvious in leads V_4 to V_7. Therefore a synthesis can be made of the different waves by using the timing from different leads (Fig. 45–17). In sinus tachycardia, the P wave may begin before the T wave has been completed. At rapid rates, P waves become much more pointed than T waves. Again, in leads V_6 or V_7 almost all of the wave is likely to be a T wave while in lead II, the maximum P wave is likely to be visible. In supraventricular tachycardia, the most pointed of the waves are P waves. P waves can also be identified as discrete deflections usually lasting 0.06 sec or less, which occur with an improper timing for a QRS complex or a T wave (Fig. 45–18). Using this type of analysis,

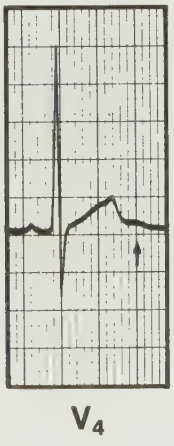

Fig. 45–13. Notched T wave followed by a U wave.

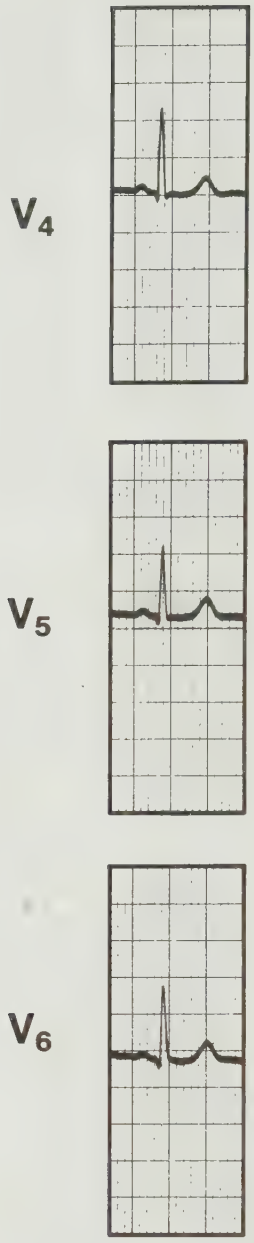

Fig. 45–14. There is no notch in any of the waves following the QRS complex and so these should all be considered T waves. Simultaneous leads V_4, V_5, and V_6.

we have found it possible to distinguish P waves in 55% of children during supraventricular tachycardia.[14]

Q–T Interval

The Q–T interval begins at the onset of the QRS complex and terminates at the end of the T wave. The longest interval in any lead should be used. As noted in the previous section, in certain conditions, it may be difficult to choose the proper end of the T wave. I agree with James[15] that "In electrocardiography, there is no more nebulous measurement than the Q–T interval," but some rules may be helpful (Fig. 45–19). 1) If a separate T and U wave are visible and the U-wave amplitude is 50% or less of the T-wave amplitude, the Q–T interval ends at the end of the T wave.

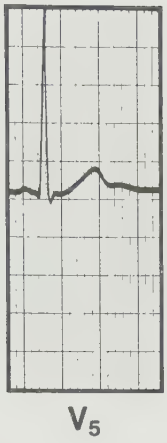

Fig. 45–15. T wave followed by a notch with an amplitude less than 50% of the peak of the T wave. In this case, the T wave is considered to have merged with the U wave and the T wave ends at the extrapolated downslope of the larger wave.

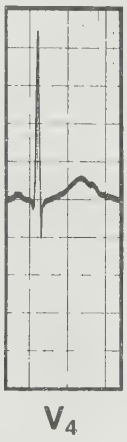

Fig. 45–16. T wave with a notch and the peak of the terminal segment is greater than 50% of the peak of the T wave. In this case, both of these waves should be considered as part of the T wave.

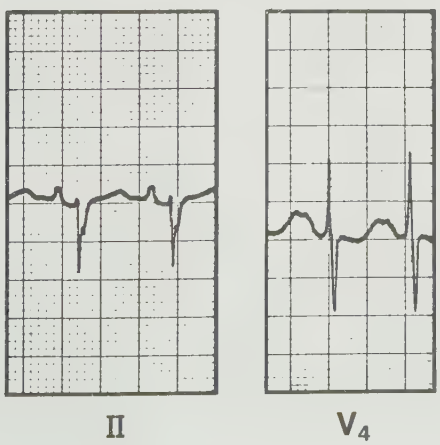

Fig. 45–17. Distinction of P waves from T waves. In lead V_4, it is not possible to tell whether these waves are merged P waves with T waves or T and U waves. It is apparent from examination of lead II in the same patient that the second notch in lead V_4 is caused by the P wave.

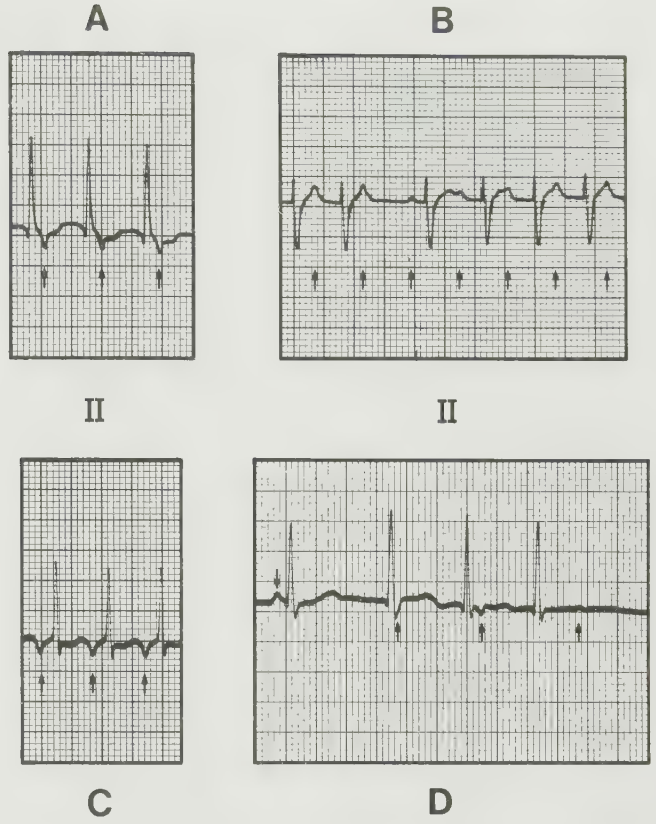

Fig. 45–18. Identification of P waves (arrows). (A) P waves in the early part of the ST segment. (B) P waves directly on top of T waves. The only way of distinguishing these waves was to observe an episode of spontaneous type I second-degree atrioventricular block in which the P wave was not followed by a QRS complex. This allowed observation of the P wave preceding the next QRS complex with a lengthening P–R interval in subsequent beats. (C) P waves on the downslope of the T wave. (D) P waves with differing relations to the QRS and T wave. In the second QRS complex, the widened S wave is caused by a superimposed P wave.

2) If a single wave is visible and there is no notch in any lead, the entire wave is included in the Q–T interval. 3) If a single wave is visible but a notch is present in the wave and the terminal portion of the wave has an amplitude of 50% or less of the peak, then the initial downslope should be extrapolated and the extrapolation used for the Q–T interval. 4) If a single wave is visible, has a notch, and the terminal portion has an amplitude of more than 50% of the peak, then the entire wave is included as the T wave. 5) If a P wave is superimposed, extrapolate the T wave back to the base line from the initial downstroke (see Fig. 45–19). The Q–T interval varies with heart rate. The Q–T interval can be corrected for heart rate by Bazett's (1918) formula: The corrected Q–T interval (Q–Tc) is equal to the Q–T interval (in seconds) divided by the square root of the R–R interval (in seconds). The corrected Q–T interval is abnormal if it is greater than 0.44 sec at most ages; some normal newborns may have normal Q–Tc of 0.45 sec.

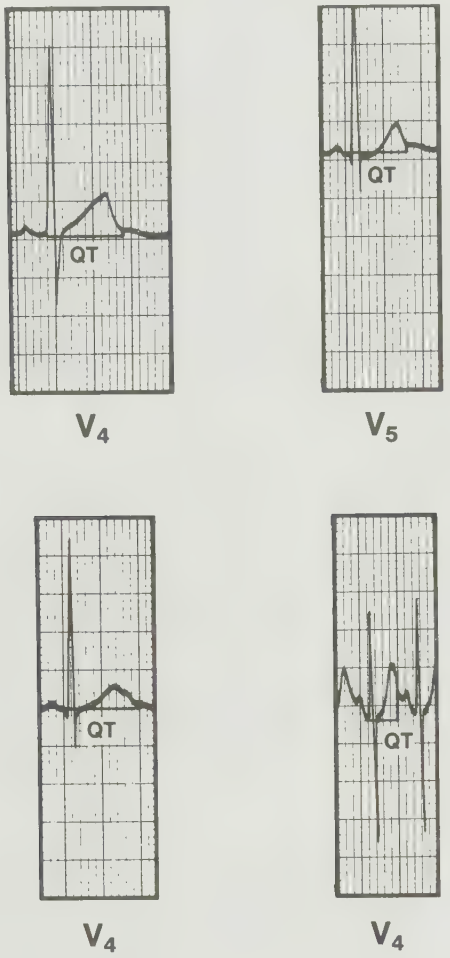

Fig. 45–19. Measurement of the Q–T interval. (A) With a notched T wave followed by a U wave, the downslope of the T wave is extrapolated to the base line. (B) With a notch less than 50% of the peak of the T wave, the early segment is extrapolated to the base line. (C) With a notch greater than 50% of the peak of the T wave, the second portion of the wave is extrapolated to the base line. (D) With superimposed P waves, the downslope of the T wave is extrapolated to the base line.

Q–OT Interval

The interval from the onset of the QRS complex to the onset of the T wave is the Q–OT interval. This interval may be corrected for heart rate in a similar way to the Q–T interval thus determining the Q–OTc interval. In hypocalcemia, the entire T wave is shifted later in the cardiac cycle (due to a prolonged ST segment) and the Q–QTc interval provides a measure of this prolongation (Fig. 45–20). In premature infants, the normal corrected Q–OTc is 0.20 sec or less and in full-term infants, it is 0.19 sec or less.[16]

MALPOSITION OF THE HEART

Atrial Situs

In the majority of cases, the atrial situs may be determined from the electrocardiogram. In situs solitus of the atria and viscera, the P-wave mean vector in the frontal plane is approximately +60°, pointing away from its site of origin in the high right atrium, or away from the right shoulder. This results in a positive P wave in leads I and aVF (Fig. 45–21). In atrial situs inversus, a normal sinus impulse still originates high in the anatomic right atrium but since the anatomic right atrium is on the patient's left, the origin of the P wave appears to be from the left shoulder and the P-wave mean vector in the frontal plane, pointing away from the site of origin, is +120°, resulting in a P wave that is negative in lead I and positive in aVF. The P-wave mean vector in the horizontal plane is generally not helpful because activation proceeds posteroanteriorly in this plane.

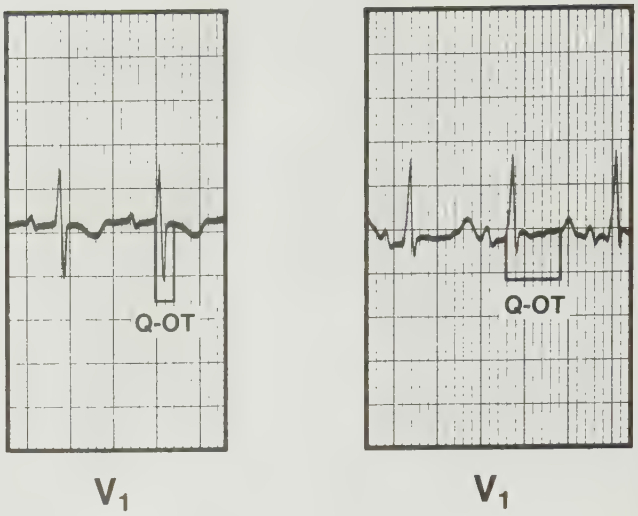

Fig. 45–20. Q–OT interval. (A) Q–OT interval in a normal newborn infant. The Q–OT interval is 0.10 sec and the P–R interval is 0.45 sec. Therefore the Q–OTc interval is 0.15 sec. A normal Q–OT interval is 0.20 sec or less. (B) Q–OT interval in an infant with hypocalcemia. The Q–OT interval is 0.27 sec and the P–R interval is 0.47 sec. The Q–OTc interval of 0.39 sec is prolonged.

It may be impossible to determine atrial situs in the presence of an ectopic atrial rhythm.[17] However, in patients with normal situs and left atrial ectopic rhythm, despite the negative P wave in lead I, there may be a dome-and-dart P wave in lead V_1 (see Fig. 45–21), indicating that the anatomic left atrium is activated before the anatomic right atrium.[18] In the rare case of a patient with atrial situs inversus and an ectopic rhythm originating from the right-sided anatomic left atrium, this patient would have a normal frontal plane P-wave axis (+60°) but with a dome-and-dart configuration in lead V_1 (see Fig. 45–21).

In cases of situs ambiguus associated with splenic malformations, the P waves may be characteristic. In asplenia, there may be two anatomic right atria, one on either side, and there may be two sinus nodes.[19] In such cases, competition between the sinus nodes may occur with two P waves (one positive in lead I and one negative in lead I), each having a slightly different rate. In polysplenia, there may be absence of any sinus node and the pacemaker characteristically is located in the low atrium, giving a frontal plane P-wave mean vector that is directly superior (−90°).

Ventricular Position

Since atrial situs is independent of ventricular position, the P waves and QRS complexes should be interpreted independently

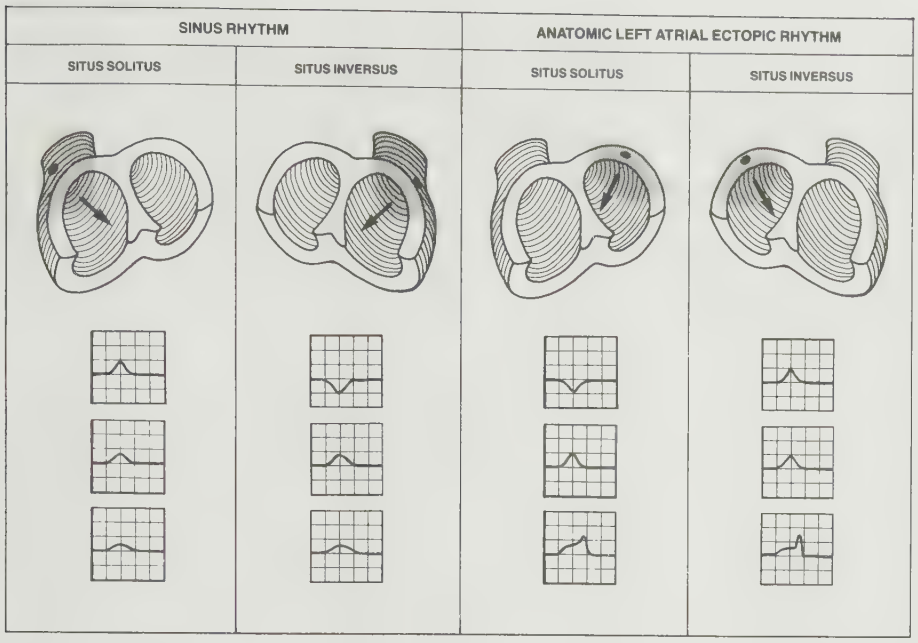

Fig. 45–21. P-wave morphology in sinus rhythm and anatomic left atrial ectopic rhythm with different atrial position. In sinus rhythm, the P wave is positive in lead I with situs solitus and negative in lead I with situs inversus. If the anatomic right atrium is depolarized before the anatomic left atrium, there is a normal P wave in lead V_1. If the anatomic left atrium is activated before the anatomic right atrium, a "dome-and-dart" P wave is found in lead V_1. Therefore in situs solitus with anatomic left atrial ectopic rhythm, there is a negative P wave in lead I and a dome-and-dart P wave in lead V_1. With atrial situs inversus and anatomic left atrial ectopic rhythm, there is a positive P wave in lead I and a dome-and-dart P wave in lead V_1.

(i.e., a negative P wave in lead I suggests atrial situs inversus but not necessarily dextrocardia). There are four major electrocardiographic patterns that describe ventricular position: normal, mirror-image dextrocardia, dextrorotation, and ventricular inversion (Fig. 45–22). In the normally positioned heart, the maximal biphasic QRS voltage in the chest leads (transition) is at the left midclavicular line at lead V_3 or V_4; in the frontal plane, the initial forces are directed superiorly and to the right (Q wave or R wave in leads I, aVF, and V_6), the major forces are directed inferiorly and to the left (tall R wave in leads I, aVF, and V_6), and the terminal forces are directed superiorly and to the left (small S wave in lead aVF, R wave in leads I and V_6) (Fig. 45–23).

Mirror-Image Dextrocardia

"Dextrocardia" implies only that the ventricular mass is in the right chest. In mirror-image dextrocardia, there is a reversal of anatomic left–right relation, but with anteroposterior relation maintained, i.e., the anatomic right ventricle is to the left and anterior. Whenever the ventricles are in the right chest, the maximal biphasic voltage is recorded in one of the right chest leads. If the total voltage (top of the R wave to bottom of the S wave) in lead V_3R or V_4R is larger than the total voltage in lead V_3 or V_4, the patient has dextrocardia. In mirror-image dextrocardia, if all the right chest leads are recorded (V_1 and V_3R to V_7R) the QRS morphologies in these leads should be the same as those found recording the left chest leads in a normally situated heart. In the frontal plane, in a patient with mirror-image dextrocardia, the initial forces are directed superiorly and to the left (initial deep Q wave in leads I, aVF, and V_6); the major forces are directed inferiorly and to the right (small R, deep S, or QS, in leads I and V_6, tall R in aVF) and the terminal forces are directed superiorly and to the right (S wave in leads I, aVF, and V_6) (see Fig. 45–23).

In summary, mirror-image dextrocardia should be suspected 1) if the magnitude of the total QRS deflection is greater in lead V_3R or V_4R than in lead V_3 or V_4; 2) if lead I has a deep Q wave and a small R wave; or 3) if in leads V_3 to V_7, the QRS complexes

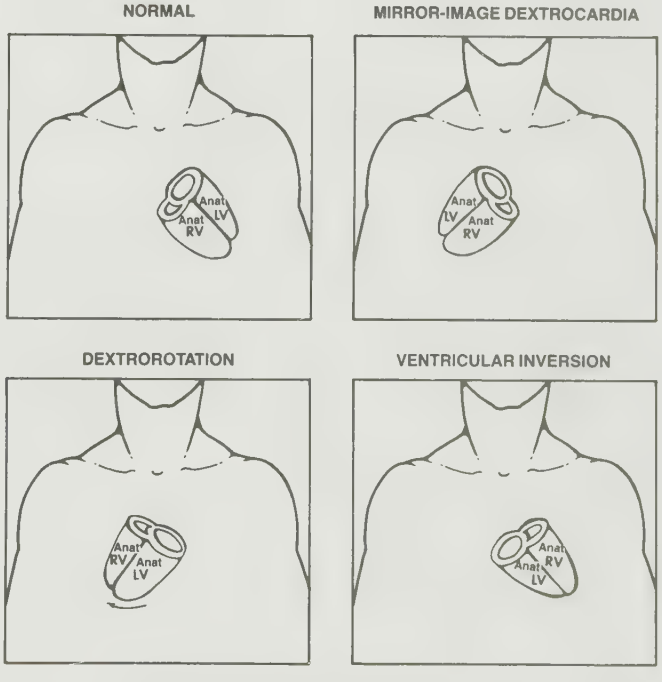

Fig. 45–22. Ventricular position. In the normal heart, the anatomic right ventricle is to the right of and anterior to the anatomic left ventricle. The cardiac mass is in the left chest. In mirror-image dextrocardia, the anatomic right ventricle is to the left of and anterior to the anatomic left ventricle. The ventricular mass is in the right chest. In dextrorotation, the anatomic right ventricle is to the right of and posterior to the anatomic left ventricle. The ventricular mass is in the right chest to a varying degree. In ventricular inversion, the anatomic right ventricle is to the left of and usually side by side of the anatomic left ventricle. In ventricular inversion without dextrocardia, the ventricular mass is in the left chest.

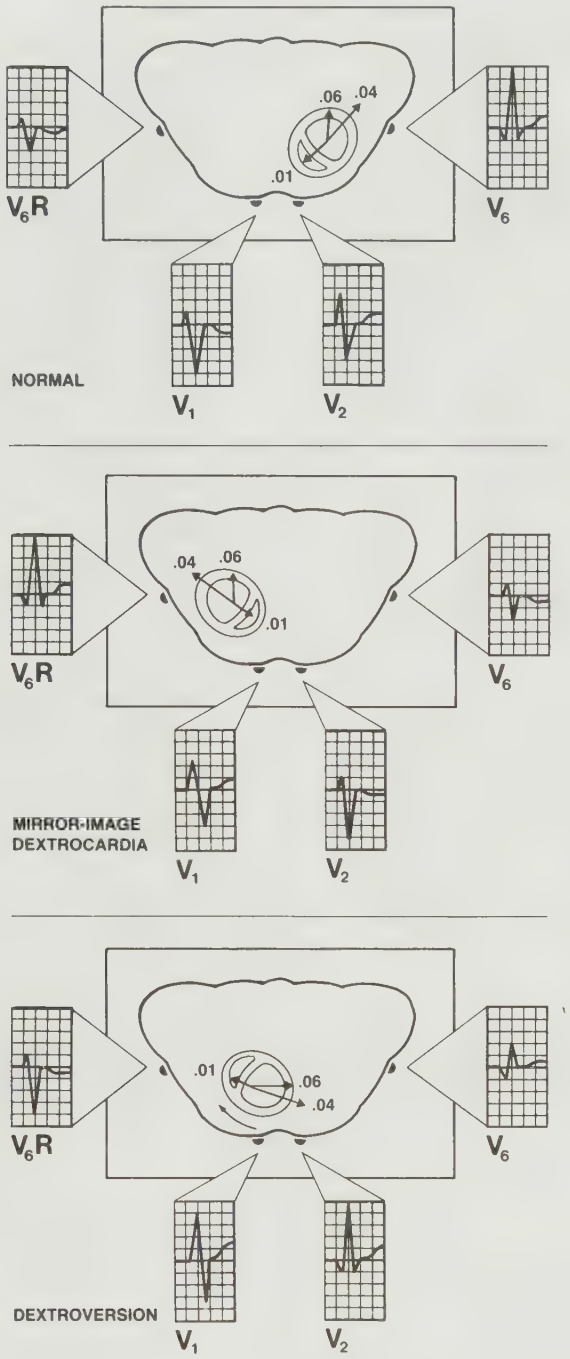

Fig. 45–23. Horizontal-plane vectors in different cardiac positions. In the normal, the middle (0.04 sec) vector points left and posterior. In miror-image dextrocardia, the middle (0.04 sec) vector points to the right and posterior and in dextroversion, the middle (0.04 sec) vector points left and slightly anterior.

become progressively smaller with a small R, deep S, or QS, configuration.[6]

In assessing ventricular hypertrophy in mirror-image dextrocardia, the same criteria can be applied as with normally situated ventricles except that instead of lead V_6, lead V_6R should be substituted and instead of lead V_1, lead V_2 should be substituted (Fig. 45–24). Therefore, even in the absence of a tracing with all the right chest leads, ventricular hypertrophy can be assessed by interpreting lead V_2 as if it were lead V_1 in a normally situated heart.

Dextrorotation

In dextrorotation, the anatomic relations between the ventricles are preserved (i.e., the right ventricle is on the right and the left ventricle is on the left), but the heart is shifted to a varying degree into the right chest. This shift is usually accompanied by a counterclockwise rotation of the heart (viewed from the apex) such that the left ventricle is anterior to the right ventricle (see Fig. 45–22). Since the amount of rightward shift is variable, the classic signs of dextrocardia with greater voltage in the right chest leads than the left, may be missing. In the frontal plane, the direction of the initial, major and terminal deflection may be similar to normally situated ventricles. The mean frontal-plane QRS vector is inferior and slightly to the left or right. The major effect is on the precordial leads, where the transition is found in leads more to the right than normal, i.e., in lead V_3R or V_4R (see Fig. 45–23). The far right chest leads (e.g., lead V_6R) appear similar to the normal V_1 and the anterior leads (V_3) appear similar to the normal V_6. This can be suspected in a routine electrocardiogram when the anterior chest leads (V_2 to V_4) have small Q waves and tall R waves (similar to the normal V_6) and the transition is just beginning in lead V_1 or V_3R.

Ventricular hypertrophy is less accurately assessed in dextrorotation since the degree of rotation is unknown; but similar criteria to those used for mirror-image dextrocardia may be applied with caution.

Ventricular Inversion

One other condition in which the ventricles are malposed is ventricular inversion. In ventricular inversion with otherwise normal cardiac position (atrial situs solitus and levocardia, i.e., with the ventricles in the left chest), the ventricular septum is oriented straight anteroposteriorly and parallel to the diaphragm with the ventricles side by side and the anatomic right ventricle to the left of the anatomic left ventricle (see Fig. 45–22). Since the anatomic left bundle branch is on the right, this results in reversed septal depolarization with a Q wave in lead V_1, and an absent Q wave in lead V_6 (Fig. 45–25). The other characteristics of ventricular inversion and an otherwise normal heart are left-axis deviation in the frontal plane and atrioventricular block (first-, second-, or third-degree). Usually ventricular inversion is accompanied by additional cardiac malformations and the electrocardiogram may deflect these additional anatomic abnormalities.

Pectus Excavatum and Straight Back Syndrome

In both of these conditions, the mediastinum is shortened in the anteroposterior dimension, causing the heart to shift to the left and rotate clockwise as viewed from the apex. This brings the right atrium more anterior relative to the left atrium and so the

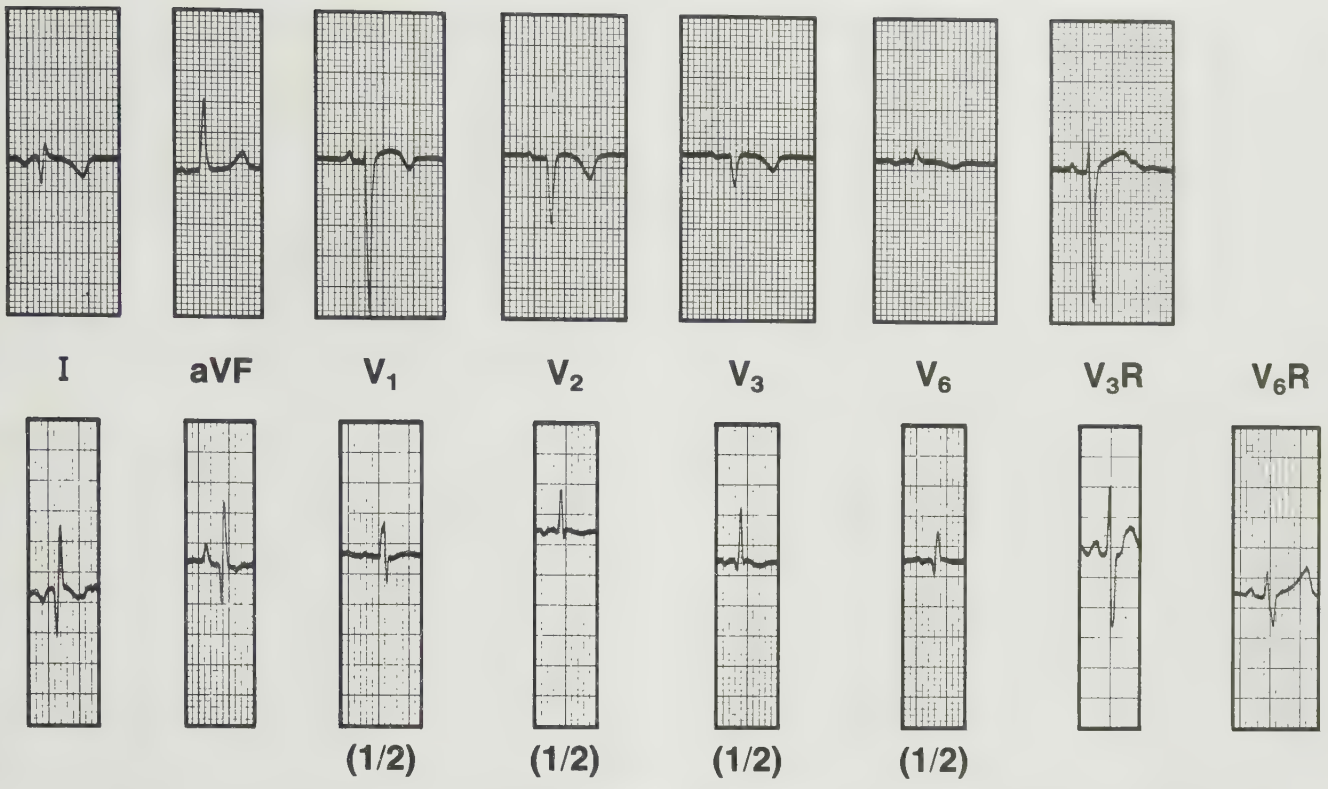

Fig. 45--24. Top tracing: 7-yr-old with dextrocardia and situs inversus with an otherwise normal heart. Bottom tracing: 6-mo-old with dextrocardia, situs inversus, and anterior ventricular hypertrophy. There is a QR pattern in lead V_2 and a deep S wave in lead V_6R.

mean vector of atrial depolarization is oriented straight posteriorly. Therefore, in lead V_1, the P wave may be entirely negative.[8]

Clockwise rotation moves the left side of the heart posteriorly and superiorly causing some patients to have left-axis deviation of the QRS in the frontal plane.[20] The right side of the heart is rotated anteriorly and inferiorly such that the vector of depolarization in the pulmonary outflow tract is shifted from its normal superior and rightward position to a straight anterior position. This is responsible for the normal duration RSR′ pattern in lead V_1 often found in these patients.[21] The transition is shifted to the left and there may be a persistent S wave in lead V_7. Abnormally deep QS waves followed by an R wave of normal duration and inverted T wave in the anterior and midprecordial leads may occur rather than the RSR′ and simulate anterior myocardial infarction. These changes can be explained by the clockwise rotation shifting the major QRS forces even more posteriorly, causing the deep QS and concordantly the inverted T wave. The terminal R wave has the same genesis as the R′ that may be found in this condition: normal terminal depolarization of the right ventricular outflow tract.

Pneumonectomy

The chronic electrocardiographic changes following pneumonectomy result from shift and rotation of the heart. Following a right pneumonectomy, the findings are similar to those of congenital dextrorotation with the transition moved to the right in the chest leads.[22] In over 90% of children after a left pneumonectomy, the heart was rotated clockwise with findings similar to those reported in pectus excavatum.

Pneumothorax and Pneumomediastinum

Since air is a poor conductor of electrical activity, if there is air between the heart on the recording electrode, the voltage of the P, QRS, and T waves will be decreased. In pneumomediastinum, the voltage may be decreased in all leads. In pneumothorax, the voltage may be decreased only in certain leads corresponding to the location of the air. Depending upon the amount of air, a pneumothorax may cause shift or rotation of the heart similar to that found following pneumonectomy on the opposite side. Finally, depending upon the amount of hemodynamic compromise caused by the condition, nonspecific ST- and T-wave changes, as well as arrhythmias, may occur. In pneumothorax, if the patient is placed in a sitting position, the electrocardiogram may normalize as the air moves superiorly away from the heart.

Kyphoscoliosis

There may be virtually any positional abnormality with kyphoscoliosis.[8] In severe cases, both rotation and shift occur thus making it even more difficult to interpret the electrocardiogram. Since respiratory insufficiency and cor pulmonale may occur in these children and cause right atrial enlargement, right-axis deviation, and right ventricular hypertrophy, an electrocardiographic diagnosis may be helpful in the treatment of the patient. As a general rule, a P-wave amplitude of more than 2.5 mm in any lead constitutes right atrial enlargement. Right ventricular hypertrophy should be considered if a complex is found in any precordial lead to the right of the transitional leads with a tall R wave and a small S wave, and the height of the R wave is greater than the normal value for age given for lead V_1.

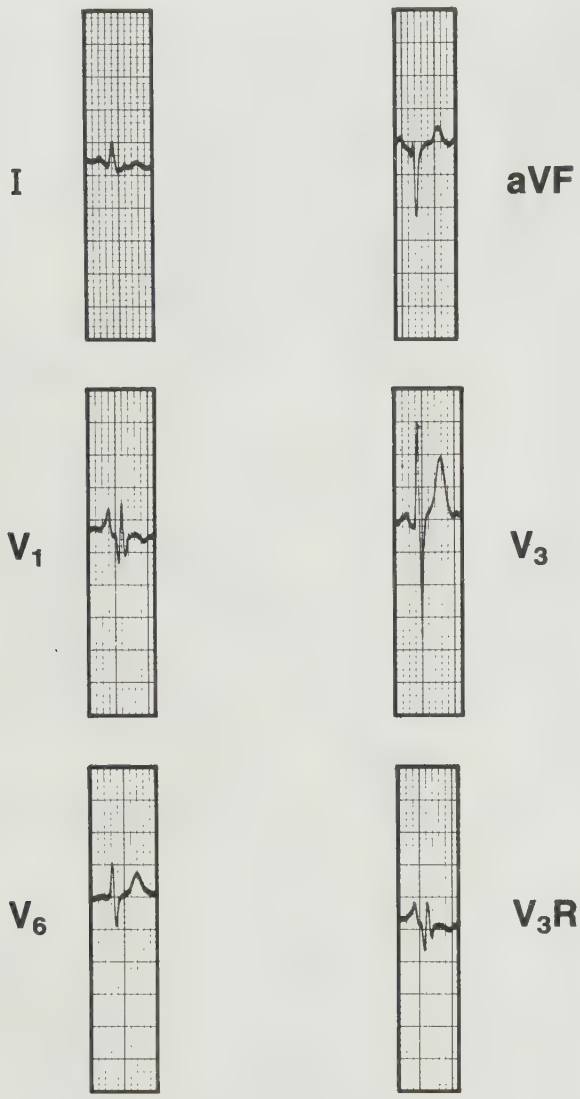

Fig. 45–25. Ventricular inversion. Note the deep Q waves in lead V_1 with a relatively small R wave. There are no Q waves in lead V_6.

CHAMBER ENLARGEMENT AND HYPERTROPHY

The electrocardiogram can be helpful in the diagnosis of enlargement or hypertrophy of the cardiac chambers. While the electrocardiogram correlates with chamber size better in pediatric patients than in adults, there is still only about a 60 to 70% predictive value of the electrocardiogram in children.[23,24] Therefore if either the presence or absence of an abnormality on an electrocardiogram does not agree with the clinical or echocardiographic findings, the electrocardiogram should be viewed critically. In the following discussion, criteria are listed for chamber enlargement or hypertrophy with the most reliable signs presented first.

Right Ventricular Hypertrophy

The electrocardiogram can provide important data on right ventricular hypertrophy or elevated right ventricular systolic pressure that are not currently available by noninvasive means. The criteria for right ventricular hypertrophy are described below.

QR Pattern in the Right Chest Leads (Fig. 45–26). The Q wave is due to dominant early wave of excitation moving posteriorly. This may be due to the hypertrophied and dilated right side of the septum providing a larger surface area for a normally insignificant posterior vector. In this case, left to right septal activation occurs normally but is overshadowed by a stronger posterior vector. Alternatively, in right ventricular hypertrophy, the inferior wall of the right ventricle directly contiguous to the septum may bulge posteriorly and to the left of the septum. Therefore, instead of the earliest activation continuing left to right, the initial septal depolarization may begin normally toward the right for a few milliseconds but then change orientation and move to the left as the parts of the inferior wall of the right ventricle that are situated to the left of the septum depolarize.[25]

The Q wave in the QR pattern of right ventricular hypertrophy is generally only 0.5 to 1 mm deep in infants but may become 3 to 5 mm deep in older children. The QR pattern is reliable and implies a right ventricular systolic pressure of 70 mm Hg or more at any age.[26] A QR pattern may also be seen in ventricular inversion with reversed septal depolarization. In general, in the QR pattern of right ventricular hypertrophy in lead V_1 or V_4R, the R wave is tall (more than 10 mm). In ventricular inversion, the Q wave may be slightly deeper than the usual Q wave seen in right ventricular hypertrophy and the R wave may not be as tall (see Fig. 45–25). This distinction may not be possible in an individual patient. A final cause of a QR pattern in lead V_1 or V_3R is the rare case of an anterior myocardial infarction involving either the right ventricle or the anterior ventricular septum. Before making the diagnosis of a QR pattern, it is important to be certain that the QRS complex does not begin with a tiny R wave, thus making the complex an RSR′ pattern rather than a QR pattern.

T-Wave Changes. Between 1 wk of age and the onset of adolescence, the T waves in the right chest leads should be negative. In mildly increased right ventricular systolic pressure, the electrocardiogram is normal with a small R wave and a symmetrically inverted T wave in lead V_1 (Fig. 45–27). With increasing severity of pulmonary stenosis, usually before the R wave height is abnormal, the T wave becomes isoelectric or upright (see Fig.

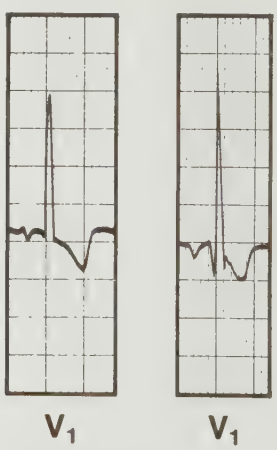

Fig. 45–26. Left: Typical QR pattern in lead V_1 with a small Q wave. This is from a 9-mo-old patient with unoperated transposition of the great arteries. Right: Deep Q wave with a tall R wave and ST depression in a 4-yr-old after Mustard operation for transposition of the great arteries.

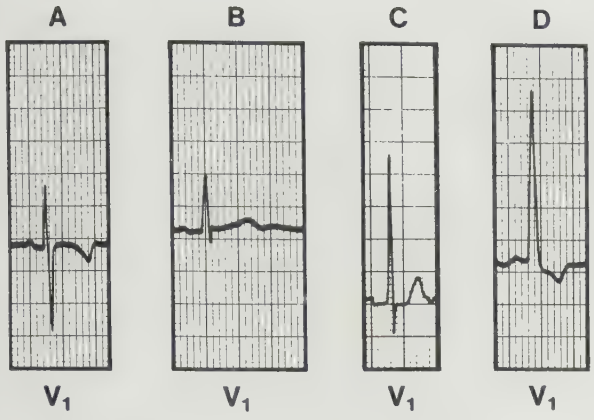

Fig. 45–27. Progression of T-wave changes in lead V_1 in right ventricular hypertrophy. (A) Normal T wave in a 4-year-old child. (B) Upright T wave in a 7-yr-old child with mild pulmonary stenosis. The R wave is 9 mm tall. (C) Tall R wave with upright T wave in a 2-year-old with severe pulmonary stenosis. (D) Tall R wave with asymmetrically inverted T wave ("right ventricular strain") in a 3-yr-old patient with critical pulmonary stenosis.

45–27). The upright T wave is due to elevated right ventricular systolic pressure and not necessarily to right ventricular hypertrophy, since in a patient with increased right ventricular systolic pressure due to upper airway obstruction and hypoxia, the upright T waves may invert immediately with intubation and ventilation. In general, if the height of the R wave in lead V_1 is less than 10 mm, an inverted T wave is associated with less severe disease than an isoelectric or upright T wave (see Fig. 45–27). When the R-wave height increases above 10 mm, the upright T wave may become asymmetrically inverted with a concave upward terminal portion (see Fig. 45–27). Therefore the progression and severity is as follows: normal R with symmetrically inverted T; normal or slightly increased R with upright T; tall R with upright T; and tall R with asymmetrically inverted T. The asymmetrically inverted T wave in lead V_1 is called the "right ventricular strain" pattern and may be associated with ST depression in the same lead. This is thought to be a primary T-wave change due to the reversed direction of repolarization, which occurs from endocardium to epicardium in hypertrophy.[4] The right ventricular strain pattern generally indicates a right ventricular systolic pressure equal to or greater than systemic pressure.[6,26] The deeply asymmetrically inverted T waves in the right ventricular strain pattern may extend as far to the left as lead V_4 and, rarely, V_5 but usually not to V_6.[25] Conversely, the T-wave inversion found in leads V_5 and V_6 indicating "left ventricular strain" may cause reciprocally upright T waves in the right chest leads. Therefore, before the diagnosis of right ventricular hypertrophy is made on the basis of an upright T wave in lead V_1, leads V_5 and V_6 should be examined for left ventricular strain.

One other T-wave change of severe right ventricular hypertrophy is T-wave inversion in lead aVF.[26] This is a nonspecific sign, since it may also be indicative of left ventricular strain or another condition (see section on "Ischemia"). But in the presence of other signs of right ventricular hypertrophy, T-wave inversion in lead aVF indicates severe right ventricular hypertrophy.

R-Wave Amplitude in Lead V_1. If the amplitude of the R wave in lead V_1 exceeds the ninety-eighth percentile for age (see Table 45–1) right ventricular hypertrophy is suspected. This sign is more specific but less sensitive than others; i.e., there may be children with right ventricular hypertrophy with a normal R wave in lead V_1.[8] The magnitude of the R wave in lead V_1 is directly proportional to the right ventricular systolic pressure. Two correlative formulas have been devised from children with pulmonary stenosis. Right ventricular systolic pressure equals three times the R wave in V_1 plus 47, or right ventricular systolic pressure equals five times the R wave in V_1.[25,26] If the R wave in V_1 is 20 mm Hg or more at any age, the right ventricular systolic pressure is equal to or more than systemic pressure.

One other reason for an abnormally tall R wave in lead V_1 in a patient without right ventricular hypertrophy is ventricular septal hypertrophy. This may cause deep Q waves in leads V_5 and V_6, with reciprocally tall R waves in lead V_1. Since septal depolarization is completed relatively early in the QRS complex, the tall R wave in lead V_1 due to septal hypertrophy is "narrow" and usually lasts 0.03 sec or less. Conversely, in right ventricular hypertrophy, ventricular activation is slightly prolonged and the R wave of right ventricular hypertrophy in lead V_1 generally lasts 0.04 sec or longer.[8] Finally, in patients with muscular dystrophy, a similar pattern of a tall narrow R wave in V_1 may occur with Q waves in the left chest leads. This is thought to be due to posterobasal left ventricular fibrosis.

S-Wave Amplitude in Lead V_6. If the depth of the S wave in lead V_6 exceeds the ninety-eighth percentile for age (see Table 45–1), right ventricular hypertrophy is suspected. This is more sensitive and less specific than other signs; i.e., a deep S wave in lead V_6 may be associated with conditions other than right ventricular hypertrophy. One of these is left ventricular hypertrophy localized to the superior septum. This part of the left ventricle is the last to be activated, and since it is usually in the anterior part of the left ventricle, this may cause a delayed vector directed anteriorly, causing an S wave in lead V_6 or even a normal duration RSR′ in lead V_1. This has been termed the "incomplete right bundle branch block of coarctation of the aorta or aortic stenosis."[25] One other cause of a deep S wave in lead V_6 is left anterior hemiblock caused by delayed activation of the anterior left ventricle (see section on "Interventricular Conduction Disturbance").

R/S Ratio in Lead V_1. This ratio suffers the inaccuracies of each of the single measurements. Nonetheless, an abnormally large R/S ratio does correlate with right ventricular hypertrophy (see Table 45–1), and it is a stronger sign for right ventricular hypertrophy in the presence of a deep S wave in lead V_6.

RSR′ in Lead V_1. In more than 90% of children with a secundum atrial septal defect, there is a normal duration RSR′ pattern in lead V_1. This correlates well with the mild right ventricular hypertrophy found in these children.[6] Thus the RSR′ pattern is quite sensitive for mild right ventricular hypertrophy but also quite nonspecific, since it may be found in normal children and those with incomplete right bundle branch block (see the sections on "The Normal Electrocardiogram" and "Interventricular Conduction Disturbance"). In right ventricular hypertrophy, the S wave tends to be smaller and the R′ wave larger than in normal children. With a QRS complex of normal duration, right ventricular hypertrophy is usually the cause of an R′ wave greater than 15 mm in an infant under 1 year of age, or an R′ greater than 10 mm over 1 year (Fig. 45–28). If the R′ is small with a normal duration RSR′ complex, the diagnosis could be normal, incomplete right bundle branch

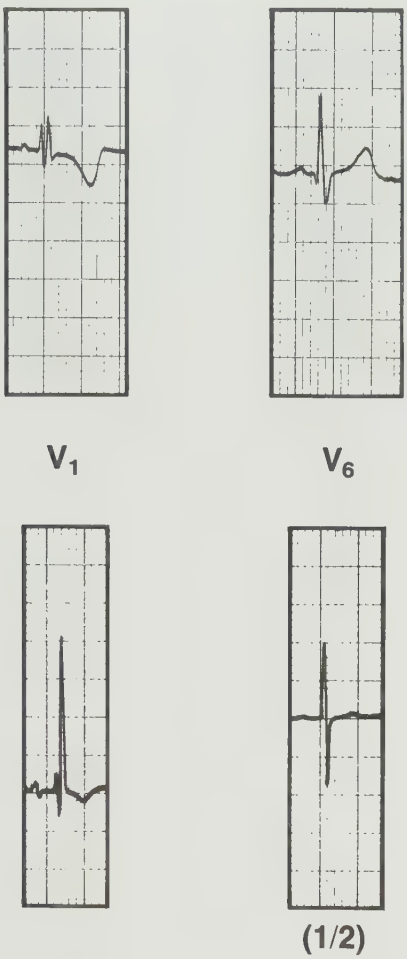

Fig. 45–28. The RSR′. Top tracings: QRS complex of normal duration with RSR′ pattern in V_1 in a 6-yr-old child. The R′ is not tall. No specific diagnosis can be applied. Bottom tracings: QRS complex of normal duration with an RSR′ pattern in lead V_1. The R′ wave is tall. This is a 6-mo-old child with right ventricular hypertrophy.

block pattern or right ventricular hypertrophy and we would prefer the description "RSR′ pattern in right chest leads" rather than attempting to make a specific diagnosis.

Right-Axis Deviation. Over the age of 3 mo, right-axis deviation correlates with right ventricular hypertrophy.[27] In adults, one of the common causes of right-axis deviation is left posterior hemiblock (see section on "Interventricular Conduction Disturbance"). Left posterior hemiblock is rare in children, so right ventricular hypertrophy is by far the leading cause of right-axis deviation in children. Nonetheless, right-axis deviation should be considered as supporting evidence, and the electrocardiogram should meet one of the other criteria for right ventricular hypertrophy. The diagnosis of right-axis deviation may be stronger supporting evidence for right ventricular hypertrophy in the patient with an RSR′ pattern in lead V_1.[28]

Left Ventricular Hypertrophy

Recent echocardiographic and autopsy studies have shown that the electrocardiographic diagnosis of left ventricular hypertrophy is accurate only about 50% of the time. The more of the criteria described below that are met by an electrocardiogram, the more certain is the diagnosis of left ventricular hypertrophy.[4]

T-Wave Changes. The T waves are normally upright in leads V_5 and V_6 after 48 hr of age. The most reliable sign of left ventricular hypertrophy is asymmetric T-wave inversion with an upward convexity in the terminal portion of the T wave in leads V_5 or V_6—the so-called left ventricular strain pattern (Fig. 45–29). This may coexist with ST depression in the same leads. These changes become more prominent with increasing left ventricular to aortic gradient in aortic stenosis in children. In all children with a gradient less than 50 mm Hg, the T waves in lead V_6 were upright, whereas 50% of those with gradients of 80 mm Hg or more had inverted T waves in lead V_6. The T waves in lead aVF also became inverted with increasing gradient in aortic stenosis, but the findings in leads V_5 and V_6 were more reliable.[24]

The ST–T-wave changes of left ventricular strain are the opposite of what would be expected in hypertrophy. In mild hypertrophy, the R wave in lead V_6 is increased in amplitude and the positive T waves are also increased in amplitude. In severe left ventricular hypertrophy, there is a variable amount of conduction delay and endocardial repolarization begins before epicardial depolarization has ended, causing T-wave inversion and ST-segment depression (see Fig. 45–29). Left ventricular strain is therefore a primary change unrelated to the height of the R wave.[4]

T-wave inversion in the inferior and lateral leads is found in conditions other than severe left ventricular hypertrophy (see section on "Ischemia"). But if no other cause is found for the T-wave inversion, even in the absence of other criteria, the diagnosis of severe left ventricular hypertrophy should be suspected on the basis of the T waves.

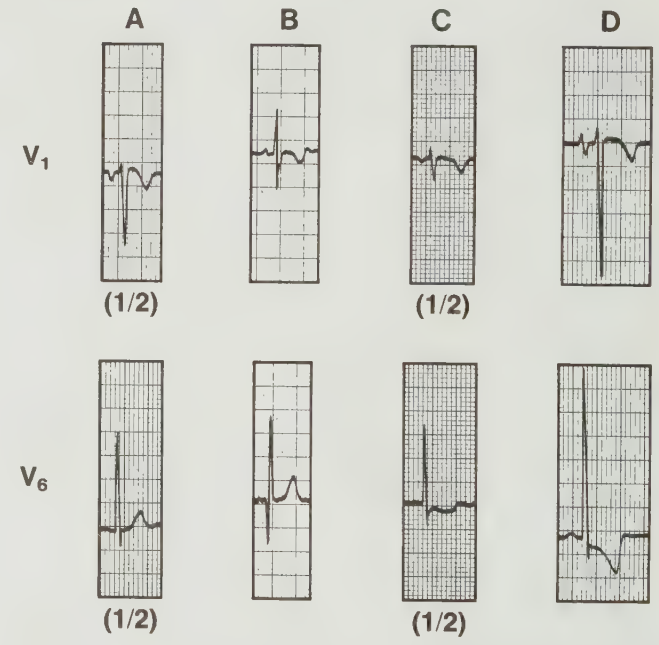

Fig. 45–29. Left ventricular hypertrophy. (A) Voltage criteria with deep S wave in lead V_1 and tall R wave in lead V_6. (B) Deep Q waves in lead V_6. (C) Absent Q wave in lead V_6. (D) T-wave inversion in lead V_6 with ST depression ("left ventricular strain").

R-Wave Amplitude in Lead V_6 or S-Wave Amplitude in Lead V_1. An R wave in lead V_6 or an S wave in lead V_1 that is greater than the ninety-eighth percentile for age (see Table 45–1) should be designated as "left ventricular hypertrophy by voltage criteria" (see Fig. 45–29). Morganroth et al.[29] reported on 11 teenagers with either an abnormally deep S wave in lead V_1 or an abnormally tall R wave in lead V_6, all of whom had a normal echocardiogram and no other evidence of cardiac disease. All of these children had normal T waves. Therefore an individual adolescent may have prominent voltage without an increased left ventricular mass. In the absence of T-wave changes, the diagnosis of left ventricular hypertrophy based entirely on voltage criteria must be viewed critically.

Amplitude of the R Wave in Lead V_6 plus the Amplitude of the S Wave in Lead V_1. This measurement suffers from the same problem as the individual measurements, but does correlate with left ventricular hypertrophy. This should also be considered as "left ventricular hypertrophy by voltage criteria" if greater than the ninety-eighth percentile for age (Table 45–1). The R/S ratio in the precordial leads is less helpful in left ventricular hypertrophy than right ventricular hypertrophy.

Q-Wave Abnormalities. The 0.01-sec vector consists of the net result of almost simultaneous activation of the anterior left ventricle, posterior left ventricle, and left side of the septum. Therefore if any of these areas is hypertrophied the normal balance of forces may be upset and the initial portion of the QRS complex may change. The Q waves may vary independently from the R and S waves.

In left ventricular hypertrophy due either to a dilated left ventricle (aortic insufficiency or ventricular septal defect), septal hypertrophy (hypertrophic cardiomyopathy), or mild aortic stenosis, the initial forces may be increased in the right anterior-superior direction causing abnormally deep Q waves in the inferior and lateral leads (leads II, III, aVF, V_5, V_6).[30] The other causes for abnormally deep Q waves are discussed in the section on "Infarction."

In advanced concentric left ventricular hypertrophy with increased thickness of the posterior wall and septum, the QRS vector shifts to the left and posteriorly, causing the initial forces to be directed more to the left. This may cause the absence of a Q wave in lead V_6 (Fig. 45–29C). In children with aortic stenosis, an absent Q wave in lead V_6 was more than twice as common in those with a severe gradient than in those with a gradient less than 50 mm Hg.[24] Nonetheless, 53% of those with a gradient of at least 80 mm Hg had a 1- or 2-mm Q wave in lead V_6. The terms "volume overload" and "pressure overload" type of left ventricular hypertrophy have been associated with deep Q waves and absent Q waves, respectively.[30] Since there is so much overlap, I prefer not to use this terminology. Nonetheless, the absence of a Q wave or the presence of an abnormally deep Q wave may be supportive evidence of left ventricular hypertrophy.

Biventricular Hypertrophy

Abnormal Voltage in Both the Right and Left Chest Leads. In the presence of isolated hypertrophy of one ventricle, the forces reflecting the other normal ventricle usually appear diminished on the electrocardogram. For example, in isolated right ventricular hypertrophy with a tall R wave in lead V_1 and a deep S wave in lead V_6, the forces reflecting the left ventricle (S wave in lead V_1 or R wave in lead V_6) are usually diminished because of the dominance of the other ventricle. Thus biventricular hypertrophy can be diagnosed if in the presence of voltage criteria for hypertrophy of one ventricle the other ventricle generates at least normal forces. Therefore, one criterion for biventricular hypertrophy is right ventricular hypertrophy (abnormally tall R wave in lead V_1 or deep S wave in V_6) and either an S wave in lead V_1 or an R wave in lead V_6 exceeding the mean for age. (This criterion should not be applied in the same lead [i.e., if the diagnosis of right ventricular hypertrophy is made on the basis of a tall R wave in V_1, then biventricular hypertrophy must be based upon an additional tall R wave in V_6].) Another criterion is left ventricular hypertrophy (abnormally tall R wave in lead V_6 or deep S wave in lead V_1) and either an S wave in lead V_6 or an R wave in lead V_1 exceeding the mean for age (Figs. 45–30A and 45–30B). The same rule about two separate leads applies in left ventricular hypertrophy as was explained for right ventricular hypertrophy. Biventricular hypertrophy should not be diagnosed based on Q-wave or T-wave morphology.

Abnormal Voltage in the Midprecordial Leads. Prominent midprecordial voltage is a sign of biventricular hypertrophy. Katz and Wachtel originally described large biphasic QRS complexes in the limb leads of patients with congenital heart disease.[31] The Katz–Wachtel criterion has become broadened to refer to increased midprecordial voltage in patients with biventricular hypertrophy (Fig. 45–30C). In lead V_4, the voltage from the top of the R wave to the bottom of the S wave varies with age (Table 45–1). Biventricular hypertrophy can be diagnosed if the R wave plus the S wave exceeds the ninety-eighth percentile. The Katz–Wachtel criterion of increased midprecordial voltage may be inaccurate because of proximity effects enlarging the midprecordial QRS voltage or cancellation effects reducing the voltage. Usually, if any equiphasic complex has a total R and S more than 60 mm, the patient has biventricular hypertrophy.

Right Atrial Enlargement

Right atrial depolarization is responsible for the early part of the P wave and therefore when right atrial enlargement occurs, this is manifest in the first 0.04 to 0.06 sec of the P wave. The criteria described below may be used in diagnosis.

Increased Amplitude of the P Wave. The right atrium enlarges anteriorly and inferiorly, causing an enlarged P wave of normal duration. The increased early vector causes the P wave to appear peaked. If the P wave in any lead is greater than 2.5 mm in amplitude at any age, right atrial enlargement is diagnosed (Fig. 45–31A).[25,31] The right atrium may occasionally enlarge and wrap around the superior vena cava and inferior vena cava posteriorly as well as anteriorly. In this case, there is an early negative deflection in the first 0.04 to 0.06 sec, which is usually pointed (Fig. 45–31B). This negative deflection, by itself, is not a criterion for right atrial enlargement but needs to be distinguished from the more rounded late terminal negative deflection that is a criterion of left atrial enlargement. If the mean vector of the P wave is such that atrial depolarization is thought to originate from an area other than the sinus node, the electrocardiogram should not be interpreted as indicating atrial enlargement.

The electrocardiographic criteria of right atrial enlargement are related both to high right atrial pressure and high right atrial volume in children.[33] The presence of these changes immediately after an episode of supraventricular tachycardia or pulmonary embolism and their absence after several hours have elapsed implies that

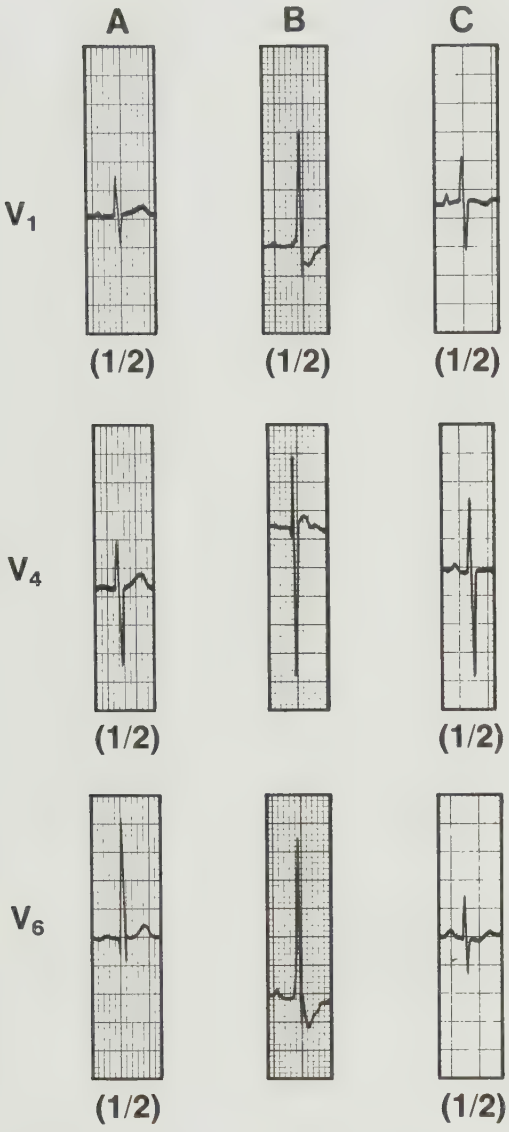

Fig. 45–30. Biventricular hypertrophy. (A) The wave in lead V_6 is 42 mm high. This meets the criterion for left ventricular hypertrophy. The R wave in lead V_1 is 15 mm high. This exceeds the mean voltage for the R wave in lead V_1 for this 1½ year old child, and therefore the diagnosis of biventricular hypertrophy is made. (B) The R wave in lead V_1 is 40 mm high. This meets the voltage criteria for right ventricular hypertrophy. The R wave in lead V_6 is 12 mm high. This exceeds the mean for the R wave in lead V_6 at 1 wk of age and so the diagnosis of biventricular hypertrophy is made. (C) The voltage in leads V_1 and V_6 are not distinctly abnormal for a 1-wk-old baby, however, the voltage in lead V_4 constitutes abnormally prominent midprecordial voltage, and the diagnosis of biventricular hypertrophy is made on this basis. This is the "Katz–Wachtel" criterion.

Fig. 45–31. Right atrial enlargement. Left: tall peaked P wave. Right: early (first 0.04 sec) pointed, negative deflection in lead V_1.

hemodynamics rather than hypertrophy are related to these changes.

Left Atrial Enlargement

Left atrial depolarization is responsible for the terminal portion of the T wave and therefore when left atrial enlargement occurs, this is manifest in the latter part of the P wave. The criteria described below may be used in diagnosis.

Increased Terminal Posterior Forces. The most reliable indicator of left atrial enlargement is a late negative deflection in lead V_1. This deflection begins later than 0.04 sec after the onset of the P wave. In children and adults, if the terminal deflection in lead V_1 is greater than 1 mm deep and greater than 0.04 sec in duration, this indicates left atrial enlargement (Fig. 45–32A).[34] As the left atrial enlargement gets more severe, the depth and duration of the terminal segment increase such that in the most severe left atrial enlargement in children, the mean depth of the P terminal segment in lead V_1 was 2.8 mm and the duration 0.08 sec.[35]

Increased terminal posterior forces are related more to left atrial volume than to pressure. As with the changes in right atrial en-

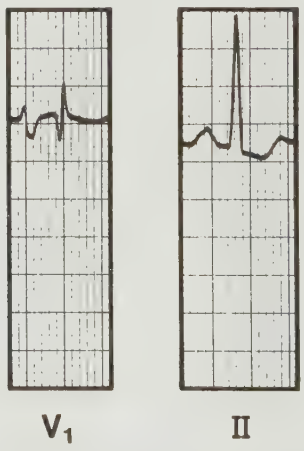

Fig. 45–32. Left atrial enlargement. Left: increased terminal negative deflection. The terminal portion of the P wave is 2.5 mm deep and 0.06 sec wide. Right: increased P-wave duration.

largement, the P waves may become abnormal with an abrupt increase in left atrial volume, such as acute mitral insufficiency, and then may return to normal shortly after the stress is removed, again implying that hypertrophy is not necessary for these changes. In general, the increase in P terminal forces is a specific sign of left atrial enlargement but there may be false negatives.[36] As with right atrial enlargement, if the pacemaker does not originate in the sinus node, left atrial enlargement should not be diagnosed on the basis of the electrocardiogram.

Increased P-Wave Duration. This is a more nonspecific sign either of left atrial enlargement or interatrial conduction delay, which may be found in damage to the atrial myocardium due to myocarditis, fibrosis, or ischemia.[37] An abnormal P-wave duration is defined as longer than 0.09 sec in children younger than age 3 and longer than 0.10 sec in children 3 yr of age or older (Fig. 45–32B). This sign, similar to the increased terminal negative deflection, indicates abnormality when present, but it is not sensitive enough to diagnose most cases of left atrial enlargement in children detected echocardiographically.[36]

Biatrial Enlargement

Since the right and left atria depolarize sequentially, causing different parts of the P wave, and since the signs of enlargement of one atrium do not distort the changes of enlargement in the other atrium, biatrial enlargement is diagnosed when the signs of right atrial enlargement coexist with the signs of left atrial enlargement.

Abnormal Voltage and Duration. If the first 0.04 sec of the P wave are taller than 2.5 mm and the P wave is either prolonged for age or has a late terminal deflection in lead V_1 that is greater than 1 mm deep and 0.04 sec in duration, the diagnosis is biatrial enlargement (Fig. 45–33).

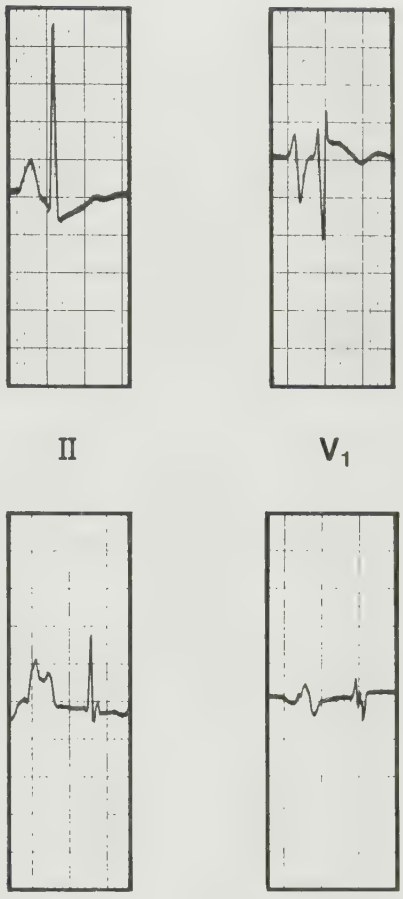

Fig. 45–33. Biatrial enlargement. Top tracings show P waves with increased positive amplitude in lead V_1 as well as a large terminal negative deflection in lead V_1. The P waves also have prolonged duration in addition to increased positive amplitude in lead II. Bottom tracings show P waves that are larger than the QRS complexes. The P wave is the first complex in each lead. The P wave in lead II begins with the sharp positive upstroke and is 6 mm tall. The P wave is 0.16 sec in duration. In lead V_1, there is also a large terminal negative deflection.

INTERVENTRICULAR CONDUCTION DISTURBANCE

Conduction through the ventricles can be disturbed either by delay or by preexcitation resulting in an abnormal sequence of ventricular activation.

Conduction Delay

Right Bundle Branch Block

Right bundle branch block results from delay in right ventricular activation. There is sequential activation of the right ventricle after activation of the left ventricle, rather than simultaneous activation. The conduction delay can occur in the distal His bundle in fibers destined for the right bundle branch, or it may occur in the main portion of the right bundle branch. The pattern is of delayed, slurred activation oriented anteriorly and rightward.[38] It has recently been questioned whether interruption of the peripheral ramifications of the right bundle branch cause the same electrocardiographic pattern.

Complete Right Bundle Branch Block. The QRS pattern is most important for the diagnosis of complete right bundle branch block. There is an initial rapid deflection, followed by a slurred, slower terminal deflection. In lead V_1, the rapid component consists of an R wave and an S wave of varying magnitudes followed by a slurred tall R wave. There may be no S wave, resulting in an RR′ complex (Fig. 45–34). In leads I and V_6, the late slurred terminal deflection causes a broad S wave.

This pattern can be quantified such that the mean duration of the "fast" component (RS of the RSR′) is 0.038 sec in adults, and the time from the end of the fast component to the peak of the R′ is 0.061 sec. Essentially, in lead V_1 the R′ is twice the width of the RS, or in lead V_6, the S wave is twice the width of the R wave. This pattern of discrepancy between the initial and terminal components is a more reliable sign of complete right bundle branch block than the exact duration of the total QRS complex, especially since 0.01 sec or even 0.02 sec may be difficult to measure accurately. The criteria for complete right bundle branch block are QRS duration prolonged for age (greater than 0.09 sec up to the age of 4 yr and over 0.10 sec for 4 yr to 16 yr), normal initial forces (first 0.04 sec), and terminal conduction delay directed anteriorly and to the right.

The axis in complete right bundle branch block considers the frontal plane QRS axis calculated based upon the "fast" initial portion of the complex. Generally, this is the first 0.04 msec; but, the initial rapid portion before the "break" to the terminal slow

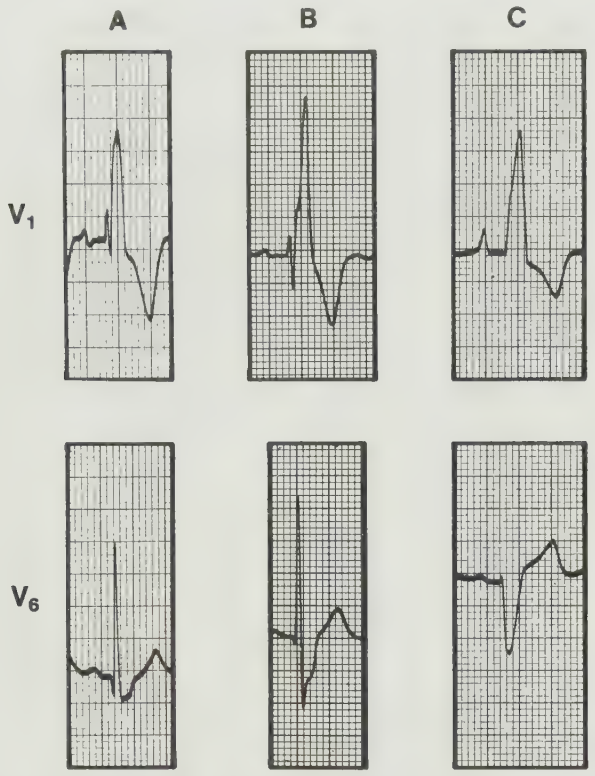

Fig. 45–34. Variations of complete right bundle branch block. In the tracings on the left (A), there is a large R wave and a small S wave; in the tracings in the middle (B), there is a mall R wave and a deeper S wave; and in the tracings on the right (C), there is an R wave without an S wave. The latter part of all three complexes has a slurred component, which is the R′ wave. All three tracings have broad terminal S waves in lead V_6.

portion should be used, regardless of the specific timing. If the frontal-plane axis of the initial "unblocked" portion is between −30° and −90°, this is considered to be left-axis deviation in addition to complete right bundle branch block. This distinction is important in the diagnosis of bifascicular block and will be discussed further in that section.

Attempts have been made to use the axis, as well as the absolute height and proportions of the R, S, and R′ components to diagnose hypertrophy in the presence of complete right bundle branch block. The correlation of these parameters with the ventricular pressure or free wall thickness is insufficient to permit the diagnosis of either right ventricular or left ventricular hypertrophy in the presence of complete right bundle branch block.[39,40] The T-wave changes in complete right bundle branch block are secondary to the abnormal sequence of depolarization.

The most common cause of complete right bundle branch block is surgery involving closure of a ventricular septal defect. Congenital complete right bundle branch block is rare in children, but may occur with autosomal dominant inheritance. Isolated congenital complete right bundle branch block does not appear to progress to further conduction disturbances.[41,42] Complete right bundle branch block may also be a manifestation of inflammation from myocarditis or endocarditis and may progress to complete atrioventricular block.[38] In normal children, functional right bundle branch block or left bundle branch block may occur because of ventricular aberration of a supraventricular rhythm. However, rate-dependent bundle branch block is extremely rare in children and occurred in only 2% of children reported with supraventricular tachycardia.[43]

"Incomplete Right Bundle Branch Block" Pattern. The RSR′ pattern in lead V_1, in which the duration of R′ is approximately equal to the duration of the RS wave (i.e., no terminal conduction delay) has been referred to as the "incomplete right bundle branch block" pattern (Fig. 45–35). The duration of the QRS complex may be normal or slightly prolonged for age (up to 0.09 sec under the age of 4 yr or 0.10 sec from 4 to 16 yr). Approximately 7% of normal children over the age of 6 mo have this pattern.[6] The only major pathologic cause of an incomplete right bundle branch block pattern in childhood is right ventricular diastolic volume overload, and this is found in 93% of children with a secundum atrial septal defect. In children with atrial septal defect, it has been demonstrated that the central right bundle conduction time is normal, therefore implying that the pattern is due to more peripheral factors.[44] This pattern of terminal activation directed anteriorly and rightward is currently explained either by selective hypertrophy of the right ventricular outflow tract or by stretching of the peripheral specialized conduction fibers due to distention of the right ventricular outflow tract.[45] Numerous attempts have been made to distinguish normal children from those with atrial septal defect and among those with atrial septal defect to predict the size of the shunt or right ventricular pressure. These attempts have been unsuccessful, with a few general exceptions. In atrial septal defects, the R′ wave tends to be slightly wider than normal; in children with an atrial septal defect with a small shunt, there is a deep S wave as compared with those with larger shunts or high pulmonary pressure, where both the R and R′ waves become taller and the S wave disappears. Specifically, atrial septal defect was more common in those less than 1 yr of age if the R′ wave was greater than 15 mm and in those older than 1 yr if the R′ was greater than 10 mm.[46,47] Despite these generalities, it may be im-

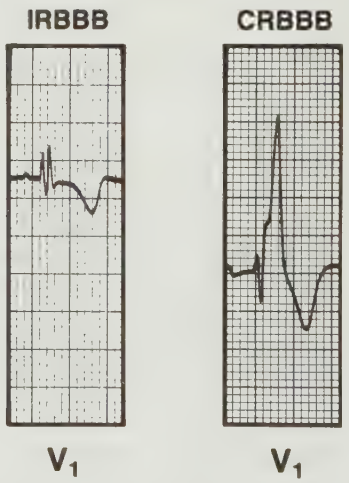

Fig. 45–35. Distinction of "incomplete" from "complete" right bundle branch block. Left: normal duration RSR′ complex. There is no break. The duration of the R wave and R′ wave are almost the same. This is the incomplete right bundle branch block pattern. Right: In the complete right bundle branch block pattern, there is a definite break and the R′ is three times the duration of the R wave.

possible to distinguish normal from atrial septal defect on the electrocardiogram in an individual patient.[48]

Left Bundle Branch Block

Complete Left Bundle Branch Block. Complete left bundle branch block results from delay in left ventricular activation. Since fibers of the left bundle branch initiate normal ventricular depolarization, if there is delay in left bundle branch conduction, the entire QRS complex is aberrant. This is different from the situation in right bundle branch block in which only the terminal portion is aberrant. In left bundle branch block, the right ventricle is activated first; therefore the normal initial vector, due to left to right septal spread, is absent. The slow activation of the left ventricle occurs from the right ventricle and the resultant slurred QRS complex is directed to the left, posteriorly and superiorly. The criteria for complete left bundle branch block are abnormally wide QRS complex (greater than 0.09 sec at under 4 yr of age, or greater than 0.10 sec from 4 to 16 yr), absent normal initial forces (absent Q wave in leads I, aVL, and V_6), and notched, slurred QRS complexes directed leftward and posterior (in lead V_1 a QS or small R–deep S, and in lead V_6 a tall, notched R wave) (Fig. 45–36). The T waves in complete left bundle branch block are approximately 180° discordant from the QRS complex for the same reasons as in complete right bundle branch block.

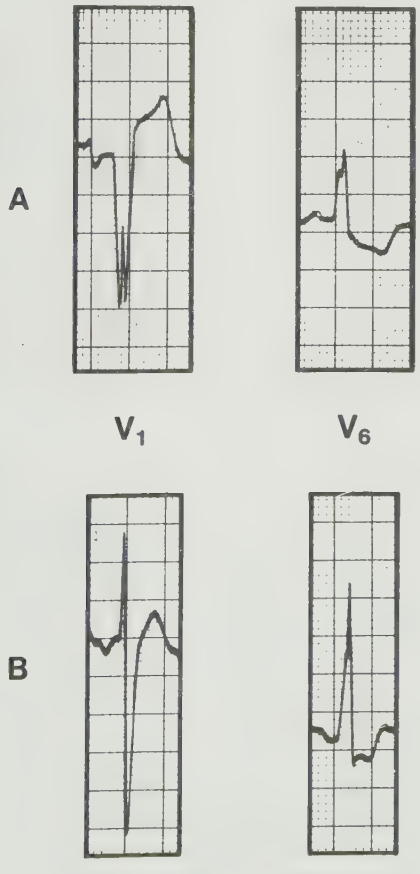

Fig. 45–36. Variations of complete left bundle branch block. In the top tracings (A), there is a QS pattern in lead V_1, and in the bottom tracings (B) there is an RS pattern in lead V_1. In lead V_6, both tracings are similar and marked by the absence of a Q wave.

The frontal-plane QRS axis in complete left bundle branch block is calculated based on the major deflection of the QRS complex. If the initial and terminal parts have different vectors, the terminal part of the complex should be used. Adults with left bundle branch block and left-axis deviation are more likely to develop complete atrioventricular block than those without left-axis deviation.[49] These data are not available for children.

Left bundle branch block is rare in children. The most common cause is surgery on the aortic valve or subvalve area. It may occur as a result of myocarditis, endocarditis, hypertrophic cardiomyopathy, or myocardial infarction.[38]

"Incomplete Left Bundle Branch Block" Pattern. Left ventricular hypertrophy may cause delayed left ventricular activation or stretching of the Purkinje fibers and produce a pattern of "incomplete left bundle branch block." The QRS duration may be normal or prolonged by 0.01 sec for age. There are absent Q waves and tall slurred R waves in leads I and V_6 (Fig. 45–37). On surface electrocardiograms, it is not possible to distinguish patients with incomplete left bundle branch block on the basis of left ventricular hypertrophy from those with mild conduction system disease.

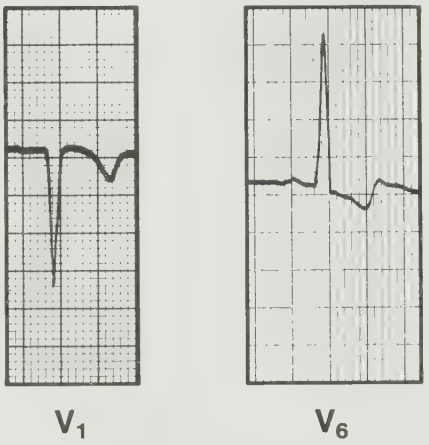

Fig. 45–37. Incomplete left bundle branch block pattern. There is an absent Q wave in lead V_6 and a normal QRS duration for this 11-yr-old child, and no R wave in lead V_1.

Fascicular Block

Although the anatomic correlation is not exact, there are patterns on the surface electrocardiogram that correspond to lesions in the anterior and posterior fascicles of the left bundle branch and these patterns are called left anterior hemiblock and left posterior hemiblock, respectively.

Left Anterior Hemiblock. The pattern of left anterior hemiblock results from asynchronous left ventricular activation where the posterior-inferior wall is activated before the anterior-superior wall, and there are two sequential vectors. The "earlier" activation of the posterior-inferior diaphragmatic surface of the left ventricle is directed inferiorly and slightly to the right at +120° in the frontal plane. The "later" activation occurs in the opposite direction when the anterior-superior wall is activated at −60° in the frontal plane (Fig. 45–38). The QRS duration is prolonged by less than 0.02 sec in pure left anterior hemiblock because part of the left ventricle is activated normally, and spread to the rest of the

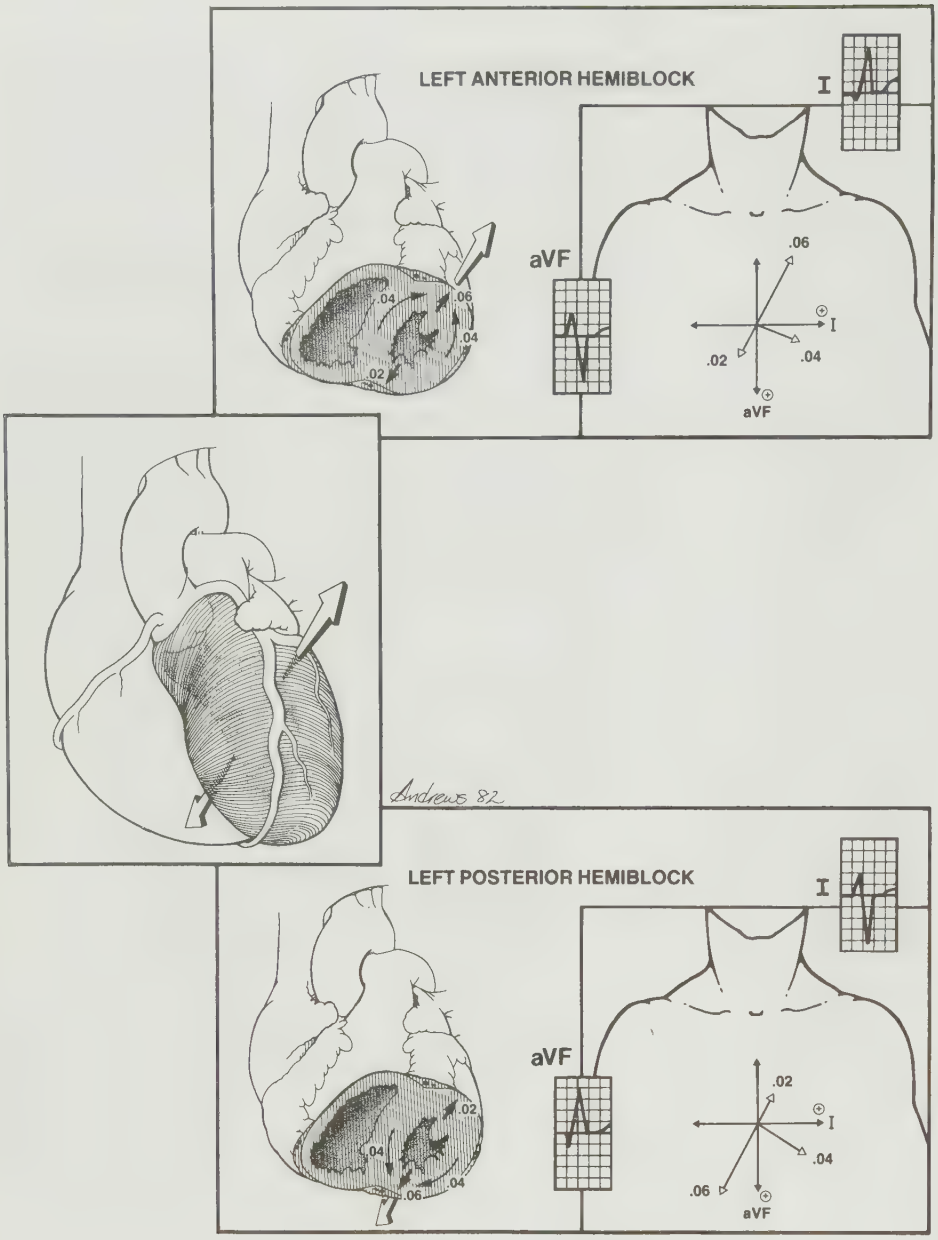

Fig. 45–38. Comparison of activation in left anterior hemiblock and left posterior hemiblock. (A) Left anterior hemiblock. The initial 0.02-sec vector is directed at +120° and the terminal 0.06-sec vector is directed at −60°. This causes an initial Q wave in lead I and a deep S wave in lead aVF. A coronal section through the heart is shown with the posterior-inferior wall activated before the anterior-superior wall. The mean QRS vector is directed superiorly as shown by the large arrow in the top diagram. (B) Left posterior hemiblock. The initial 0.02-sec vector is directed at −60° and the terminal 0.06-sec vector is directed at +120°. This causes a Q wave in lead aVF and a deep S wave in lead I. The anterior-superior wall is activated before the posterior-inferior wall. The mean QRS vector in the frontal plane is directed at +120° as shown by the large arrow in the bottom diagram. The orientation of the posteroinferior and anterosuperior walls are shown in the middle diagram.

left ventricle occurs relatively rapidly through the endocardium. The criteria for left anterior hemiblock are initial forces directed inferiorly and slightly to the right at +120°, major QRS forces directed superiorly and leftward (Left-axis deviation resulting from a horizontal heart position may give a QRS axis of −30°; therefore for the diagnosis of left anterior hemiblock, the frontal plane QRS axis must be to the left of −30°, i.e., negative in lead II; in most children with left anterior hemiblock, the QRS axis is −60°); and normal or minimally prolonged QRS duration (Fig. 45–39A). The T waves in left anterior hemiblock are normal.

In children, the most common cause of the left anterior hemiblock pattern is congenital heart disease. This may be due either to elongation of the left anterior fibers, to shortening of the left posterior fibers, or to a different orientation of the conduction system, such that the posterior left ventricular wall is activated before other parts of the heart.[50] These mechanisms may explain the left-axis deviation found in endocardial cushion defects (including ostium primum atrial septal defect, atrioventricular canal, and single atrium), single ventricle, and double-outlet right ventricle. Recent observations on tricuspid atresia suggest a different mechanism.[51] The activation times of the proximal left anterior and posterior fascicles were found to be normal, and it has been postulated that in tricuspid atresia, selective hypertrophy of the basal anterolateral left ventricle is responsible for sufficient conduction delay to cause the pattern of left anterior hemiblock on the surface electrocardiogram.[52] In anomalous left coronary artery, the left-axis deviation frequently observed may also be due to selective hypertrophy of noninfarcted superior portions of the left ventricle. This mechanism may also account for the occasional left-axis deviation found in aortic stenosis, aortic insufficiency, or cardiomyopathy. Isolated injury to the left anterior fascicle resulting in left anterior hemiblock from myocarditis has been

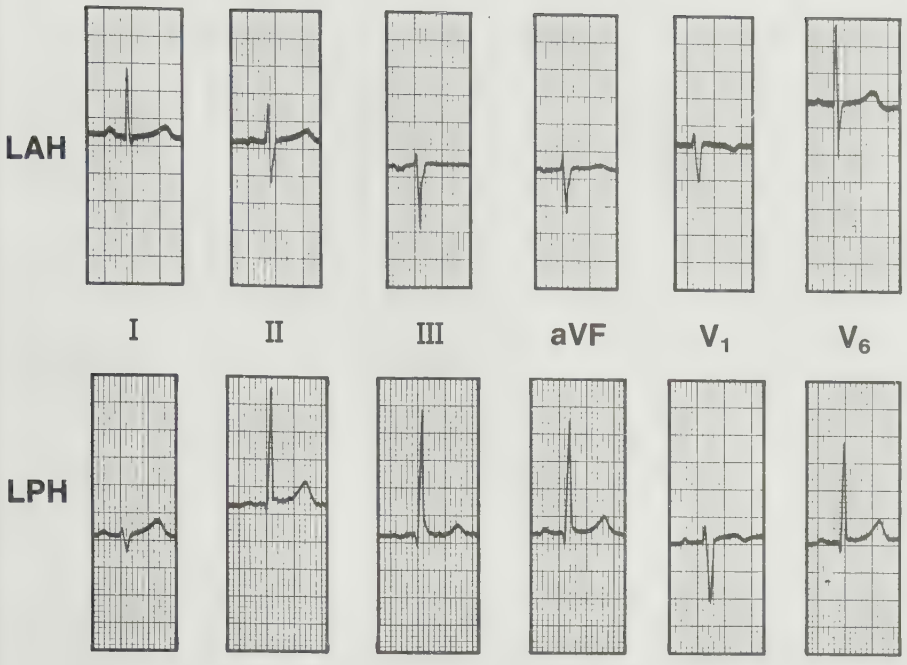

Fig. 45–39. Comparison of the electrocardiograms of left anterior hemiblock (top) and left posterior hemiblock (bottom). Note the absence of right ventricular hypertrophy in this 15-yr-old with left posterior hemiblock.

postulated as the cause of the left-axis deviation observed in up to 50% of infants with the rubella syndrome. Left anterior hemiblock may also result from myocardial infarction, ventricular septal myectomy, aortic valve surgery, or subvalvar aortic resection. Usually in closure of a ventricular septal defect, the left anterior hemiblock is accompanied by right bundle branch block (see section on "Bifascicular Block"). Left anterior hemiblock may rarely be familial and occur in otherwise normal children.[42]

Left Posterior Hemiblock. The activation sequence in left posterior hemiblock is exactly the opposite of that found in left anterior hemiblock (see Fig. 45–38B). The anterior-superior wall is activated first with a frontal plane QRS axis of $-60°$ and the posterior-inferior wall is activated last with a frontal plane QRS axis of $+120°$. The criteria for left posterior hemiblock are initial forces directed superiorly (Q waves in leads II, III, and aVF), major frontal-plane QRS forces directed inferiorly and rightward with an axis of $+90°$ to $+180°$, and normal or minimally prolonged QRS duration (Fig. 45–39B). This constitutes a normal electrocardiogram in most children and so left posterior hemiblock is difficult to diagnose. Left posterior hemiblock can be diagnosed if the frontal-plane QRS axis is between $+120°$ and $180°$ in a child over the age of 1 yr who does not have right ventricular hypertrophy or right atrial enlargement (i.e., another reason for right-axis deviation). Left posterior hemiblock is quite rare in children and has been diagnosed mainly in cases due to surgical trauma, myocarditis, or endocarditis.[53]

Bifascicular Block

Considering the trifascicular conduction system as the left anterior fascicle, left posterior fascicle, and right bundle branch, bifascicular block is blockage in any two of the three fascicles. In the strict sense of the term, complete left bundle branch block is a form of bifascicular block. The combination of right bundle branch and left posterior hemiblock is practically never diagnosed in children because the right bundle branch block is most often the result of an operation on a lesion with preexistent right ventricular hypertrophy and right-axis deviation. Therefore, in children, the term bifascicular block is almost synonymous with right bundle branch block plus left anterior hemiblock.

Right Bundle Branch Block–Left Anterior Hemiblock Pattern. Left anterior hemiblock changes the first "fast" part of the QRS complex and right bundle branch block changes the terminal "slow" part. The criteria are initial forces (first 0.02 sec) directed inferiorly and rightward at $+120°$ in the frontal plane giving a Q wave in lead aVL and possibly lead I, major axis of the "unblocked" initial part of the QRS complex to the left of $-30°$ giving a dominant S wave in the initial part of lead II and possibly leads V_5 and V_6, and slurred terminal portion of right bundle branch block directed to the right (Fig. 45–40).

The most common cause of right bundle branch block and left anterior hemiblock in children is surgery for tetralogy of Fallot, and occurs in approximately 10% of such patients.[54] This pattern may also occur in any injury to the area of the distal His bundle or proximal right bundle branch, since the right bundle branch and left anterior fascicle lie in such close proximity. This pattern may also be seen after other intracardiac operations involving surgery near the atrioventricular junction, or it may be found in myocarditis, cardiomyopathy, and endocarditis. Familial bifascicular block occurs and may progress to complete atrioventricular block.[55]

Trifascicular Block

Trifascicular block is defined as delay in all three fascicles. It can only be diagnosed by intracardiac electrograms as a prolonged H–V interval, and cannot be diagnosed on the surface electrocardiogram. The combination of right bundle branch block, left anterior hemiblock, and first-degree atrioventricular block has been erroneously termed trifascicular block. This combination has many different possible causes. Most children with this pattern have atrioventricular nodal delay and bifascicular block with a normal H–V interval.[56,57]

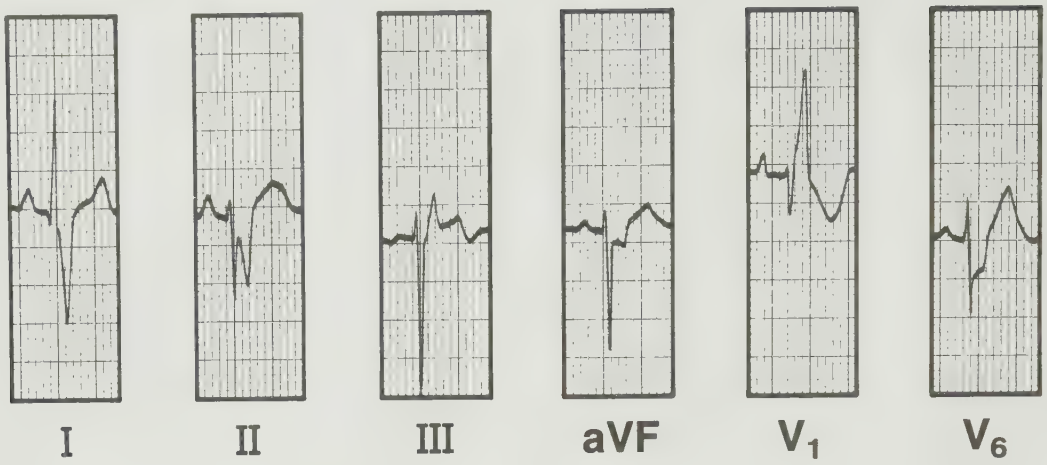

Fig. 45–40. Right bundle branch block with left-axis deviation.

Interventricular Conduction Delay

The QRS complex is prolonged for age but has no specific pattern of right bundle branch block or left bundle branch block. This may be found in children with quinidine or procainamide toxicity, myocarditis, hypoglycemia, myocardial ischemia, or hyperkalemia (Fig. 45–41).[58]

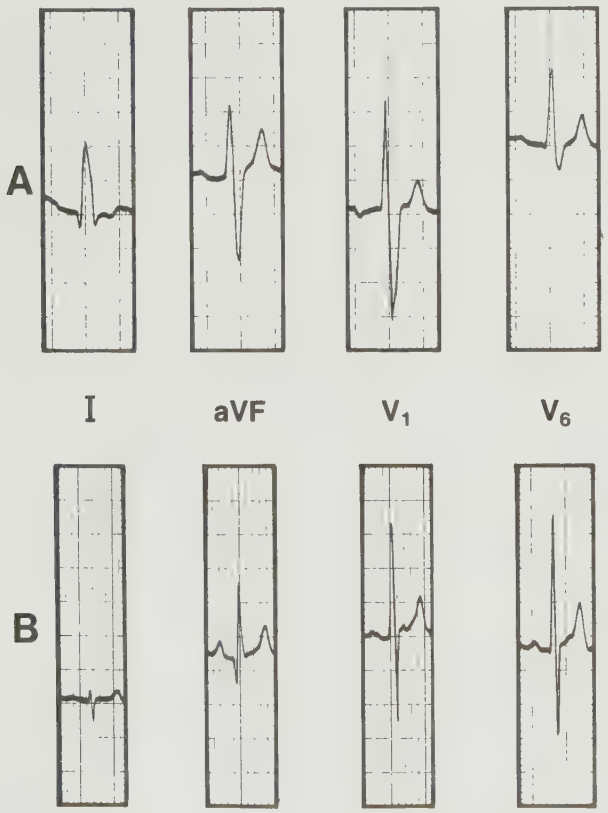

Fig. 45–41. Interventricular conduction delay. Top tracings taken from a 1-mo-old child with renal failure who was hyperkalemic. The bottom tracings were taken from the same child after dialysis. The QRS complexes are similar in comparison of the same leads but they have a prolonged duration in the top tracings.

Preexcitation

Preexcitation is defined as an abnormally rapid transit of the wave of depolarization from atria to ventricles. In most cases of preexcitation, the ventricles are activated asymmetrically from a point other than the bundle of His, in addition to being activated via the normal conduction system. Since atrioventricular conduction can occur by two possible pathways, usually with different properties, one of the possible consequences of preexcitation is reciprocating supraventricular tachycardia.

Wolff-Parkinson-White Syndrome

Wolff, Parkinson and White first described the syndrome of short P–R interval with a prolonged QRS duration in 1930.[59] It has since been demonstrated that the cause of this pattern is a direct muscular connection between the atria and the ventricles: "a Kent bundle" or "accessory atrioventricular connection." The accessory connection runs perpendicular to the atrioventricular ring and can be located anywhere around either valve orifice except the point of fibrous continuity between the mitral and aortic valves. Most Kent bundles conduct much faster than the atrioventricular node, so the atrial depolarization is transmitted to the ventricles prematurely, resulting in a short P–R interval. The ventricles than begin to depolarize from the point of insertion of the accessory connection. If there was no atrioventricular nodal conduction and the ventricles were completely excited by the accessory connection, the QRS complex would appear similar to a premature ventricular contraction that originated at the site of insertion of the accessory connection. However, in the majority of cases, the atrioventricular node also conducts the impulse from atria to ventricles, and the depolarization wave resulting from the accessory connection and the atrioventricular node collide in the ventricles causing a "fusion" QRS complex (Fig. 45–42). The characteristics of this complex are that the beginning is more slurred (resulting from eccentric slow ventricular activation by the accessory connection) and the end of the complex is more normal (resulting from normal ventricular activation via the His bundle and bundle branches). In any individual child, the amount of the ventricles activated via the Kent bundle and the His bundle can vary from day to day; this accounts for our observation that one third of children with

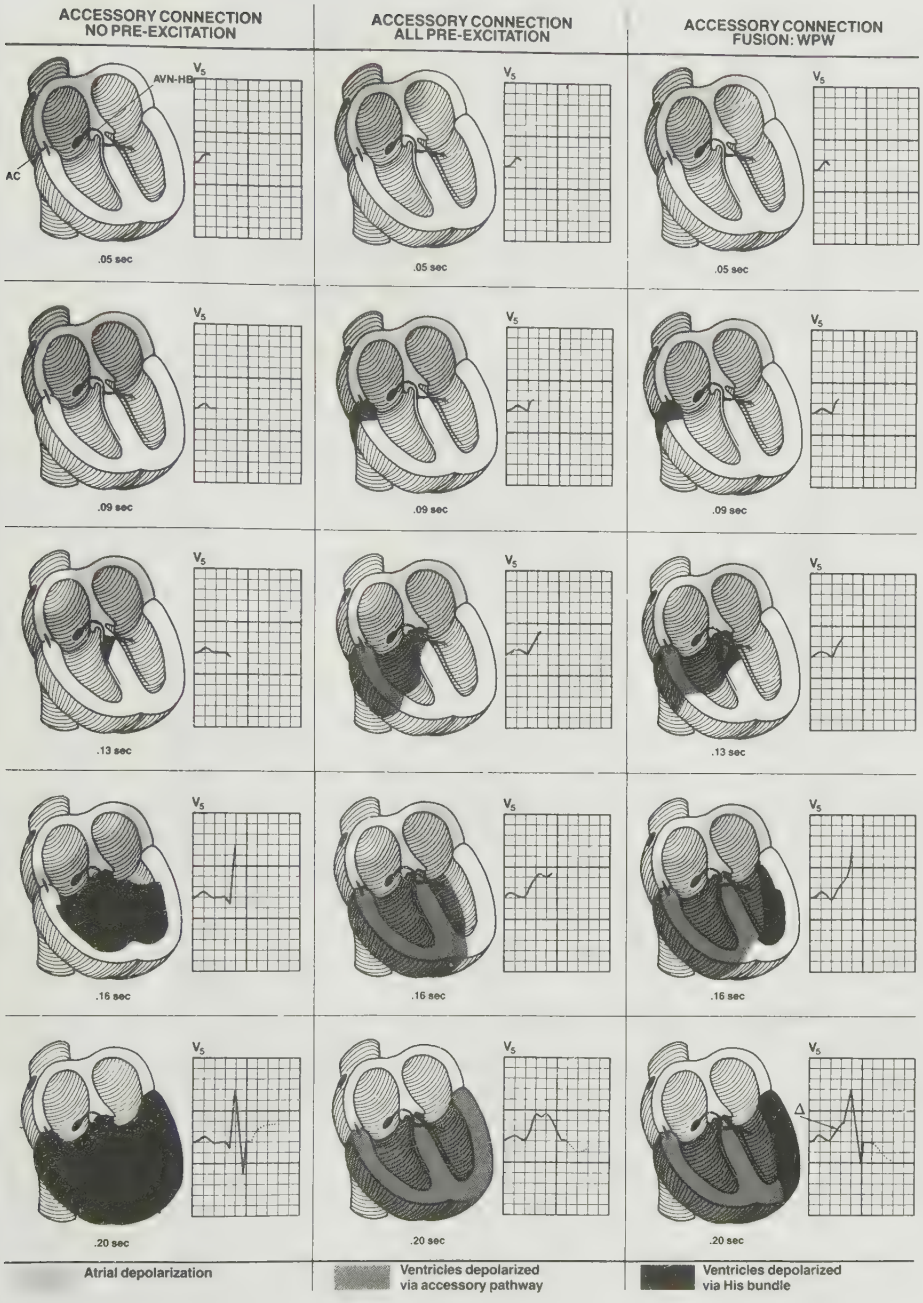

Fig. 45–42. Wolff-Parkinson-White syndrome with varying degrees of conduction through the accessory connection and the atrioventricular node. The numbers refer to timing after the onset of the P wave. The left column of diagrams indicates the activation sequence in the patient with an accessory connection who is not conducting through the accessory connection but entirely through the atrioventricular node. Note the normal P–R interval, the Q wave, and the lack of a delta wave. In the middle column, the activation sequence of a patient who is conducting entirely through the accessory connection are shown. Note the short P–R interval and the wide QRS complex. There is no real "delta" wave because the entire QRS complex is wide. In the right column, the usual situation of Wolff-Parkinson-White syndrome is shown, in which there is a "fusion" complex resulting from conduction through both the accessory connection and the atrioventricular node. The parts of the ventricles activated through the atrioventricular node are shaded differently in the diagrams from those activated by the accessory connection. Note that there is a short P–R interval and a delta wave (indicated by the "delta" at 0.16 sec in the right column of diagrams). The delta wave occurs because there is fusion of the completely wide QRS with the completely narrow QRS, causing an abrupt change in slope.

Wolff-Parkinson-White syndrome had at least one electrocardiogram without any preexcitation (normal P–R interval and normal QRS complex), which was later followed by the reappearance of Wolff-Parkinson-White syndrome.

The criteria for Wolff-Parkinson-White syndrome are short P–R interval for age (see Table 45–1), and a QRS complex with initial slurring—the "delta wave." All electrocardiographic leads may not show a short P–R interval and delta wave if the vector of the delta wave is perpendicular to that lead (see Fig. 45–6). Rosenbaum classified the Wolff-Parkinson-White pattern on surface electrocardiograms into types A and B in an attempt to predict localization of the Kent bundle.[60] In type A, the major QRS deflection is positive in lead V_1, predicting a left lateral accessory connection (Fig. 45–43A). This simulates right bundle branch block, but the two can be distinguished, since the initial forces in Wolff-Parkinson-White syndrome are slow in comparison to the rapid initial forces in right bundle branch block. In type B, the major QRS deflection is negative in V_1, predicting a right-sided accessory connection (Fig. 45–43B). This simulates left bundle branch block, except that usually Wolff-Parkinson-White syndrome has normal terminal forces. Despite the general helpfulness of this classification scheme, we have not found that the exact site of the accessory connection can be predicted from the 15-lead surface electrocardiogram. Since Wolff-Parkinson-White syn-

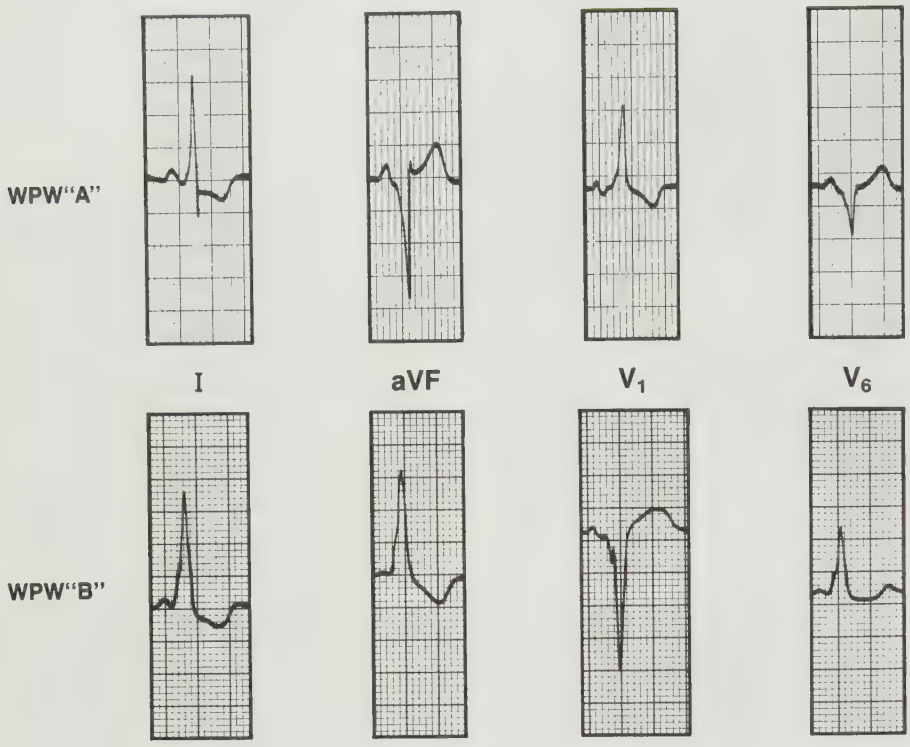

Fig. 45–43. Wolff-Parkinson-White syndrome. (A) Rosenbaum "type A." (B) Rosenbaum "type B."

drome is more common in children than left bundle branch block, in any child with a pattern similar to left bundle branch block, the P–R interval should be measured carefully.

Lown-Ganong-Levine Syndrome

Lown, Gangong, and Levine described the syndrome of short P–R interval without a delta wave in sinus rhythm in 1952.[61] All their cases had associated supraventricular tachycardia. Although it does not cause interventricular conduction disturbance, we have included Lown-Ganong-Levine syndrome in this section because by our definition it results in ventricular preexcitation (Fig. 45–44). Lown-Ganong-Levine syndrome should probably not be diagnosed in the absence of supraventricular tachycardia, since a short P–R interval may be found in normal children without a predisposition to supraventricular tachycardia.[62]

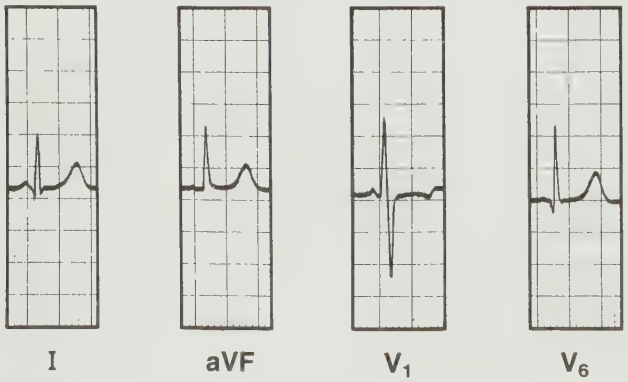

Fig. 45–44. Lown-Ganong-Levine syndrome. The P–R interval is short and the QRS complex is normal in all leads.

Short PR intervals are also observed in mannosidosis, Fabry's disease, and Pompe's disease.[63,66] All these diseases may have in common an increase in cell size in the atrioventricular node; this may be related to rapid atrioventricular nodal conduction.[64] Patients with these diseases do not appear to be at risk for supraventricular tachycardia.

Mahaim Conduction

Mahaim and Benatt first described muscular connections between the His bundle and ventricular septum in 1938.[67] The definition of a Mahaim fiber has been broadened to include a fiber that originates in the atrioventricular node, His bundle, or proximal bundle branch and inserts in the ventricular muscle. This is a "bundle branch bypass" tract and results in preexcitation. Usually, the bundle inserts into the right ventricle, giving a left bundle branch block morphology to the QRS complex.[68] As conduction can also occur via the normal pathway (His bundle and bundle branches) and through the Mahaim fiber, there may be a fusion QRS complex similar to that seen in Wolff-Parkinson-White syndrome. In many cases, the QRS complex is normal in sinus rhythm. However, with a Mahaim fiber, the P–R interval is normal (Figs. 45–45 and 45–46). Since two pathways exist with different properties, reciprocating supraventricular tachycardia can occur with a left bundle branch block morphology due to antegrade activation via the Mahaim fiber.

ISCHEMIA, INJURY, AND INFARCTION

The major changes that occur with ischemia, injury, and early infarction involve the T waves and ST segments.

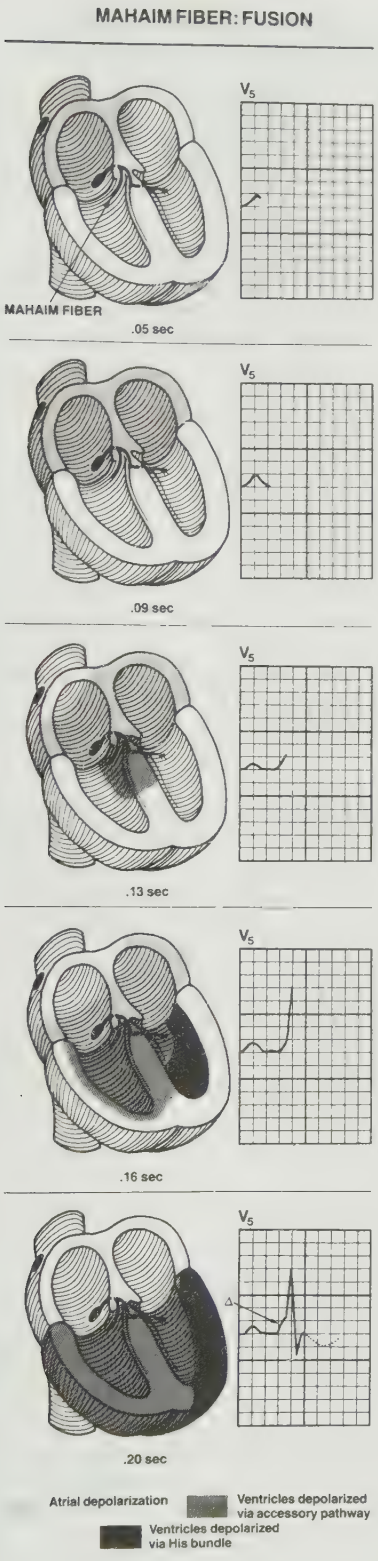

Fig. 45–45. Mahaim conduction. Interventricular conduction is shown for a Mahaim fiber. The P–R interval is normal and there may be a delta wave resulting from fusion of the impulse passing through both the Mahaim fiber and the atrioventricular node.

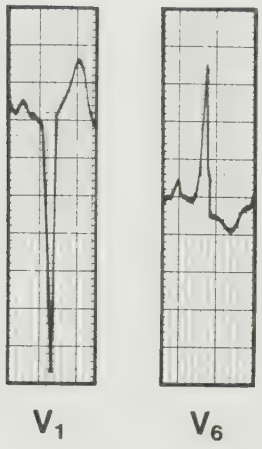

Fig. 45–46. Mahaim conduction. The P–R interval is normal and there is a delta wave in lead V_6. The morphology of this complex is similar to left bundle branch block.

Primary and Secondary T-Wave Changes

Primary T-wave changes occur when repolarization is affected, independent of changes in depolarization. These may occur either with uniform alteration in the shape or duration of all action potentials without a change in the sequence of depolarization (e.g., hyperkalemia), or with nonuniform changes in the shape or duration of the action potentials in different parts of the ventricle, resulting in an altered sequence of repolarization (e.g., localized ischemia). The majority of the primary T-wave changes occur with ischemia or other systemic alterations that have an effect on the heart.

Secondary T-wave changes occur when altered repolarization is caused by an abnormal sequence of depolarization. In children, these are much more common than primary changes and occur in such conditions as bundle branch block, preexcitation and hypertrophy. Frequently, a secondary T-wave change is mistaken for a primary change because the minor QRS abnormality responsible for the secondary change is not recognized. Minor changes in the duration and shape of the QRS complex, especially in the terminal portion, may be responsible for significant secondary T-wave changes. Therefore, before assigning a T-wave change to the primary category, it is important to be sure the changes cannot be explained by an abnormal QRS complex.[4]

Functional T-Wave Changes

The majority of these changes appear to have a link to the sympathetic nervous system. Fear and anxiety are known to cause inverted T waves without a change in coronary blood flow.[69] Sympathetic mechanisms are thought to be responsible for the T-wave changes in hyperventilation. Ten percent of teenagers had inverted T wave in at least one chest lead after 10 to 15 sec of hyperventilation and 70% had inverted T waves after 45 sec.[70] The degree of alkalosis or hypocarbia could not be related to the T-wave changes. Orthostatic T-wave changes have been described in the inferior leads in 3% of normal adults who stand up after lying down for several minutes.[4] It is not known whether the postural change is due to catecholamines or a physical shift of the heart. Approximately 4% of normal adults develop flat or inverted T waves in several leads within 30 min of eating a high-carbohydrate

meal or drinking a high-concentration glucose solution. If a child has flat or inverted T waves without a known cause, the electrocardiogram might be repeated in the postabsorptive state.[8]

There are two other functional changes that are most common in adolescence. The "early repolarization syndrome" is recognized by J-point elevation in several leads and may mimic true ST elevation. Usually, the T waves in early repolarization are very large. This pattern is due to the early appearance of the T wave while the ventricles are still depolarizing.[71] This eliminates the ST segment. Sympathetic stimulation either by exercise or isoproterenol infusion generally normalizes the J-point elevation (Fig. 45–47). Alternatively, in the asymptomatic patient, one can wait for several days and check another electrocardiogram. In early repolarization, the J-point elevation is persistent, whereas in pericarditis, the other common cause of elevated ST segments in children, the changes evolve.

The second functional T-wave change found in adolescence is the isolated inverted T wave in a midprecordial lead with an upright T wave in the leads on either side. This occurs in 1% of adolescents and has no pathologic correlate.[69] In general, benign T-wave changes are labile.[72]

Ischemia

Myocardial ischemia is manifest electrocardiographically by distortion of the T-wave amplitude, configuration, and axis. The first area to become ischemic in the heart is generally the subendocardium, and in cases of subendocardial ischemia, the T wave points toward the normal epicardial tissue overlying the ischemic area. In subendocardial ischemia, the T waves are symmetrical and peaked, with an increase in amplitude and duration in the leads overlying the ischemic area. In subepicardial ischemia, the T waves are inverted, overlying the ischemic area. In transmural ischemia the T waves are inverted, overlying an area of transmural ischemia.

Myocardial ischemia is rare in children. It can occur in the early stages of reduced coronary blood flow from neonatal stress, anomalous left coronary artery, or mucocutaneous lymph node syndrome (Kawasaki's disease) before infarction occurs. Subendocardial ischemia may occur in children with aortic stenosis or pulmonary stenosis. The flattened or inverted T waves that accompany rapid sinus tachycardia or supraventricular tachycardia may be due to ischemia but they may also be secondary T-wave changes attributable to minor degrees of ventricular aberration obscured by the rapid rate. The persistence of these T-wave changes up to days after the event may be related to potassium loss with slow replenishment of metabolic stores.[71] In 10% of children with mitral valve prolapse, there is T-wave inversion in the inferior and lateral leads. These changes may be explained either by the presence of small ischemic areas due to traction interfering with the vascular supply or by uneven repolarization.[8] Other changes with mitral prolapse include a prolonged Q–T interval and prominent U waves.[73]

In pure left ventricular hypertrophy, the usual electrocardiographic pattern is an increase in the T-wave amplitude; in advanced left ventricular hypertrophy, there is ST depression with inverted T waves—the "strain" pattern.[74] Thus "strain" is different from subendocardial ischemia, in which there is ST depression and upright or flat T waves. It has been suggested that "strain" is a primary T-wave abnormality, is due to a difference in endocardial and epicardial conduction times, and has a different mechanism from ischemia.[75] Alternatively, the ST–T-wave changes observed in hypertrophy and strain may be simply more severe changes in a spectrum from subendocardial to transmural ischemia.

Injury

Myocardial injury is evidenced electrocardiographically both by deviations from the base line and changes in the contour of the ST segment. In subepicardial injury, an electrode immediately over the area of injury shows ST elevation. In subendocardial injury the electrode immediately over this area shows ST depression. Thus, with injury, the ST segment is displaced toward the injured surface. When the ST segment is elevated, the contour may be either upwardly convex or concave; with ST depression, the contour is usually concave or flat. In children, injury patterns that are not due to systemic alterations are found most frequently in pericarditis and ischemic episodes.

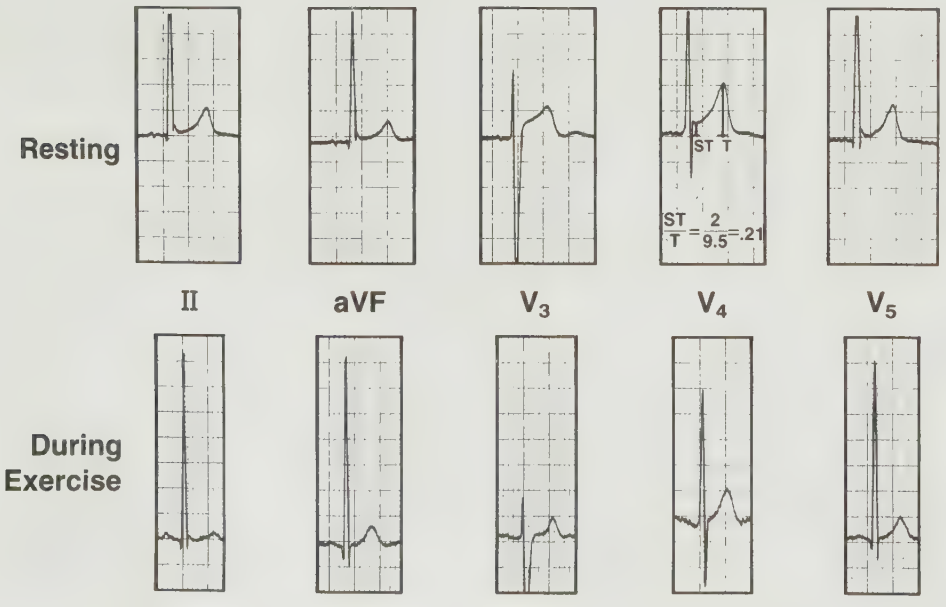

Fig. 45–47. Early-repolarization syndrome. In the resting electrocardiogram shown at the top, there is J-point elevation in the inferior and lateral leads. In this patient, leads I and aVL were normal. There was 1 mm of J-point depression in aVR. After 6 min of treadmill exercise, the bottom tracings were taken, showing normalization.

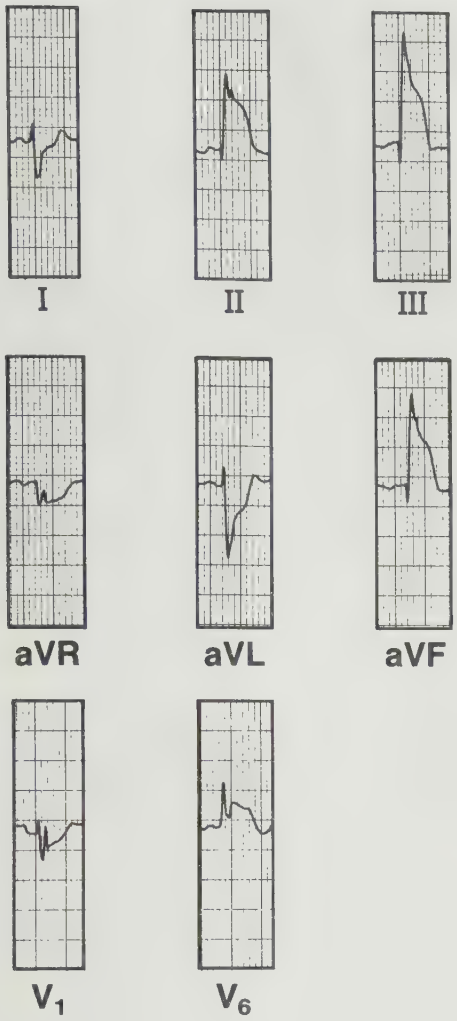

Fig. 45–48. Acute inferior myocardial infarction in a 3-mo-old child with staphylococcal sepsis. At autopsy, there was extensive abscess in the left ventricle. There is considerable ST elevation in leads II, III, and aVF. There is reciprocal ST depression in leads I, aVL, aVR and V_1.

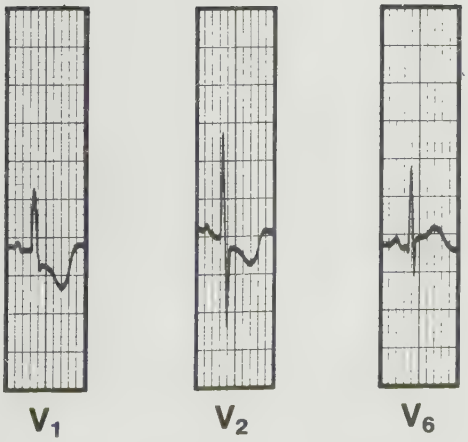

Fig. 45–49. ST-segment shift with patent ductus arteriosus. This tracing was taken from an 840-g infant with cardiomegaly due to a patent ductus arteriosus. Note the ST depression in leads V_1 and V_2 and ST elevation in lead V_6. The ST–T-wave changes resolved after ductus ligation.

Injury due to Ischemia

It is rare to obtain an electrocardiogram from an infant or child who is undergoing an acute myocardial infarction, but this diagnosis should be included when considering ST elevation (Fig. 45–48). A more common kind of ST-segment shift seen in children is the ST depression found in some infants with patent ductus arteriosus (Fig. 45–49). In 15 of 19 severely ill infants who required patent ductus arteriosus ligation, ST depression of 2.5 to 10 mm was found in leads V_1 and V_2. The ST change disappeared after ligation of the ductus. The explanation for these changes is a marked myocardial oxygen supply–demand imbalance primarily in the right ventricle: The supply is reduced due to the low aortic diastolic pressure with reduced coronary flow and the myocardial oxygen demand is increased due to the high pulmonary artery systolic pressure.[76]

Injury due to Myocarditis

Cellular injury occurs with myocarditis. Approximately 70% of children with myocarditis have electrocardiographic changes.[77] An abnormal electrocardiogram implies myocardial damage; however, a normal electrocardiogram does not preclude severe injury. The electrocardiogram may normalize within 2 to 3 weeks of the onset of the disease, but it may remain abnormal for up to 4 mo with later reversion to normal. A normal electrocardiogram after myocarditis also does not preclude severe residual damage.[71]

The most prominent electrocardiographic changes are flat or inverted T waves (primarily in the left chest leads) and "low-voltage" QRS complexes (see the section on low QRS voltage under "The Normal Electrocardiogram"). The T-wave changes are probably due to altered repolarization of injured cells throughout the myocardium rather than to true ischemia. The Q–T interval may be prolonged. The low-voltage QRS complex results from myocardial edema. Myocarditis also commonly results in ST depression due to extensive subendocardial injury. ST elevation is rare in myocarditis without pericarditis.[78] There have been several reports of the appearance of new Q waves in association with myocarditis. These have mostly been in children who later died. The Q waves were accompanied by ST elevation in those patients. There was no characteristic electrocardiographic location for these changes. In different children, the Q waves were in the inferior, lateral, or anterior leads (Fig. 45–50). Pathologic studies have documented extensive areas of necrosis and scarring that correlate with the electrocardiographic location of the Q waves in these patients.[79,80]

Atrioventricular block and interventricular conduction delay may occur in any type of myocarditis, but right bundle branch block is particularly common to the myocarditis due to Chagas' disease. Premature ventricular contractions occasionally occur in myocarditis.[71]

Injury due to Pericarditis

Pericarditis is by far the most common pathologic cause of ST elevation in children. Other causes of primary ST changes include myocardial infarction, cor pulmonale, head injury, digitalis, hy-

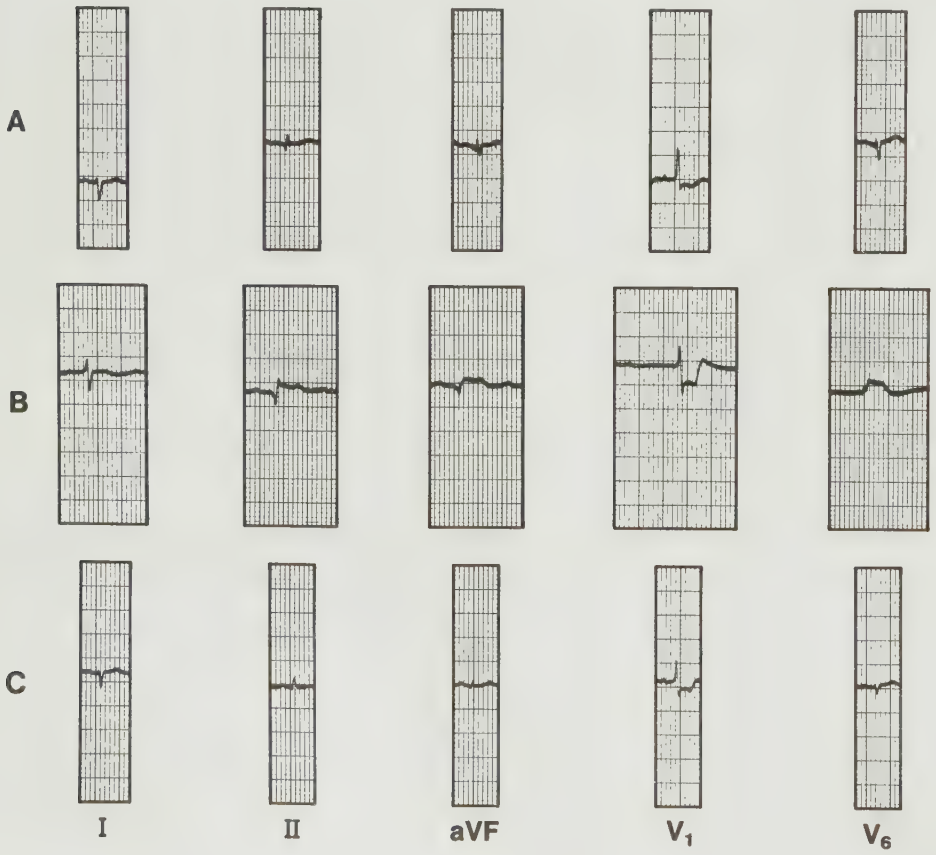

Fig. 45–50. Myocarditis in a 1-wk-old infant. (A) Low-voltage QRS complexes in both the limb leads and precordial leads. The T waves are concordant but decreased in amplitude. (B) Twelve hours later, complete atrioventricular block and deep, wide Q waves in leads III and aVF develop, accompanied by ST elevation in leads III, aVF, and V_6, with ST depression in lead V_1. This is compatible with an inferolateral myocardial infarction. (C) On the next day the infant has evidence of even less voltage in the inferior and lateral leads. He died the following night and was shown at autopsy to have diffuse areas of myocarditis and areas of necrosis throughout both ventricles.

perkalemia, emetine intoxication, pneumothorax, pneumopericardium, early ventricular repolarization, and normal atrial repolarization.

The electrocardiogram in pericarditis characteristically evolves through four stages (Fig. 45–51), as described below.

Stage 1, ST Elevation. This is thought to be due to subepicardial myocarditis. The ST elevation occurs in leads facing the epicardium (leads II, aVF, and V_3 to V_6). Depending upon the position of the heart, lead I or III may also be involved. The leads without epicardial representation, which are usually facing away from the left ventricle (leads aVR and V_1), may show reciprocal ST depression. In neonates, the right ventricle constitutes more of the epicardial surface, and the right chest leads may show ST elevation with the left chest leads showing ST depression.[71]

Pericarditis can usually be differentiated from acute myocardial infarction. In pericarditis, the ST elevation is found in numerous leads, whereas in myocardial infarction it is generally limited to a few leads. Also, the ST elevation in pericarditis is associated usually with an upright T wave, whereas in myocardial infarction, beyond the hyperacute phase, the T wave is usually inverted. In pericarditis during the time of ST elevation, it may also be possible to detect P–R segment elevation (greater than 0.8 mm) due to atrial subepicardial injury in leads overlying the right atrium (aVR and V_1) and reciprocal P–R depression (greater than 0.5 mm) in leads normally showing ST elevation.[8]

Stage 2. Stage 2 is characterized by normalization of ST segments with T-wave flattening. This occurs as an intermediate to stages 1 and 3.

Stage 3. In stage 3, there is T-wave inversion in the same leads in which the ST elevation previously appeared.

Stage 4. Stage 4 is resolution.

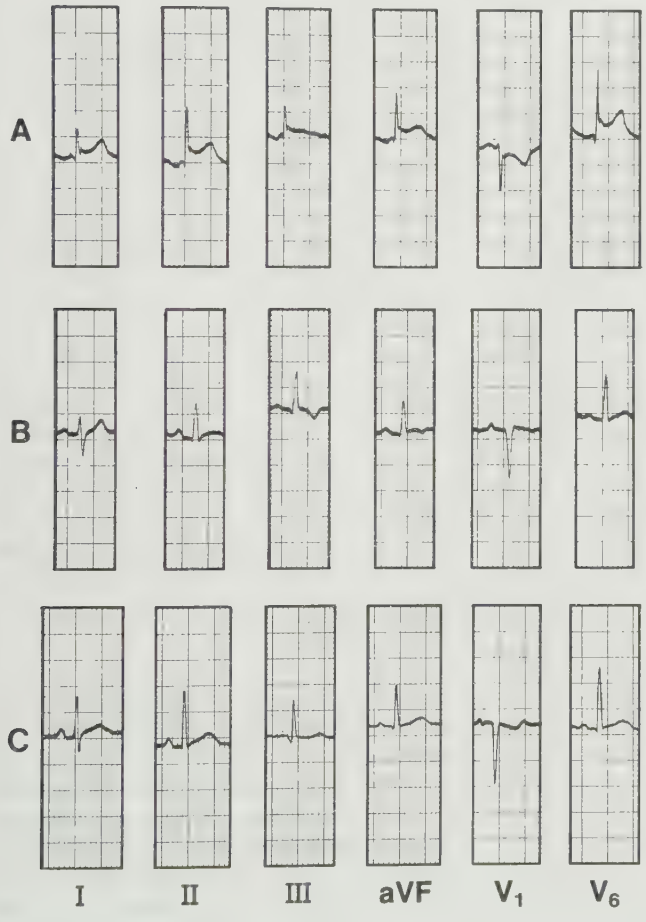

Fig. 45–51. Evolution of pericarditis in a 12-yr-old. (A) ST elevation with upright T waves in all leads except V_1. (B) The ST elevation is resolving and is replaced with T-wave inversion in leads III and aVF. This electrocardiogram was taken 4 days after the first one. (C) Two weeks later the ST–T-wave changes are resolved, but there is a Q wave in lead III that is wider than on previous tracings. This could indicate a small area of old inferior myocardial infarction.

In a prospective study of adults, 92% had electrocardiographic changes in pericarditis. In only half of these, typical ST elevation occurred, followed by T-wave inversion. In those without preceding ST elevation, T-wave inversion did not occur. P–R segment elevation occurred in 64% of these adults, and in 10% this was the only change of pericarditis.[81] The QRS complex is generally not affected by pericarditis. Even in the presence of a large pericardial effusion, the QRS may have normal voltage in pericarditis.[8]

Infarction

Infarcted muscle is electrically inert. The loss of electrical forces normally generated by the region of infarcted myocardium leaves unbalanced forces of unaltered magnitude in the opposite direction, resulting in Q waves overlying the area of infarction (Fig. 45–52). The earliest electrocardiographic manifestations of myocardial infarction are "hyperacute" very tall, peaked T waves. Hyperacute T waves occur in the first minutes, and are therefore infrequently observed. Soon thereafter, ST elevation is observed in leads overlying the infarction and a current of injury to that area is displayed. There may be reciprocal ST-segment depression in leads opposite the infarction. Within several hours to days, the ST elevation is typically followed by the development of Q waves and inverted T waves in leads overlying the infarction. Q waves of myocardial infarction in children are wide (0.04 sec or more), similar to those found in adults (Fig. 45–53). In children, Q waves related to myocardial infarction may disappear. As growth occurs, the infarcted area may become smaller relative to the greater total mass of the heart.

Anomalous Left Coronary Artery Originating from the Pulmonary Artery

In infancy, wide Q waves are more prominent than in later childhood.[82] Q waves are almost invariably present in lead I and are usually present in lead aVL, and may extend from the midprecordial to the lateral precordial leads (V_3 to V_6). There may be an abrupt loss of R wave in the midprecordium with a normal R wave in V_1, V_6, and V_7. In the frontal plane, the QRS mean vector is usually $+90°$.[47] The T waves are usually inverted in leads I and aVL and the lateral precordial leads. In older children, the Q waves become less prominent, resulting in compensatory hypertrophy of the posterobasal left ventricle. The major terminal QRS vector is superior, left, and posterior, frequently causing left-axis deviation in the frontal plane. There may be loss of the normal right ventricular dominance and deep S wave in leads II, III, aVF, and V_1 with tall R waves in leads aVL, V_5, and V_6. The T waves

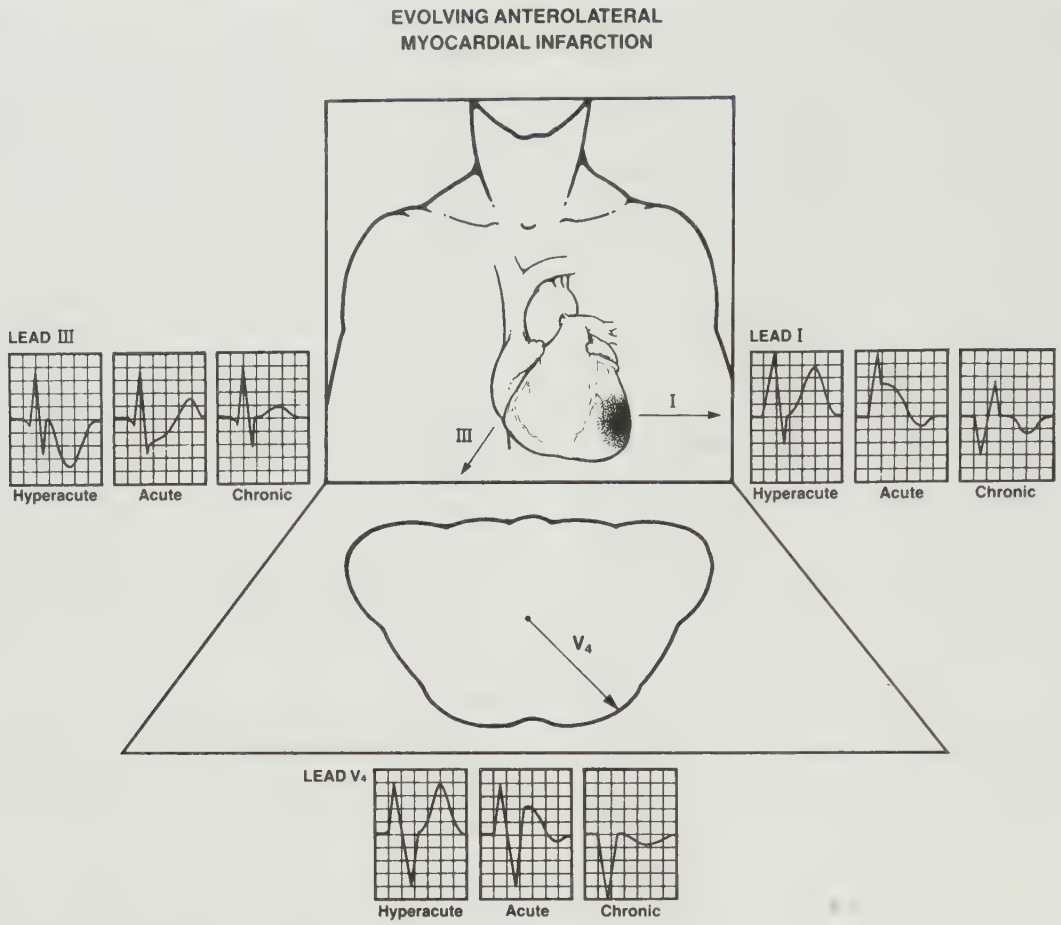

Fig. 45–52. Evolution of an anterolateral myocardial infarction.

are discordant in leads I, V_1, and V_6. While this evolution is characteristic, an individual patient may present with any combination of these findings (Fig. 45–54).

Papillary Muscle Infarction

Newborn infants with severe neonatal stress, or infants with severe pressure or volume overload may develop papillary muscle infarction. Characteristic electrocardiographic findings have been found in infants with aortic stenosis or total anomalous pulmonary venous return who were proven at autopsy to have had anterior papillary muscle infarction of either the right ventricle or left ventricle. In these infants, Q waves were present in lead V_3R. There was also a progressive diminution of the R wave in lead V_3R on serial electrocardiographic tracings.[83] This is to be distinguished from the other major causes of Q waves in the right chest leads in infancy—severe right ventricular hypertrophy or reversed septal depolarization from ventricular inversion.

Kawasaki's Disease

Kawasaki's disease (mucocutaneous lymph node syndrome) is the most common acquired cause of myocardial infarction in infants and children. The Q waves that occur in Kawasaki's disease are abnormally deep (especially in the inferior leads) and are usually abnormally wide (especially in the lateral leads).[84] Abnormally deep Q waves are defined in the section on "The Normal Electrocardiogram." Q waves may develop in the first 2 weeks of the illness and may be due to severe myocarditis. These may subsequently resolve. If Q waves develop later than 2 weeks into the illness, this is usually associated with a coronary artery aneurysm and myocardial necrosis. In some patients, a serial deepening of the Q waves was the only sign of infarction (Fig. 45–55). The absence of Q waves implies neither an absence of aneurysms nor an absence of significant areas of myocardial necrosis at autopsy.[84]

Pseudoinfarction

Other causes of abnormal Q waves, with or without ST–T-wave changes include left ventricular hypertrophy with strain and a QS pattern in lead I along with ST elevation, with reciprocal ST depression in V_6; right ventricular hypertrophy with a QR pattern in lead V_1; ventricular inversion with normal anatomic left ventricular to right ventricular activation occurring in a right-to-left direction, resulting in a narrow Q wave in lead V_1 and an absent Q wave in lead V_6; clockwise rotation of the heart from lung disease or pneumothorax may move the transition leads leftward to lead V_5 or V_6 and therefore lead V_1 may have a QS pattern; hypertrophic cardiomyopathy with asymmetric septal hypertrophy (deep and usually not wide Q waves are found in the lateral leads due to septal hypertrophy.); replacement by nonfunctioning living tissue (myocarditis, progressive muscular dystrophy, Friedreich's ataxia, scleroderma and cardiac tumors); replacement with pros-

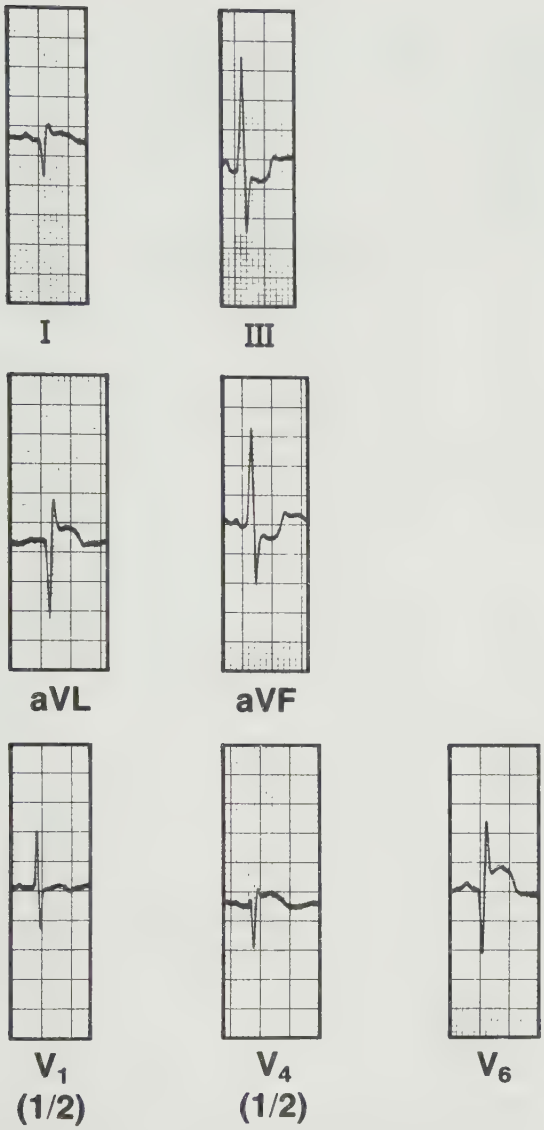

Fig. 45–53. Acute lateral myocardial infarction in a 4-mo-old infant with anomalous left coronary artery originating from the pulmonary artery. The "acute" and "chronic" stages diagrammed in Figure 45–52 occurred simultaneously in this patient. There is both ST elevation and the development of deep, wide Q waves in leads I, aVL, and V_6.

thetic material (when a large prosthetic patch is used on the right ventricular outflow tract, deep, wide Q waves may occur in the anerior chest leads; left bundle branch block, causing a QS pattern in lead V_1; left anterior hemiblock, with Q waves in the lateral precordial leads; Wolff-Parkinson-White syndrome, with wide Q waves in the inferior leads; and intracranial hemorrhage may produce a QS pattern in lead V_1 or V_2.

Body Chemistry

Hyperkalemia

Hyperkalemia is most commonly due to renal failure, salt-losing adrenogenital syndrome, or iatrogenic overdose.[85] The serum potassium level can be predicted from the electrocardiogram because of the different effects on the action potential. At a level of 5.5 to 6.5 mEq/L, the velocity of phase 3 of the action potential increases and the T waves on the electrocardiogram become tall and peaked. This is a poor sign because many normal children have "peaked" T waves and many children with hyperkalemia do not have peaked T waves. At a serum potassium level over 6.6 mEq/L, the cellular resting membrane potential is decreased (more toward 0) and therefore the conduction velocity (and $\dot{V}$ max) is decreased. This causes interventricular conduction delay. This may be manifested as diffuse QRS widening or it may have a specific bundle branch block or fascicular block pattern. These are generally very bizarre QRS complexes and may be combined with ST elevation, leading to the mistaken diagnosis of ventricular tachycardia if preceding P waves are missed (Fig. 45–56). If P waves are seen, these complexes may also be mistaken for acute myocardial infarction or pericarditis. At a level over 7.0 mEq/L, intra-atrial conduction delay becomes manifest with prolongation of the P wave. At a level over 8.5 mEq/L, the P wave may disappear. Direct conduction from the sinus node through atrial Purkinje fibers to the atrioventricular node and the ventricles has been hypothesized. The sinus node and atrial Purkinje fibers are most resistant to hyperkalemia. Since the ordinary atrial muscle fibers are depressed by the hyperkalemia, they neither conduct nor contract. Therefore there may be no P wave despite conduction through the atrium. This has been termed "sinoventricular conduction." At approximately 9.0 mEq/L, arrythmias begin: atrioventricular block, ventricular tachycardia, and ventricular fibrillation.

Hypokalemia

Hypokalemia is most often found with vomiting, diarrhea, endocrine disease (Cushing's disease, hyperaldosteronism, cortisone treatment), acquired renal disease, iatrogenic lack of intake, and most importantly to cardiologists, diuretic treatment. Hypokalemia causes a lengthening of phase 3 of the action potential with a loss of the plateau and a slower descent. At a level of 2.7 to 3.0 mEq/L, the electrocardiograms in 35% of adults have demonstrated abnormalities of hypokalemia and at a level below 2.7 mEq/L, 78% are abnormal.[86] The most prominent changes are the decrease in the T-wave amplitude (occasionally with ST depression) and an increase in the U-wave amplitude. Therefore hypokalemia causes broadened T and U waves with a normal onset to the T wave (Fig. 45–57). Other causes of prominent U waves are bradycardia, ischemia, left ventricular hypertrophy, quinidine, procainamide, phenothiazines, and cerebrovascular accidents. Hypokalemia may cause a minimally prolonged QRS duration. Arrhythmias are rare with hypokalemia unless the patient is receiving digitalis. In this case, hypokalemia enhances the arrhythmogenic effects of digitalis.

Hypercalcemia

Hypercalcemia may be due to hyperparathyroidism, hypophosphatasia, hypervitaminosis D, idiopathic hypercalcemia, or iatrogenic overdose with rapid infusion of calcium. Hypercalcemia shortens phase 2 of the action potential and therefore shortens the Q–T interval by shortening the ST segment. It may be difficult to diagnose hypercalcemia on the electrocardiogram in sinus rhythm, because the Q–T interval may be normal and only the ST segment is shortened. The most common effect of hypercalcemia is on the

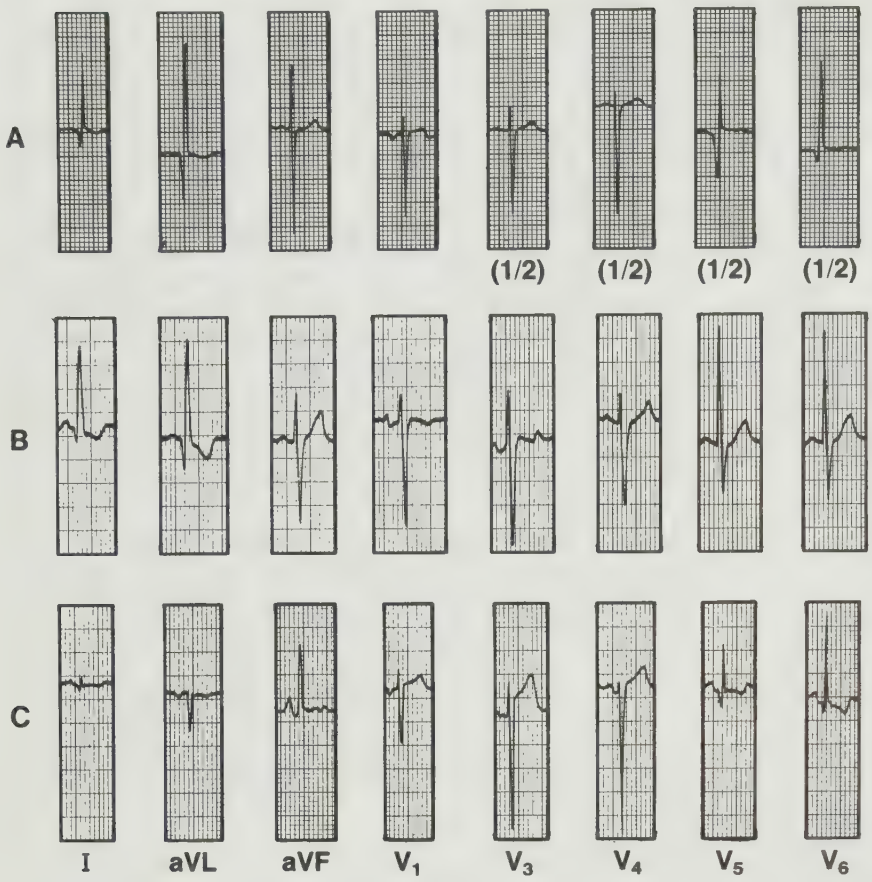

Fig. 45–54. Old myocardial infarction in three children with anomalous left coronary artery originating from the pulmonary artery. (A) The top row of tracings are from a 7-mo-old child. They demonstrate left-axis deviation of the QRS mean vector in the frontal plane, a diminished R wave between lead V_3 and lead V_6, and deep, wide Q waves in leads I, aVL, V_5, and V_6. In the middle row, the tracings are from a 7-yr-old girl. The findings are similar to those in the 7-mo-old, with the exception that there are no Q waves but deep S waves in leads V_5 and V_6. (B) The middle row therefore corresponds more to the "adult" type of electrocardiogram in anomalous left coronary artery. (C) In the bottom tracings, taken from another 7-yr-old, there is no left-axis deviation, but there are deep Q waves in leads aVL, V_5, and V_6. This is more consistent with the "infantile" pattern. This demonstrates that the labels may not be helpful. In all these electrocardiograms there is a loss of R wave in lead V_4, and both Q-wave and T-wave inversion in leads I and aVL.

sinus node, with slowing of the sinus rate, sinoatrial block, or sinus arrest. Atrioventricular block and ventricular arrhythmias are uncommon unless the patient is taking digitalis. In this case, hypercalcemia potentiates digitalis effects and digitalis-induced arrhythmias.

Hypocalcemia

Hypocalcemia can be due to malabsorption, hypoparathyroidism, vitamin D deficiency, stress in the newborn period, or iatrogenic lack of intake. This causes a prolongation of phase 2 of the action potential and prolongation of the ST segment on the electrocardiogram. Therefore hypocalcemia has a different effect from hypokalemia, which prolongs phase 3. In hypokalemia, the onset of the T wave occurs at the normal time, the T-wave duration (including the U wave) is prolonged, and the Q–T (or Q–U) interval is prolonged. In hypocalcemia, the T-wave duration is normal and the Q–T interval is prolonged because there is a prolonged ST segment and a prolonged onset of the T wave (see Fig. 45–20). The interval from the onset of the QRS complex to the onset of the T wave (Q–OT interval) correlates well with serum calcium in newborn babies (see Fig. 45–20). In premature babies, the normal corrected Q–OT (Q–OT/square root of the P–R) is 0.20 or less, and in full-term infants it is 0.19 or less.[16] Using these parameters, if the Q–OTc interval is normal, the serum calcium concentration is normal in 98% of babies; if the Q–OTc interval is prolonged, 70% are hypocalcemic with a total serum calcium concentration less than 7.5 mg/dL. The remainder of the infants with a prolonged Q–OTc interval have undergone severe neonatal stress. Although patients with hypocalcemia have a prolonged Q–T interval, arrhythmias are rare, perhaps because repolarization is uniformly prolonged throughout the ventricles. Atrioventricular block may occasionally occur.

Hypermagnesemia

Hypermagnesemia decreases the upstroke velocity of the action potential and shortens the duration of phase 2 of the action potential, simulating hypercalcemia. Isolated hypermagnesemia produces few changes on the electrocardiogram, although individual cases of prolonged P–R interval and interventricular conduction delay have been reported.[4]

Hypomagnesemia

The effects of hypomagnesemia on the action potential and the electrocardiogram are similar to those of hypokalemia. In newborns, hypomagnesemia may coexist with hypocalcemia. In these infants, the electrocardiographic pattern is similar to combined hypocalcemia and hypokalemia: prolonged plateau and slower descent. These produce a summation of effects to delay repolarization and therefore large U waves are observed with flattened T waves.

Hypernatremia and Hyponatremia

In the tissue bath, the effects of sodium on the action potential are considerable, with an increased sodium concentration causing an increase in the slope of phase 0 (increased $\dot{V}$ max) and prolonged phase 3. A decrease in sodium concentration causes the opposite effect. However, in the range of serum sodium concentrations that

are physiologically possible in the body, these effects are not usually seen on the electrocardiogram. The effects of sodium may be demonstrated in the patient with a prolonged QRS duration due to quinidine or hyperkalemia, where sodium infusion improves interventricular conduction and shortens the QRS duration.

Hypoglycemia

The electrocardiographic changes of hypoglycemia are thought to be caused by the associated hyperkalemia that is frequently present. In hypoglycemia, insulin secretion is inhibited and hyperkalemia may result.

Hypoxia and Acidosis

The effects of the action potential of hypoxia and acidosis are similar to those of increased extracellular potassium and the changes may be due, in part, to leakage of potassium out of the cell.[71] The QRS duration is prolonged, as is the Q–T interval. All types of atrial and ventricular arrhythmias may occur in addition to atrioventricular block.

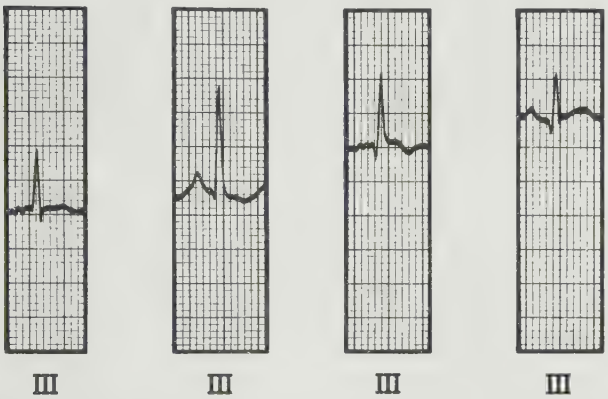

Fig. 45–55. Myocardial infarction in Kawasaki's disease. These tracings are from a 9-yr-old boy who was hospitalized on the seventh day of the illness. The first tracing is from the day of admission. He was asymptomatic at the time. The second tracing was taken 3 days later. Note the development of small Q waves, which were not present previously, and the T-wave inversion in lead III. Four days later, the Q waves have deepened and are now slightly wider. There is also ST elevation with the terminal portion of the T wave inverted. The day after the third tracing, the Q wave remains and the T waves have normalized. By radionuclide imaging, the entire inferior wall of the left ventricle was infarcted. This points out the subtle changes that may occur in an extensive myocardial infarction in a child. While the depth of the Q wave in the last tracing is not distinctly abnormal, the new appearance of the Q wave is abnormal and the width of the Q wave is also abnormal.

Antiarrhythmic Drugs

Digitalis

Digitalis shortens phase 2 of the action potential and also shortens the action-potential duration. The ST–T-wave changes can be explained by the effect of digitalis to hasten repolarization. Digitalis tends to cause all layers of the ventricle to repolarize simultaneously, resulting in greater cancellation of the repolarization vector and flat T waves. With moderate amounts of digitalis effect, primarily the onset of repolarization is affected, as represented in

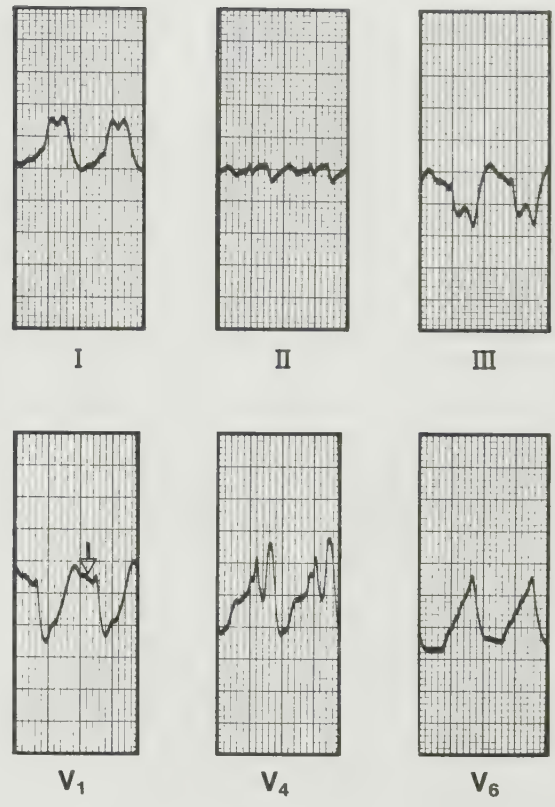

Fig. 45–56. Hyperkalemia. These tracings are from a 2-day-old infant with renal failure and hyperkalemia. The QRS complex is similar to left bundle branch block. The small P waves are marked with an arrow in lead I, indicating that this is sinus rhythm.

the ST segment. The ST segment is depressed most in the leads facing the left ventricle; taller P waves are generally associated with more ST depression.[71] The late part of repolarization is still unaffected. Therefore the terminal parts of the T waves are normal and concordant with the QRS complex, although the overall Q–Tc interval may be shortened (Fig. 45–58A). With increasing amounts of digitalis effect, the entire process of repolarization is reversed (from endocardium to epicardium) and the same leads with ST depression also show T-wave inversion. The T waves are coved and the descending limb of the ST segment and T wave has an angle of 90° wth the ascending limb (Fig. 45–58B).[86]

The effect of digitalis on impulse formation and conduction results from a combination of direct and vagotonic effects. The cellular basis of these effects has been reviewed by Reder and Rosen[87] The overall effect of digitalis is to slow the sinus rate, speed intra-atrial conduction, decrease atrial automaticity, and prolong atrioventricular condition. This may be manifest on the electrocardiogram as sinus bradycardia and a prolonged P–R interval.

Digitalis toxicity results in further slowing of the sinus rate, sinoatrial block, or sinus arrest, and second-degree atrioventricular block (usually type 1, Wenckebach), or third-degree atrioventricular block. These manifestations are more common in children than those that result in increased atrial, junctional, or ventricular automaticity; namely, premature atrial contractions, supraventricular tachycardia, nonparoxysmal junctional tachycardia, premature ventricular contractions, or ventricular tachycardia.[88,89] If atri-

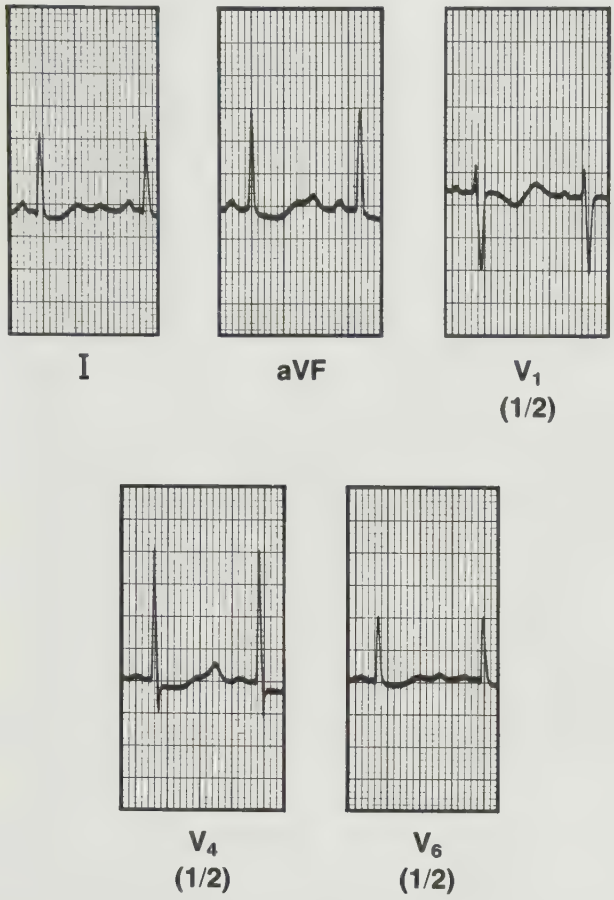

Fig. 45–57. Hypokalemia. These tracings are from a 4-yr-old with the nephrotic syndrome. Note the prominent U waves in all leads with ST depression and T-wave inversion in leads I, aVF, V_4, and V_6.

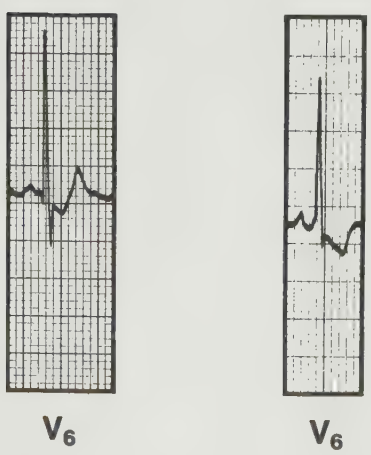

Fig. 45–58. Digitalis effect. (A) ST depression with normal terminal portion of the T wave. (B) Coved initial portion, with complete inversion of the T wave.

oventricular block and premature ventricular contractions occur on the same electrocardiogram, digitalis toxicity should be suspected. Digitalis toxicity (especially associated with hypokalemia) has been associated with "bidirectional tachycardia." This has the morphology of constant complete right bundle branch block with alternating right-axis deviation and left-axis deviation (Fig. 45–59). Bidirectional tachycardia is probably ventricular tachycardia with alternating exit pathways, rather than junctional tachycardia with alternating bundle branch block.[91]

Quinidine, Procainamide, and Disopyramide

These drugs are class IA antiarrhythmic agents and have similar actions. Quinidine's effects will be used as examples of the other type IA agents. Quinidine decreases the upstroke velocity (reduced $\dot{V}$ max) of all action potentials, prolongs phase 3 (resulting in a prolonged action-potential duration), and reduces automaticity. The decreased upstroke velocity results in interventricular conduction delay and a prolonged QRS duration. This may result in a diffusely widened QRS or a specific right or left bundle branch block pattern. The effects on the T waves are both "secondary" (to the interventricular conduction delay) and "primary" (due to prolongation of the action potential). Since the terminal part of repolarization is most affected, the early part of the T wave may have decreased amplitude and the terminal part may be increased. This is difficult to distinguish from a U wave. The Q–T (or Q–U)

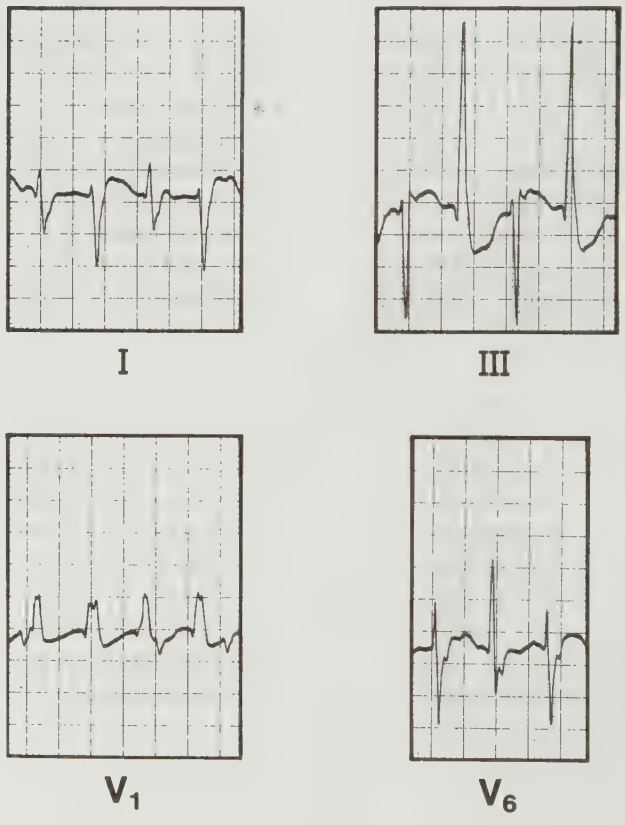

Fig. 45–59. Bidirectional tachycardia. This was due to digitalis intoxication and hypokalemia in a 5-yr-old child. There is constant right bundle branch block in lead V_1 with alternating right-axis and left-axis deviation shown in the limb leads.

interval is prolonged. Because of its vagolytic properties, quinidine may shorten the P–R interval slightly.

Quinidine toxicity is manifest on the electrocardiogram as a decreased atrial rate usually due to sinoatrial exit block; prolongation of the P-wave duration due to intra-atrial conduction delay; prolongation of the P–R interval due to prolongation of His–Purkinje conduction; prolongation of the QRS complex to 125% or more of the original QRS duration (Fig. 45–60); further prolongation of the Q–T interval due to an increase in refractory period dispersion throughout the ventricles;[91] and premature ventricular contractions and ventricular tachycardia.[92] The ventricular tachycardia in quinidine toxicity may have a similar morphology to that sometimes found in other patients with prolonged Q–T intervals and is called torsades de pointes (Fig. 45–61).[93]

Lidocaine, Phenytoin, Mexiletine, and Tocainide

These drugs increase the slope of phase 0 (increase $\dot{V}$ max) in diseased tissue (improving conduction) and shorten action-potential duration, but have very little effect on the surface electrocardiogram.[94] Rarely, with high doses of phenytoin the P–R and Q–T intervals may shorten due to accelerated atrioventricular conduction and shortened ventricular refractoriness. If phenytoin is given to a patient with a prolonged Q–T interval for prevention of ventricular tachycardia, effective antiarrhythmic treatment may occur without shortening the Q–T interval.[95]

Propranolol

Propranolol decreases the upstroke velocity of phase 0 (reduces $\dot{V}$ max), shortens the action-potential duration, and decreases automaticity. In the patient, propranolol's effects are mainly antiadrenergic. The sinus rate is slowed, the P–R interval is prolonged and the Q–T interval may be shortened. Similar to phenytoin, propranolol may not shorten the Q–T interval in a patient with a prolonged Q–T interval but it may be effective in preventing ventricular tachycardia and sudden death.[95]

Verapamil

Verapamil is a calcium antagonist with primary effects on the sinus node and atrioventricular node. It decreases the slope of phase 0 (reduced $\dot{V}$ max), prolongs the action potential duration and reduces automaticity. The electrocardiographic findings are a slowed sinus rate and prolonged P–R interval.

Amiodarone

Amiodarone is primarily a Class III agent that prolongs action-potential duration; it also has some Na-channel blocking activity to decrease $\dot{V}$ max; it also possesses beta-blocking and calcium-blocking activity. Amiodarone virtually always prolongs the Q–T interval and decreases the heart rate. There is less constant P–R and QRS prolongation.[96]

Encainide and Flecainide

These are both Class Ic agents with profound Na-channel blocking activity, therefore markedly decreasing $\dot{V}$ max. This has the effect of prolonging the QRS complex at effective, rather than toxic, doses. It is usual for children on encainide to have QRS prolongation of 50% over base line.[97] Flecainide causes less QRS prolongation. In patients receiving both of these drugs, the measured Q–T interval increases due to the QRS prolongation; repolarization (the interval from the end of the QRS complex to the end of the T wave, the so-called J–T interval) does not prolong.

Anesthetic Agents

Halothane decreases the action potential duration slightly by increasing the slope of phase 2 and phase 3. These effects are rarely seen on the electrocardiogram, but occasionally the Q–T interval is shortened and there may be a decrease in T-wave amplitude. Halothane sensitizes the heart both to vagal and sympathetic stimulation. Therefore bradycardia and ventricular arrhythmias may occur. Methoxyflurane, teflurane, and enflurane have similar effects on the electrocardiogram to those of halothane.

Chloroform, ethyl chloride (given by inhalation), trichloroethylene, and cyclopropane all may cause ventricular arrhythmias. Diethyl ether and other ethers have no effect on the electrocardiogram.[98]

Psychotropic Drugs

Phenothiazines cause shift of potassium inside the cell, thus decreasing the extracellular potassium and therefore prolonging phase 3 of the action potential.[99] These changes are similar to those found with quinidine: The T waves have reduced amplitude with prominent terminal depolarizations. It is difficult to distinguish a U wave from broad notched T waves with an increased terminal component. The Q–T (or Q–U) interval is prolonged.[100] In therapeutic doses, arrhythmias are rarely observed with phenothiazines, but in overdosage, ventricular arrhythmias may occur.

The electrocardiographic changes with tricyclic antidepressants

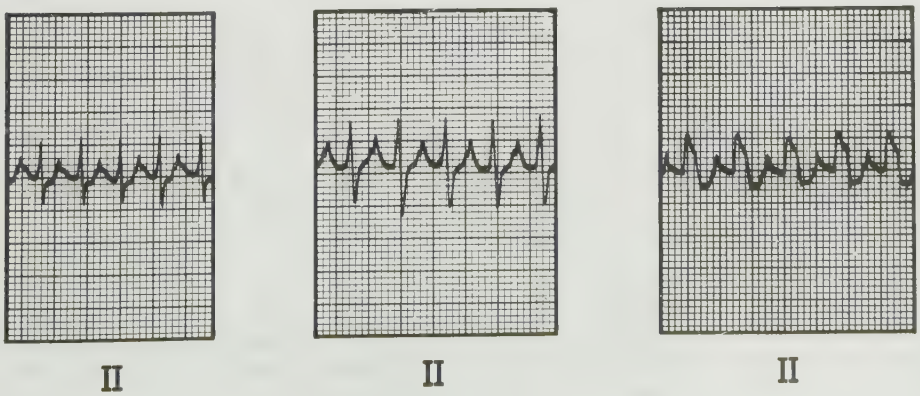

Fig. 45–60. Procainamide effect and toxicity. (A) Before medication, this 5-mo-old girl had supraventricular tachycardia due to an atrial ectopic focus at a rate of 270 beats/min. The QRS duration was 0.05 sec. (B) After 70 mg of procainamide, the rate slowed to 225 beats/min and the QRS duration increased to 0.08 sec. (C) After 80 mg of procainamide, the rate did not change, but the QRS duration increased to 0.10 sec with a pattern of left bundle branch block.

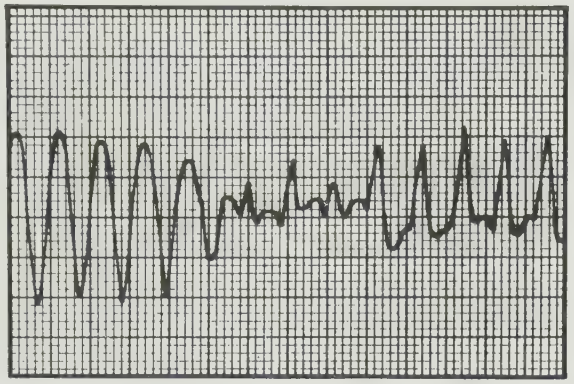

Fig. 45–61. Torsades de pointes due to quinidine toxicity. There are two different polarities to the tachycardia separated by a narrower-transition QRS.

occur in 20% of adult patients taking the drugs. The most common manifestations are sinus tachycardia, prolonged P–R interval, and flat T waves. Less commonly observed are QRS prolongation, Q–T interval prolongation, and ST–T-wave changes. Overdosage with tricyclic antidepressants may cause atrial or ventricular arrhythmias or atrioventricular block.[8]

Imipramine (Tofranil) causes an imbalance of intracellular and extracellular potassium with an increase in serum potassium. In one reported case of an overdosage in a child, atrial flutter, atrioventricular block, interventricular conduction delay, and ventricular tachycardia were observed in the same patient.[101]

Central Nervous System Effects

Congenital Prolongation of the Q–T Interval

Jervell and Lange-Nielsen[13] and Romano[102] and Ward[103] described syndromes that have in common congenital prolongation of the Q–T interval. syncope or sudden death, and hereditary transmission. In the Jervell–Lange-Nielsen syndrome, the hearing is abnormal and the heredity is autosomal recessive; in the Romano–Ward syndrome, the hearing is normal and the heredity is autosomal dominant. The electrocardiograms are similar. The T waves may be inverted, biphasic, and vary in both shape and amplitude from minute to minute. The T waves frequently have bizarre shapes with greater amplitude at the terminal portion of the T wave (Fig. 46–62).

Although the exact mechanism of the prolonged Q–T interval is uncertain, central and peripheral nervous system sympathetic imbalance is involved. Normally, innervation to the heart is asymmetric: Fibers project from the right hypothalamus to the right stellate ganglion and supply the anterior surface of the cardiac ventricles; fibers from the left hypothalamus project to the left stellate ganglion and supply the left lateral and posterior wall of the cardiac ventricles. Experimental stimulation of the left stellate ganglion prolongs the Q–T interval and causes ST depression.[71] In patients with a congenitally prolonged Q–T interval, left stellate ganglionectomy may shorten the Q–T interval and eliminate episodes of syncope, adding strength to the hypothesis of neural imbalance as a cause of this syndrome.

Central Nervous System Injury

In children with moderate to severe head trauma or in those who have undergone neurosurgical procedures, the electrocardiogram has been reported to be abnormal in 75%.[104] The most common abnormalities are a prolonged Q–T interval with either notched, bizarre-shaped T waves or prominent U waves. Occasionally, the T waves are diffusely flattened in the lateral leads or even inverted with ST depression.[105] ST elevation is rare in central nervous system lesions but has been reported.[106] Occasionally, J or Osborne waves are found (see section on "Hypothermia"). These repolarization changes are thought not to be due to increased intracranial pressure but rather to differential stimulation or suppression of the cortical representations of the sympathetic fibers. In some patients with central nervous system lesions, there is evidence at autopsy for cardiac abnormalities, primarily subendocardial ischemia. Identical lesions can be produced by catecholamine infusion.[107]

Arrhythmias can occur with central nervous system injury. Vagal tone is enhanced and there may be alternating sympathetic stimulation. The bradyarrhythmias (sinus bradycardia, wandering atrial pacemaker, junctional rhythm, and type 1 second-degree atrioventricular block) generally respond to atropine, supporting the theory of their central vagal origin. Sinus tachycardia may occur in addition to any of the pathologic tachyarrhythmias.

Hypothermia

A J wave (or Osborne wave) occurs on the electrocardiogram of patients with a body temperature below 25°C. This is a slowly inscribed extra deflection between the QRS and the early ST segment (Fig. 45–63).[108] The P–R and Q–T intervals prolong and there may be ST depression or ST elevation. Initially, the sinus node slows but at approximately 29°, 50 to 60% of adult patients with hypothermia have atrial fibrillation.

Neuromuscular Disorders

The electrocardiogram in Duchenne's progressive muscular dystrophy is abnormal in about 75% of patients. The abnormalities are most specific to Duchenne's dystrophy and occur less frequently in the other forms of muscular dystrophy.[109] The usual findings are tall R waves in the right precordial leads (with or without interventricular conduction delay) and deep narrow Q waves in the left precordial leads. These changes are thought to be due to selective scarring of the posterobasal left ventricle, rather than right ventricular hypertrophy, pulmonary hypertension, or septal hypertrophy.[110] The scarring could be due to continued stress on the left atrioventricular ring due to poor support of the mitral valve from abnormal cardiac muscle. These electrocardiographic changes do not correlate with the degree of involvement in the skeletal muscles or the degree of cardiomyopathy. Late in the disease, when cardiomyopathy is present, any type of active arrhythmias may occur: sinus tachycardia, premature atrial contractions, atrial flutter, premature ventricular contractions, or ventricular tachycardia.

In Friedreich's ataxia, the electrocardiogram is abnormal in 90% of the patients, most commonly QRST discordance; 20% have asymmetric septal hypertrophy as the cause of deep Q waves in the lateral precordial leads.[8] Either left ventricular hypertrophy or right ventricular hypertrophy may also occur. The arrhythmias are similar to those in muscular dystrophy.

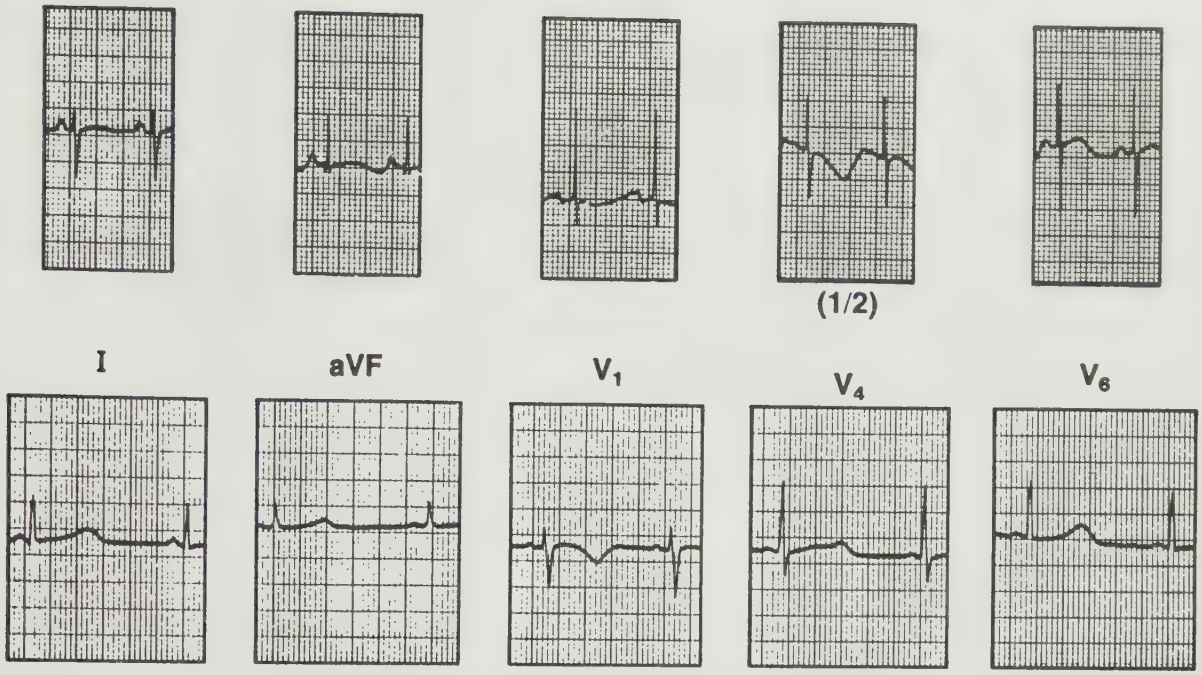

Fig. 45–62. Congenital prolongation of the Q–T interval. Top tracings from a 9-day-old infant with a history of ventricular tachycardia and ventricular fibrillation at the age of 4 days. All the T waves are abnormal, however, the T waves in lead V_4 (at half standard) are especially bizarre. Bottom tracings from a 12-yr-old child who had his first episode of syncope at the age of 10 yr. He was being treated for a familial seizure disorder. Note that the terminal portion of the T wave in lead V_4 is greater in amplitude than the initial portion.

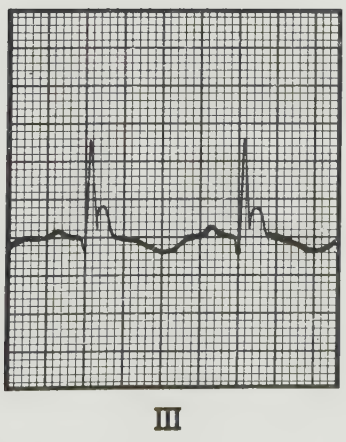

Fig. 45–63. Hypothermia. This tracing was taken from a 3-mo-old with hypothermia and severe brain damage. The J wave is the rounded, second portion of the QRS complex. The heart rate is slow for an infant of this age. The P–R interval, QRS duration, and Q–T interval are also prolonged.

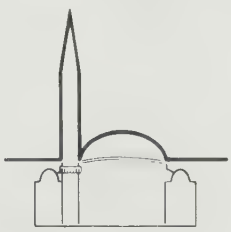

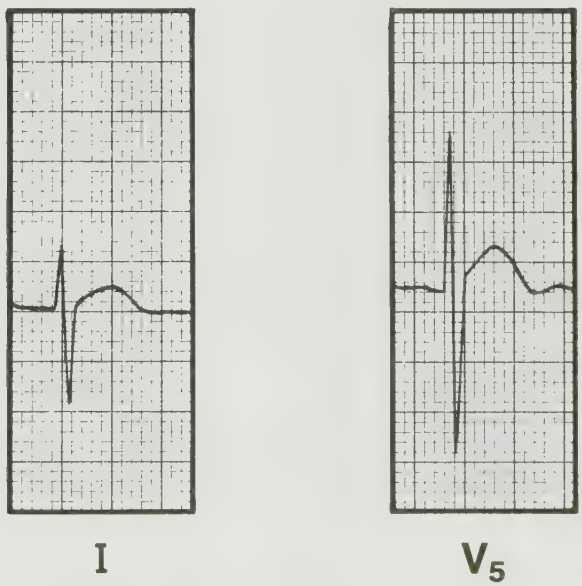

Fig. 45–64. Hypothyroidism. The "mosque" sign is demonstrated with an absence of the ST segment and a symmetrically rounded T wave.

The electrocardiogram in myotonic dystrophy is abnormal in about half of the patients, with low-voltage P waves, prolonged P–R interval, left-axis deviation, left bundle branch block, and ST–T-waves changes. Atrial fibrillation is common.

Connective-Tissue Disease

In patients with scleroderma or systemic lupus erythematosus, pulmonary hypertension may cause right ventricular hypertrophy and systemic hypertension may cause left ventricular hypertrophy. In addition, ST elevation and T-wave changes may occur as a result of pericarditis. Chronic pericarditis with fibrin insulation or diffuse myocardial fibrosis may lead to low-voltage QRS complexes. Supraventricular tachycardia, ventricular tachycardia, atrioventricular block, and bundle branch block are common in later stages of these diseases.

Metabolic Diseases

Hypothyroidism

The classic sign of hypothyroidism is the ''mosque'' sign (appropriately, originally described in Turkey by Ertugrul in 1966):[111] A dome-shaped symmetric T wave with an absent ST segment (Fig. 45–64). This was present in 37% of children with hypothyroidism. Therefore, if present, the mosque sign is helpful in the diagnosis; if it is absent, the patient still may have hypothyroidism. Low voltage of the P waves, QRS complexes, and T waves is also common, and most likely due to myocardial edema, rather than myxomatous pericarditis, which is exceedingly rare.[112] Sinus bradycardia occurs in children with hypothyroidism, usually after 3 yr of age.

Hyperthyroidism

The majority of children with hyperthyroidism have sinus tachycardia, and approximately 50% have left ventricular hypertrophy.[113] Less commonly observed are prolonged P–R interval, nonspecific ST–T-wave changes and right bundle branch block. These changes may take up to a year to reverse after the patient becomes euthyroid.

Adrenal Insufficiency

Patients with adrenal insufficiency may have Q–T interval prolongation with inverted T waves. These changes can be reproduced in adrenalectomized animals, but when the hearts are removed from the body, the cardiac action potentials are normal.[87] These changes are therefore thought to be due to autonomic imbalance.

Pheochromocytoma

Excess catecholamines are responsible for the prolonged Q–T interval and T-wave inversion occasionally encountered in patients with pheochromocytoma.

Miscellaneous Diseases

Peritoneal Inflammation

Peritonitis, appendicitis, and ileus may be associated with nonspecific ST–T-wave changes. These are thought to be due to vagally mediated reflexes.[87]

Sarcoid

The granulomas of sarcoidosis have a predilection for the conduction system. The most common lesions are complete atrioventricular block and right bundle branch block. Premature atrial contractions and premature ventricular contractions also occur.[8]

ARTIFACTS

Recognition of artifacts is both important and satisfying: An exercise in mind over matter. Causes of artifacts can be classified into seven major categories as described below.[114]

Causes of Artifacts

Incorrect Positioning of the Electrocardiogram Leads

The most common cause is reversing the right arm with the left arm or the right leg with the left leg. Only the limb leads on the electrocardiographic tracing are affected. If the arm leads are reversed, the P wave, QRS complex, and T wave are inverted in lead I. This can be checked by examining lead V_6, since V_6 has approximately the same vector as lead I. If the complexes in lead I and V_6 are completely different and the P waves are inverted in lead I, the limb leads are reversed (Fig. 45–65 first and second column). If the right leg and the left leg leads are switched, there is practically no change in the electrocardiogram (Fig. 45–65 third column). If the right leg and the right arm leads are switched, lead II is entirely isoelectric. Secondly, the complexes in aVR and aVF are completely positive. It is not possible to calculate a mean vector that is entirely positive in leads aVR and aVF at the same time. Finally, lead I is entirely different from lead V_6. These leads should record similar complexes (Fig. 45–65 fourth column). If the left leg and left arm leads are switched, unlike the other errors, the resultant electrocardiogram is not obviously faulty. This error in position results in abnormal left-axis deviation (Fig. 45–65 fifth column).

The chest leads may be positioned in an incorrect interspace (Fig. 45–66). If all the leads are placed one interspace too high (i.e., third instead of fourth interspace), the R waves are diminished and the S waves are augmented in leads V_4 to V_7. If the leads are placed one interspace too low, the R waves are augmented and the S waves are diminished.

If electrode paste is not cleaned between chest lead placement, the entire anterior chest will become a conductor and the same ''average'' QRS complex will be recorded from each lead. This is a common problem in infants. This should be suspected if every chest lead appears similar (Fig. 45–67).

Patient-Initiated Movement

Hiccoughs. These are monophasic or biphasic deflections that occur randomly throughout the cardiac cycle. They are usually midway in size between a P wave and QRS complex. There is no alteration in the basic rhythm (Fig. 45–68).

Purposeful Movement. Any random depolarization on the electrocardiogram that does not affect the basic rhythm should be suspected as an artifact. If the movement is repetitive (e.g., waving of the hand) it may simulate ventricular tachycardia.

Nonpurposeful Movement. Convulsions, ''jittery'' newborns, and somatic tremors may simulate tachyarrhythmias (Fig. 45–69).

Respirations. The size of the QRS complex may change with normal deep inspiration (Fig. 45–70).

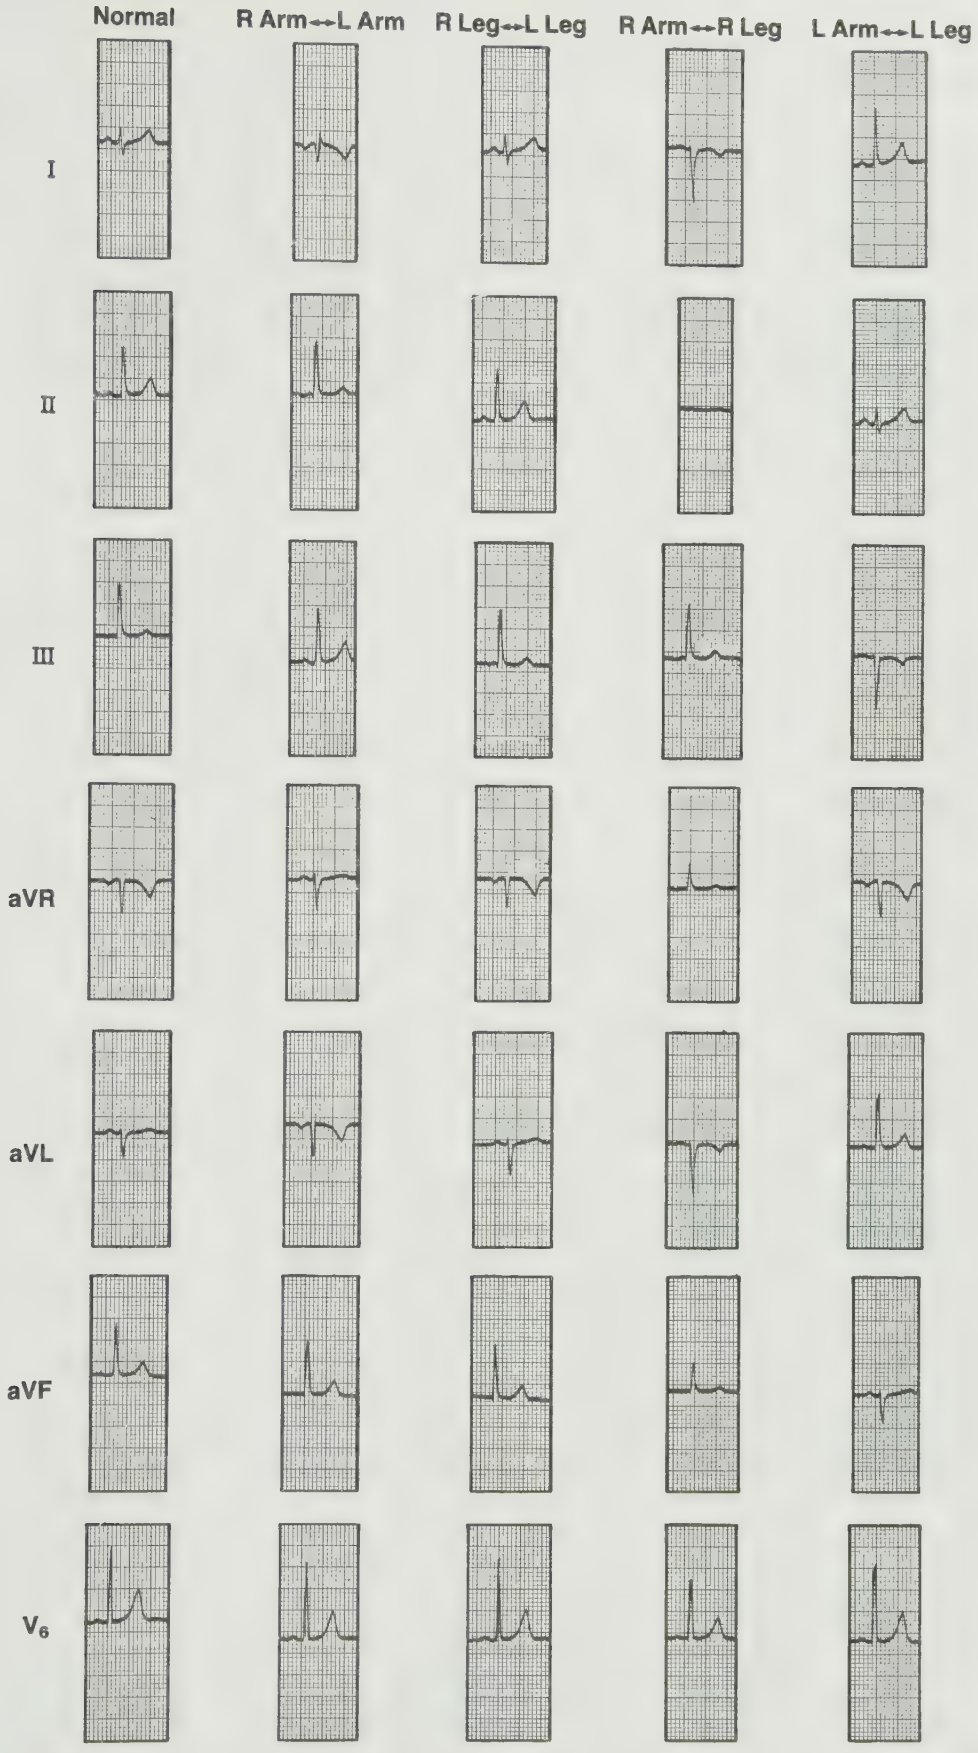

Fig. 45–65. Artifacts due to incorrect limb lead placement. The first column is with the limb leads in the normal positions; the second column is with the right arm and the left arm reversed; the third column is with the right leg and left leg reversed; the fourth column is with the right arm and right leg reversed; and the fifth column is with the left arm and left leg reversed.

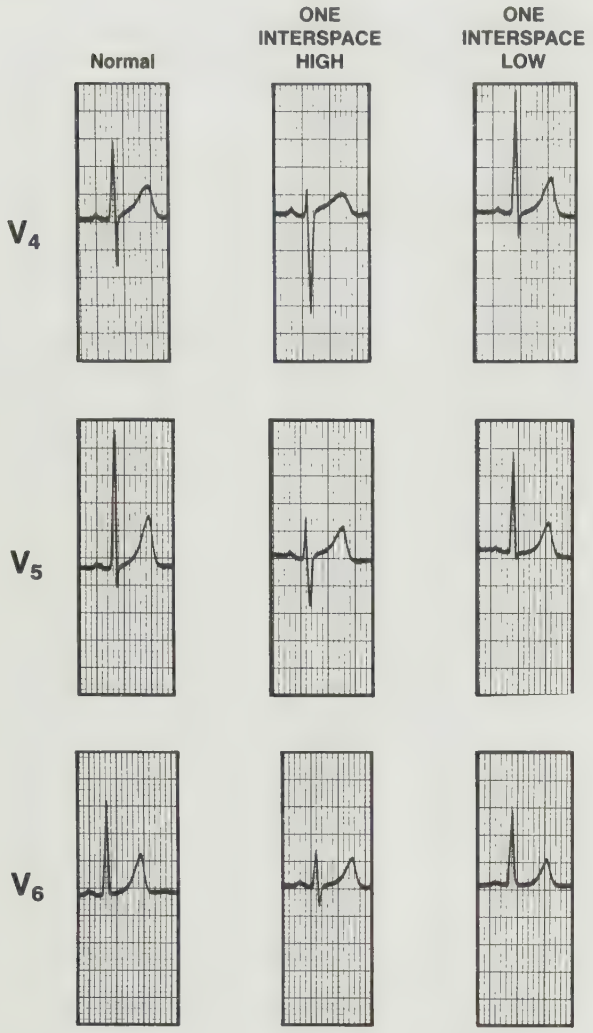

Fig. 45–66. Artifacts due to incorrect precordial lead placement. The first column is with the leads in the normal position. The second column is with the leads placed one interspace too high and the third column is with the leads placed one interspace too low.

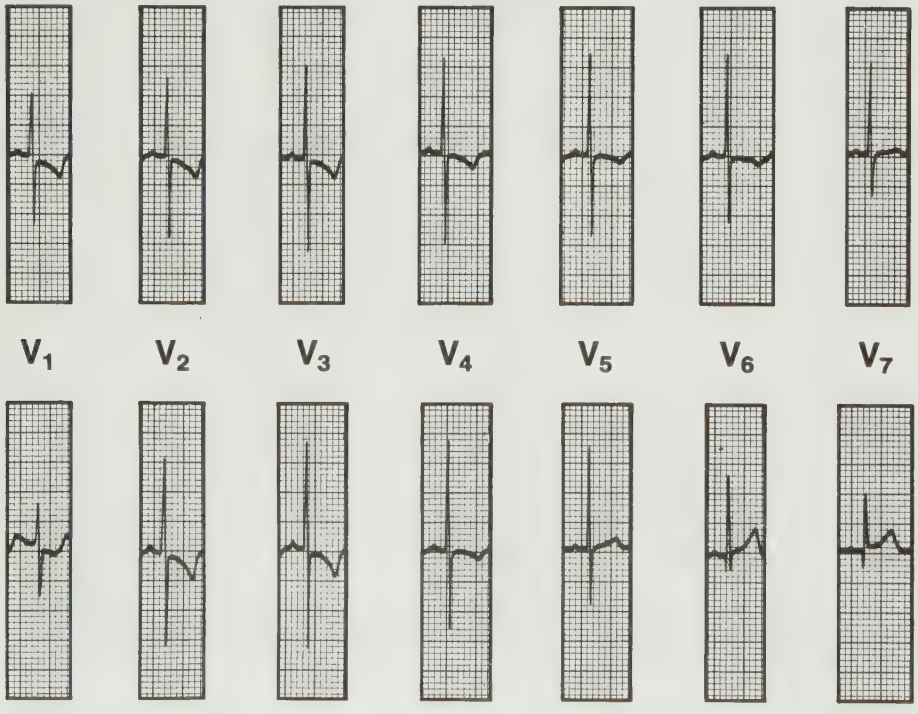

Fig. 45–67. Electrode paste not properly removed between applications of the chest electrodes. Top row with paste smeared on the anterior chest wall causing all complexes to appear the same. Bottom row with proper application of the paste showing a difference between complexes.

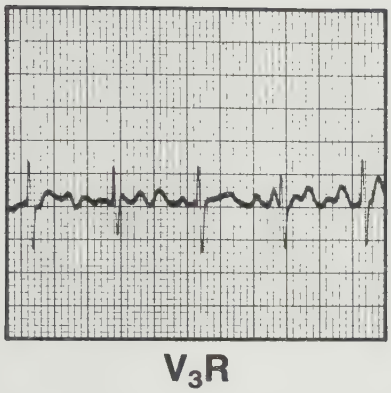
Fig. 45–68. Hiccough. The artifact can be best described as being midway in size between a P wave and a QRS complex. It is too large for a P wave. If it were a QRS complex, it should be followed by a T wave.



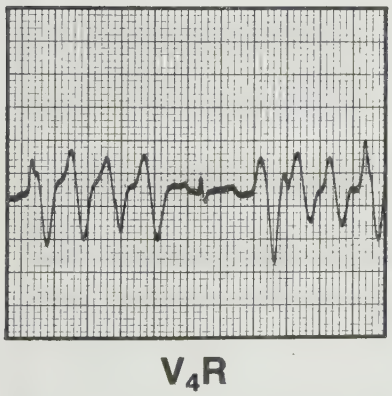


Fig. 45–69. Simultaneous tracings taken during a seizure. In lead V_4R, the tracing appears to be ventricular tachycardia but in the other two tracings, it is apparent that this is artifact and that there is a regular supraventricular rhythm at a rate of 120 beats/min. This demonstrates the value of having three simultaneous leads to aid in the identification of artifacts.

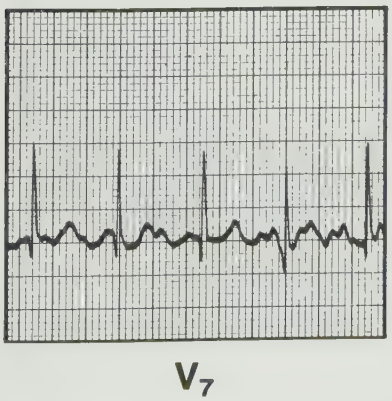

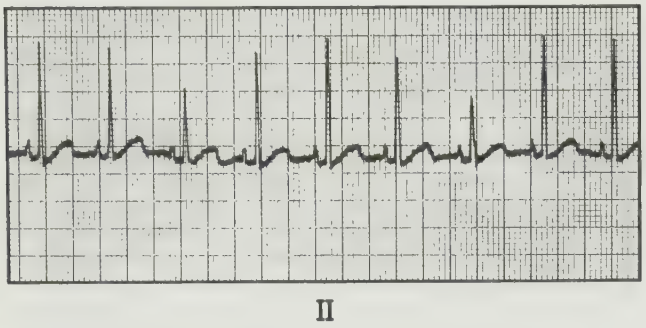

Fig. 45–70 Respiration. The QRS amplitude changes cyclically with approximately 2 sec between the smallest QRS complexes. This corresponds to a respiratory rate of 30 breaths/min.

Therapeutic Manipulation of the Patient

Chest percussion can occur at a rate of approximately 5/sec, which results in an artifact at a rate of 300 beats/min (Fig. 45–71). Open or closed chest massage adds artifactual complexes with each depression of the chest.

Properly Functioning Electrocardiographic System with "Built-in" Artifact

In certain electrocardiographic recording machines, the calibration signal is provided automatically without stopping the paper. Thus the calibration spike may be confused with parts of the true electrocardiogram and form an artifact (Fig. 45–72).

Malfunctioning Electrocardiographic System

Loss of electrode contact is usually marked by an abrupt change in the base line with an absence of cardiac depolarizations. In true asystole the base line usually does not change (Fig. 45–73).

Faulty cable shielding can cause movement artifact on the electrocardiogram.

A repetitive artifact may be produced as a result of faulty cable attachment due to low-amplitude vibration in the environment (Fig. 45–74).

Interference from 60-cycle leakage may result in artifact.

Faulty paper drive—uneven stylus marks may be present, causing the paper to appear "burned." As the paper speed varies, all parts of the P wave, QRS complex, and T wave shorten and prolong with the apparent increase or decrease in heart rate, respectively (Fig. 45–75). At the slowest abnormal paper speeds, the heart rate may appear to be faster than physiologically possible, giving a hint that this may be an artifact (Fig. 45–76).

Faulty stylus—an arc rather than a straight line is drawn for the R wave.

Incorrect stylus position or improper gain—the "isoelectric" line may be unusually flat, indicating that the stylus is at the limit of its excursion or "pegged" (Fig. 45–77A). This can be suspected by the lack of any deflection on one side of the isoelectric line, or a heavy mark at the peak of the QRS complex (Fig. 45–77B).

Current Produced from External Sources

Overhead Warmer or Respirator. Either may cause cyclic production of 60-cycle current, which may be printed on the electrocardiogram. The source of the current or electrical interference may not be identified.

The Infusion-Pump Artifact. This was originally described as a biphasic spike of 30-msec duration with a repetitive rate of 135 beats/min.[115] This artifact is similar to, but wider than, a normal bipolar cardiac pacemaker artifact. The control plunger in a defective infusion pump was the source of current leak, which was transmitted via the intravenous tubing and scalp vein to the patient and detected on the electrocardiogram. We have recently found an artifact that even more closely resembled P waves. This was again due to current leakage from an infusion pump down a nasogastric tube, through the patient and recorded on the electrocardiogram at a rate of 56/min. (Fig. 45–78).

Systematic Approach for the Recognition of Artifacts

A systematic approach is necessary for the recognition of artifacts. The following eight points are helpful in their identification.

1. The shape, amplitude or duration of the wave is atypical for a P wave or a QRS complex. The normal limits for P waves and QRS complexes are defined in the section on "The Normal Electrocardiogram." For example, many ar-

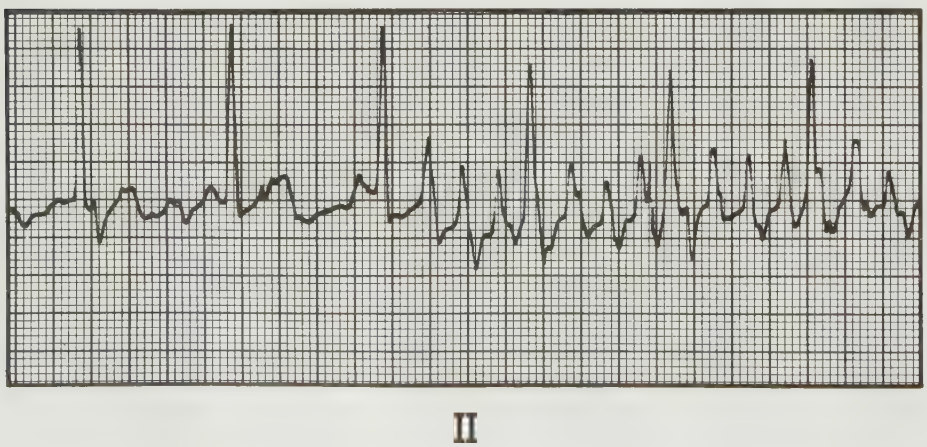

Fig. 45–71. Chest percussion. This is recorded from a 24-hr electrocardiogram and the artifact occurs at a rate of approximately 300 beats/min. Note that the P–R interval is unchanged before and during the artifact.

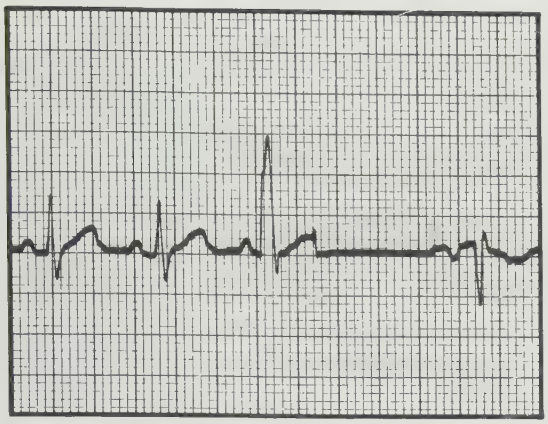

Fig. 45–72. Calibration fusion. These leads were recorded simultaneously. Most apparent in lead II is the onset of a normal QRS complex and then a further spike is introduced on top of the QRS complex. This is followed by an isoelectric segment when the electrocardiograph is not recording. This simulates a premature ventricular contraction.

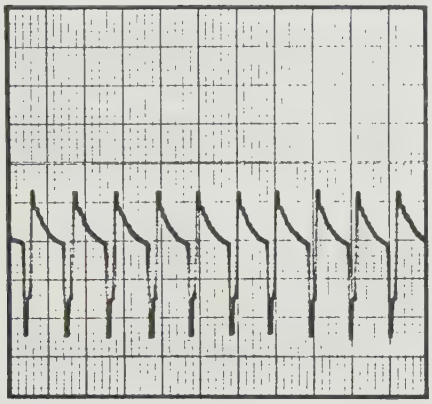
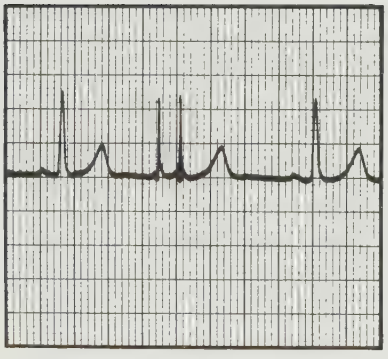
Fig. 45–73. Asystole versus loss of electrode contact. In the top tracing, there is asystole and in the bottom tracing, there is loss of electrode contact. Note the change in the base line with the loss of electrode contact.



II

Fig. 45–74. Faulty cable attachment. This artifact was eliminated when the connector between the patient cable and the electrocardiograph was secured. This presumably resulted from repetitive vibrations in the pins, which were placed loosely in the slots of the connector.



II

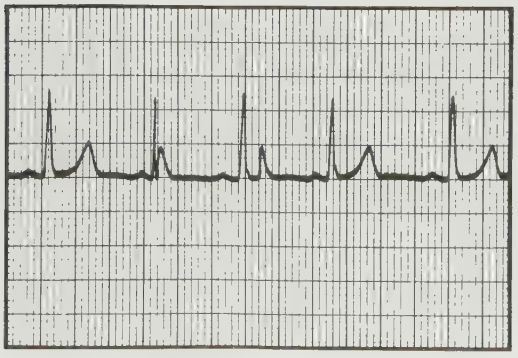


Fig. 45–75. Paper drag due to faulty paper drive. In the top tracing, the middle two QRS complexes are too narrow as compared with the others and indicate that the paper is dragging. Also, there is an uneven stylus mark causing the paper to appear burned in the third complex. In the bottom tracing, in the middle three complexes, the P–R, QRS, and Q–T intervals are all shortened to variable degrees.

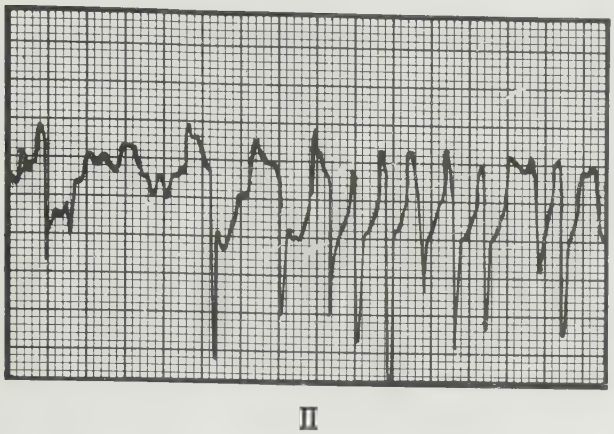

Fig. 45–76. Tape drag causing rapid and irregular rate. In this tracing from a 24-hr electrocardiogram, the rhythm is artifactually irregular, and the rate of 428 beats/min is not physiologic for a 14-yr-old.

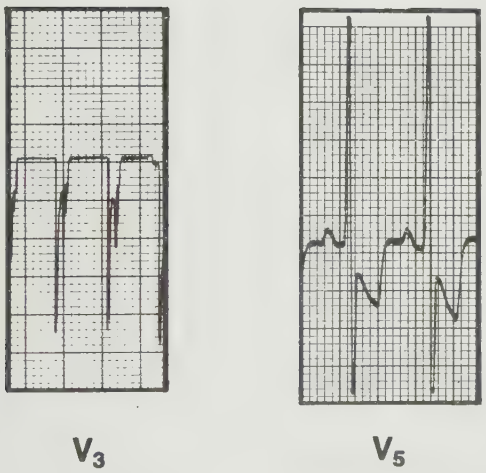

Fig. 45–77. Improper stylus position. In the tracing on the left, the isoelectric line is unusually flat and there are no complexes above this line. This indicates that the upper limit for the stylus was being reached at this point. The patient had ventricular tachycardia. In the tracing on the right, an improper gain setting has been applied such that the QRS complex is clipped at both the top and the bottom of the tracing. In cases such as these, it is impossible to tell how much larger the QRS complex would have been without changing the gain setting.

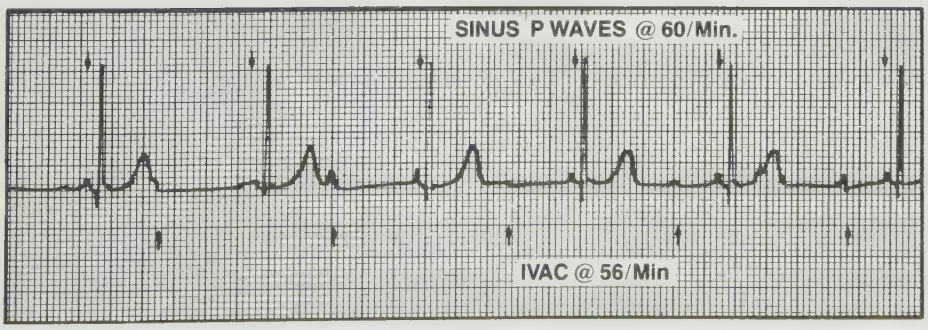

Fig. 45–78. The infusion-pump artifact. The arrows on top of the tracing demonstrate the sinus P waves occurring at a rate of 60/min. The arrows on the bottom of the tracing indicate an artifact occurring at a constant rate of 56/min, which is due to current leak from an improperly shielded infusion pump.

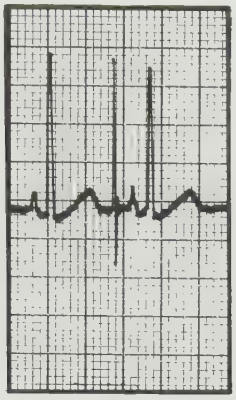
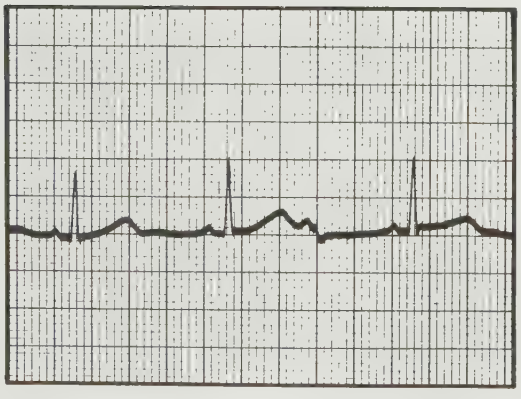


II

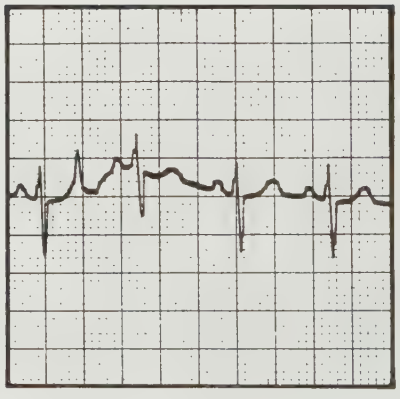
II

Fig. 45–79. Improper duration for QRS complex. Top tracing: The artifact between the two QRS complexes is too narrow to be a QRS complex and it is also not followed by a T wave. Bottom tracing: The artifact in the middle of the tracing is too wide to be a premature ventricular contraction in a 1-mo-old child. It is also accompanied by a base-line shift.



I

Fig. 45–80. This artifact has the appearance of a QRS complex but is not followed by a T wave.



III

Fig. 45–81. Base-line shift. This hiccough is suspected as an artifact because it is too large for a P wave, is not followed by a T wave, and results in a base-line shift.

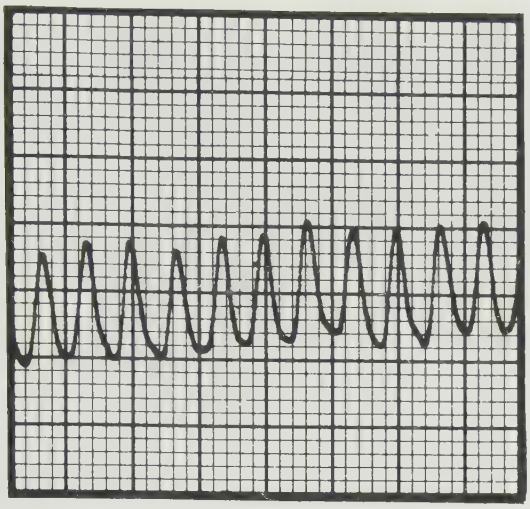


Fig. 45–82. Unphysiologically rapid rate. This tracing was recorded on a 24-hr electrocardiogram from a 6-yr-old child. While these artifacts may appear similar to QRS complexes, the rate of 480/min is not physiologic.

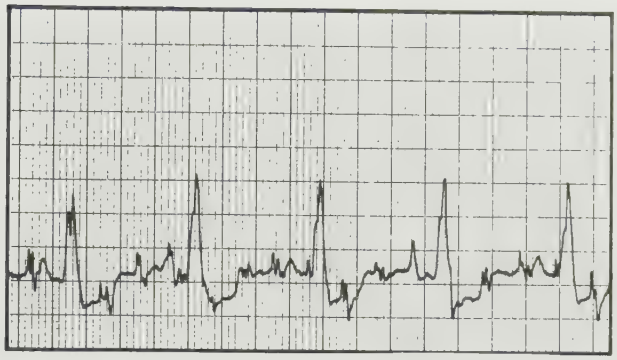

Fig. 45–84. Artifact parasystole. This tracing was recorded on a telemetry unit while a patient was brushing her teeth. The QRS complexes are regular and the artifact is somewhat irregular and occurs at approximately 300 times/min. The artifact, which simulates P waves, has a fairly regular interval between spikes, but is unrelated to the QRS complexes. Also, preceding the first, third, and fifth QRS complexes, the true P waves can be seen in the tracing.

tifacts are "narrower" than a normal QRS and some artifacts last longer than even the most prolonged bundle branch block pattern (Figs. 45–74 and 45–79).

2. If a wave has the appearance of a "QRS complex" but is not followed by a T wave, an artifact should be suspected (Fig. 45–80).
3. Artifacts may be accompanied by a shift in the base line (Fig. 45–81).
4. An artifact that repeats itself must be differentiated from tachycardia. In a repetitive artifact the rate may be too rapid to be physiologically possible. The maximum regular atrial or ventricular rate is approximately 450 beats/min in an infant (130 msec between waves) and 300/min in a child (200 msec between waves). Therefore if there is less than 130 msec between successive regular waves in an infant, or less than 200 msec in a child, an artifact should be suspected (Fig. 45–82).

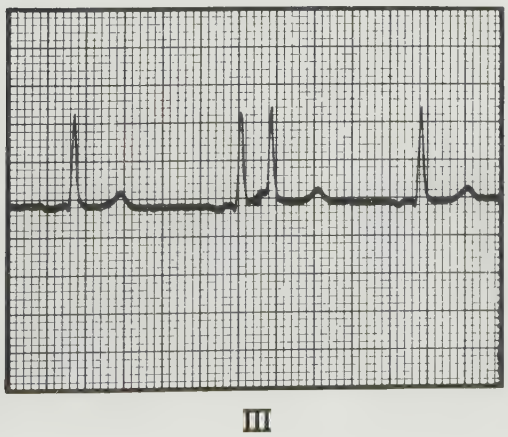

Fig. 45–83. Unphysiologically premature. This tracing was recorded from a normal 14-yr-old. The third QRS complex occurs 180 msec after the last QRS. This is not physiologic. The cause of the artifact can be established by the shift in the base line and the burned appearance to the paper. The electrocardiograph was stopped and started at this time.

A single artifact must be distinguished from a premature beat. Some artifacts occur "too early" to be physiologically possible. The normal atrial or ventricular effective refractory period is approximately 200 msec in an infant and 250 msec in a child. Thus at least this amount of time is necessary before the atrium or ventricle can depolarize again. Therefore if there is, for example, a wave that follows a QRS complex by 180 msec in a 14-year-old, this second wave is unlikely to be a QRS complex (Fig. 45–83).

5. Repetitive artifacts may simulate parasystole. The artifact will usually occur at a variable interval from the preceding P wave or QRS complex, but there may be a constant interval between the artifacts (Fig. 45–84).
6. The basic rhythm is unaffected by the artifact. An artifact may only affect part of the QRS, in which case the QRS may be "seen through" the artifact (Fig. 45–85). Alternatively, the basic R–R interval may be entirely unaffected by the artifact and the QRS "marches through" with the artifact present or absent (Fig. 45–86). In general, following an episode of supraventricular or ventricular tachycardia, the sinus node is suppressed and takes a few beats to regain its normal regular rate. Following a repetitive artifact, the sinus rate does not change, making preceding tachycardia less likely (Fig. 45–87). Finally, if a T wave is the first complex to follow a pause, the pause must have been artifactual since a T wave is unlikely without a preceding QRS complex (Fig. 45–88).
7. Artifacts may be phasic with external influences. Knowledge of the rate of the artifact may help to predict the external

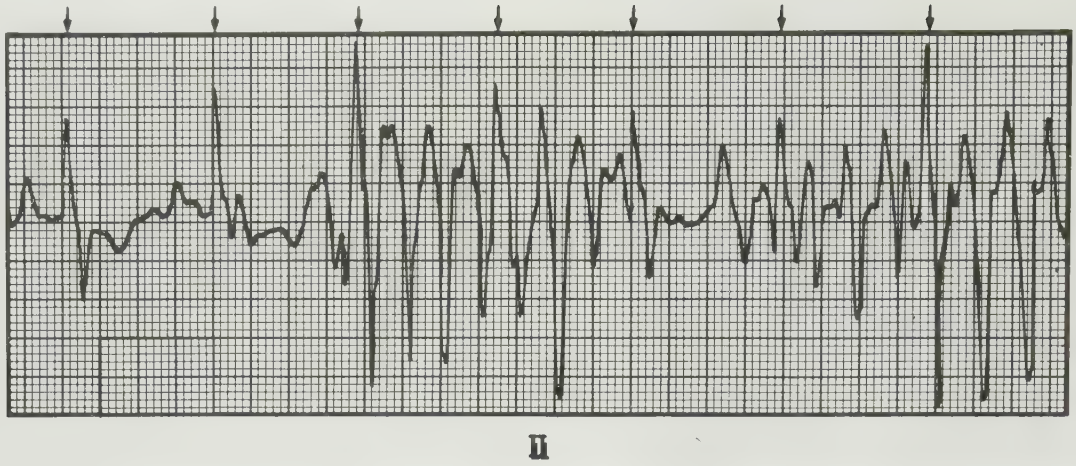

Fig. 45–85. QRS "seen through" the artifact. The arrows mark the QRS complexes, which continue undisturbed through the movement artifact.

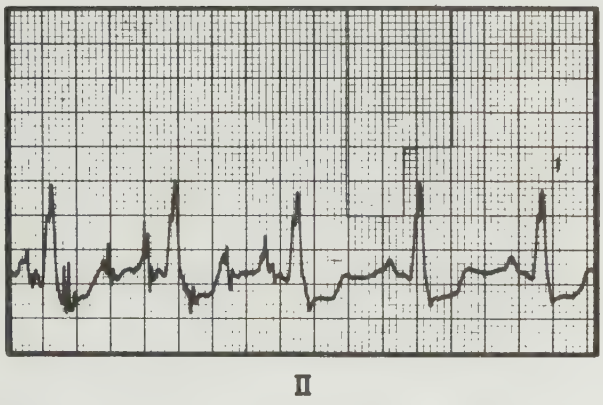

Fig. 45–86. QRS "marches through" the artifact. In the patient who was brushing her teeth during the recording in Figure 45–84, the tooth brushing stopped in this recording and the basic rhythm continued unaffected.

source. The infusion pump artifact shown in Figure 45–78 occurred at the same rate as the infusion: 56 times/min (interval, 1.07 sec between artifacts). Muscle movement related to respiration should occur between 15 and 60 times/min (interval, every 1 to 4 sec) (Fig. 45–70); or tooth brushing occurs at approximately a rate of 300/min (interval of 200 msec) (Fig. 45–84).

8. Artifacts usually occur more than once. Therefore even if a wave on the electrocardiogram cannot be positively identified as either due to depolarization of the heart or due to an artifact, further observation of the remainder of the tracing or a subsequent tracing (perhaps under different circumstances with a more rapid or slower heart rate) will usually reveal the true identity (Fig. 45–89).

Despite all the guidelines, occasionally it is impossible to distinguish artifact from arrhythmia (Fig. 45–90). In these cases clinical correlation is mandatory. A faulty interpretation of an

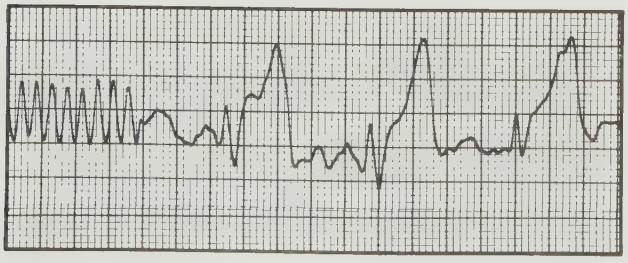

Fig. 45–87. Lack of "sinus pause." The absence of a pause in the rhythm following a rapid rate may be an indication that the rapid rate was an artifact. In this tracing, the rapid artifact stops and there is no pause in the QRS rate.

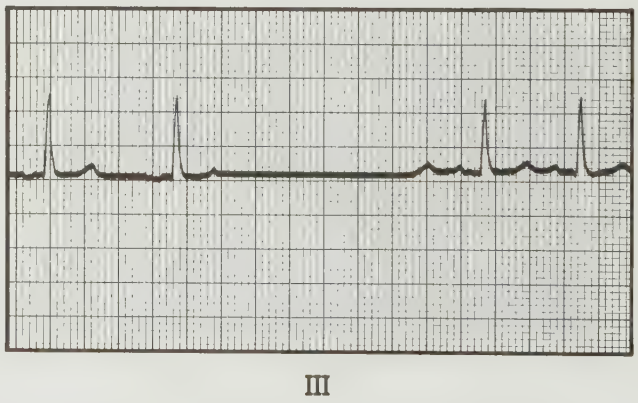

Fig. 45–88. Pause ends with a T wave. The pause in this tracing might have been real except for the undue evenness of the base line and the fact that the pause ends with a T wave, implying that there must have been a QRS complex preceding the T wave, which was not recorded.

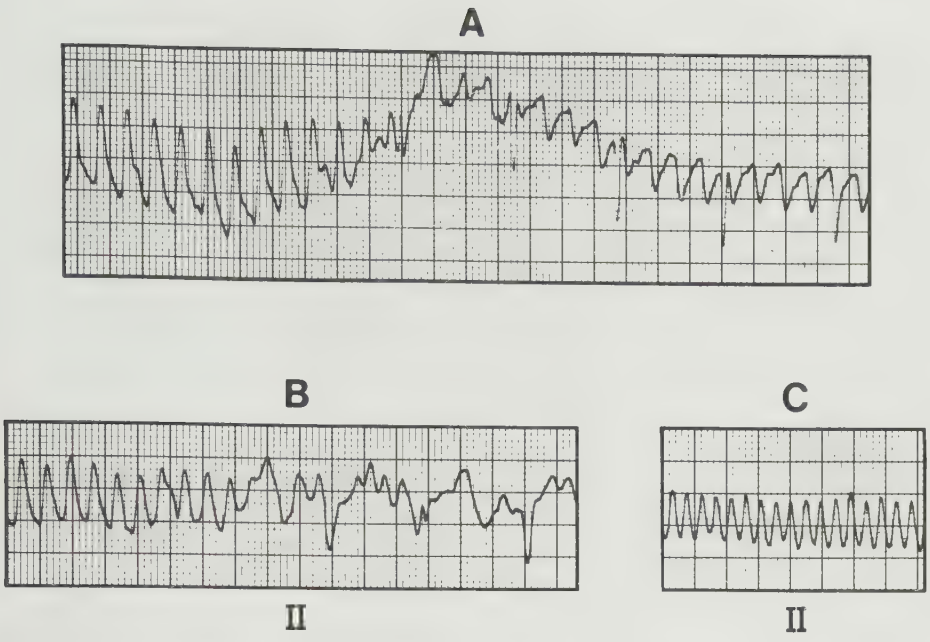

Fig. 45–89. Identification of an artifact at a different point in time. These tracings were both recorded from a 24-hr electrocardiogram. In the first tracing (A), it is not possible to identify the rhythm. It appears that there is a rapid, wide QRS rhythm that inexplicably changes to a rhythm simulating atrial flutter with block. (B) Four hours later, the artifact has a similar morphology but actually disappears before the last QRS complex in the tracing. (C) The artifact has become even smaller in size and now has an unphysiologic rate, identifying the entire process as an artifact.

artifact may cause an "electrocardiographic casualty." Sometimes these casualties are fatal.

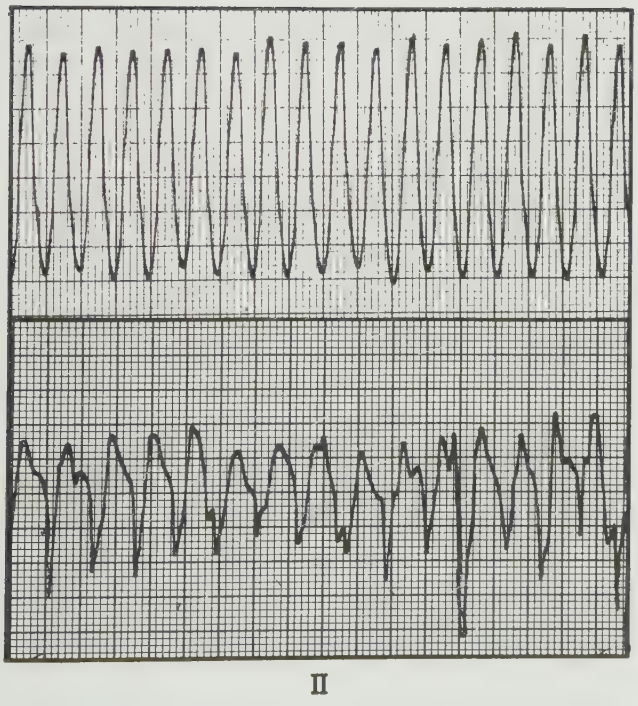

Fig. 45–90. Which is the artifact? The top tracing is ventricular tachycardia; the bottom tracing is the artifact.

CHAPTER 46

Echocardiography, Two-Dimensional and M-Mode

James C Huhta

The ability to make ultrasonic images of the heart and cardiovascular system (echocardiography) has been a major advance in pediatric cardiology in the past ten years. It has allowed for imaging of anatomy and observations relevant to ventricular function appraisal. This noninvasive modality has dramatically altered the assessment of the neonate with congenital heart disease. It may be said that this technique has slowly changed the practice of pediatric cardiology by replacing cardiac catheterization for the diagnosis of many congenital malformations of the neonate and young child. Combined with the clinical use of prostaglandin for maintenance of patency of the ductus arteriosus, echocardiography has dramatically reduced the need for emergency cardiac catheterization in the neonate.

PHYSICS OF CLINICAL ULTRASOUND

The details of this topic are presented in Chapter 33, only a brief review will be given here. Diagnostic ultrasound for imaging of tissue structures uses the amplitude of backscattered sound from tissue interfaces to construct an image. Sound is transmitted from a transducer in approximately 1000 short burst (pulses) each second. Between transmitted pulses, the returning echoes from the tissue are sensed. Ultrasonic pulses are transmitted through tissue as longitudinal waves and the length of a wave is the distance between two pulses and their respective compression waves in the tissue. The velocity of sound in the tissue is a characteristic of it and is approximately 1540 m/sec. The velocity of sound (c) is the product of the frequency of the sound and the wave length. For example, at 3 megahertz (3 million times per second) the wave length in tissue is 154,000 cm/sec and the wave length is the quotient of the two: 0.051 cm or 0.51 mm. This parameter is an important factor in the theoretical limitation on the resolving power of ultrasound and illustrates that better resolution requires higher insonating frequencies. The returning ultrasound echoes are of a much lower amplitude than those transmitted and are on the order of 0.01% (−40 decibels) of the transmitted intensity. This is because tissue absorption increases with increasing frequency. Therefore, a low frequency transducer will penetrate tissue well but have lower optimal resolution. An ultrasonic display is possible because the time for returning echoes can be converted into distance from the transducer by assuming a constant velocity of ultrasound in tissue.

Principles of Imaging

The concept of resolution may be thought of in three dimensions: axial, lateral, and azimuthal. Axial resolution is the ability of the beam to separate two objects lying along the axis of the beam and is determined primarily by the insonating frequency. Lateral resolution is the ability to separate two objects lying side by side and is determined primarily by the transducer crystal focusing. Azimuthal resolution in the third dimension is also dependent on the beam width. A-mode imaging refers to a series of amplitude spikes representing the returned echo reflections, which are separated by a distance proportional to the time difference in the returning echoes. Turning these spikes on end, so to speak, allows us to see the structure causing the reflections as a dim or bright dot, depending on the amplitude and the motion of the dots with time. An M-mode echo is the time-dependent display of the motion of returning echoes as described above. Alternatively, after individ-

ual lines of ultrasonic data are built up into an image, these can be observed on a cathode ray oscilloscope and the motion of an ultrasound plane is adjusted to allow visualization in real time of moving structures (two-dimensional echocardiography).

DIAGNOSIS OF CONGENITAL HEART DISEASE

Echocardiography has been and will continue to be the mainstay of diagnosis of congenital heart disease in neonates, infants, and children, and it will likely become more important with time as further experience is accumulated. Pioneered by Van Praagh[1] for a description of congenital cardiac defects at the autopsy table, the segmental approach has since been applied to cardiovascular diagnosis by various methods. A logical analysis of cardiovascular anatomy requires a step-by-step segmental approach. This is particularly true in complex congenital malformations where some portions of the heart may be absent or malpositioned. Several recent papers have outlined this concept in the angiographic diagnosis of cardiac anatomy.[2] Data for this interpretation is obtained by combining findings from several echocardiographic windows.[2,3] A complete, step-by-step approach to cardiac diagnosis includes atrial situs diagnosis, identification of chambers and their interconnections, plus a systematic assessment of valves, septa, coronaries, systemic and pulmonary veins, and aortic anatomy.

In review articles, Sanders[4] and Silverman[5] pointed out the need for a complete segmental examination both inside and outside of the heart. The diagnostic accuracy of two-dimensional echocardiographic imaging in children has been proven in several prospective studies including that of Gutgesell et al.[6] In 250 consecutive children with congenital heart disease, there was one surgically significant error in diagnosis.[7] The segmental approach based on the condition that all aspects of abnormal cardiovascular morphology can be broken down into discrete, mutually exclusive descriptors so that any complex congenital malformation can be described unambiguously. Therefore, such a schema must include information on the presence, position, and connection of each cardiac segment.[8] Classically, three segments have been recognized: the atria, the ventricles, and the great arteries. In complex malformations it is necessary to have a detailed approach to segmental diagnosis that can be utilized for noninvasive examination in any setting. By describing sequentially the anatomic segments and indicating normal or abnormal, a complete description of the cardiac anatomy is possible.

Echocardiography is purely a tomographic anatomic tool, but it also provides dynamic information concerning cardiac function and structure. Doppler echocardiography can provide functional information that is not available from any other methodology; for example, atrioventricular valve regurgitation can be diagnosed. However, the grading of regurgitation is currently difficult and depends on many technical and physiologic factors. In addition to seeing a ventricular septal defect, the jet of left-to-right shunt can be detected by pulsed Doppler, the pressure gradient quantitated by continuous-wave Doppler, and spatially oriented by color Doppler. Function description should be integrated into this approach—using the anatomic segment as the finding and the functional aspect as the modifier. For example, left ventricular shortening fraction is appended to the anatomic finding of left ventricular dilation, or "pulmonary valvular stenosis-severe, peak Doppler velocity of 4.2 meters per second." (See Chapter 34.)

Historically, nearly all early two-dimensional echocardiographic literature was oriented toward a "view approach" to congenital cardiac lesions, that is, the appearance of a given cardiac lesion in a standard parasternal, apical, or subcostal scan. This process can lead to diagnostic errors, e.g., a scan of aortopulmonary window from the right ventricular outflow tract can simulate origin of the aorta from the right ventricle (transposition of the great arteries). It is mandatory to integrate various views scanning from one to another from all echocardiographic windows in order to perform a complete anatomic examination. Although the echocardiographic examiner with experience learns the normal appearances of the heart without congenital defects from various echo windows, a structure oriented or anatomic approach is always superior to one based on standardized views.

Situs

Diagnosis of cardiac position and atrial-visceral situs using echocardiographic signs is a standard part of the assessment of congenital heart disease. Atrial situs and atrial morphology are diagnosed together and there are four possibilities: solitus (normal), inversus, and two types of heterotaxy, right atrial isomerism or left atrial isomerism. For example, if the situs is solitus, then the morphologic right atrium is on the right and the morphologic left atrium is on the left. Abnormal atrial situs is frequently associated with cardiac malposition, such as dextrocardia.[9] Both can be diagnosed by obtaining a short axis scan of the abdomen, identifying the spine and the left and right chest cavities. The location of the cardiac apex is important to identify for later scanning from the apex. Subcostal scanning above the diaphragm immediately shows the position of the cardiac apex. From this scan below the diaphragm, the position of the inferior vena cava and aorta can usually be identified. The descending aorta and the inferior vena cava are symmetrically oriented with respect to one another with the inferior vena cava to the right in situs solitus and to the left in situs inversus.[10] In right atrial isomerism the aorta and the inferior cava run together on either side of the spine with the cava anterior (Fig. 46–1). A venous structure that courses behind the aorta and does not enter the heart suggests azygous continuation of the inferior vena cava, which is associated with left atrial isomerism. Such patients nearly always have anomalous hepatic venous connection separately to the heart. Occasionally, atrial appendage morphology can be identified and the diagnosis of atrial situs confirmed directly (Fig. 46–1). A broad-based atrial appendage is usually a morphologic right appendage and a narrow-based appendage is morphologic left. Symmetrical appendages suggest atrial isomerism (Fig. 46–2). A prospective study of the accuracy of indirect methods showed a sensitivity of 100% and a specificity of 99% for detection of abnormal situs by echocardiography using all the above anatomic clues.[11]

Atrioventricular Connection

The diagnosis of connection of the atria and ventricles (atrioventricular connection) requires knowledge of the atrial morphology (see above) and the ventricular morphology (Fig. 46–3). The morphologic left ventricle can be identified by its usual ellipsoidal appearance, two papillary muscles, mitral-semilunar continuity, and the typical mitral valve "fishmouth" appearance.[12] The most reliable criterion for identification of the morphologic right ventricle is tricuspid valve chordal attachments to the septum.[13]

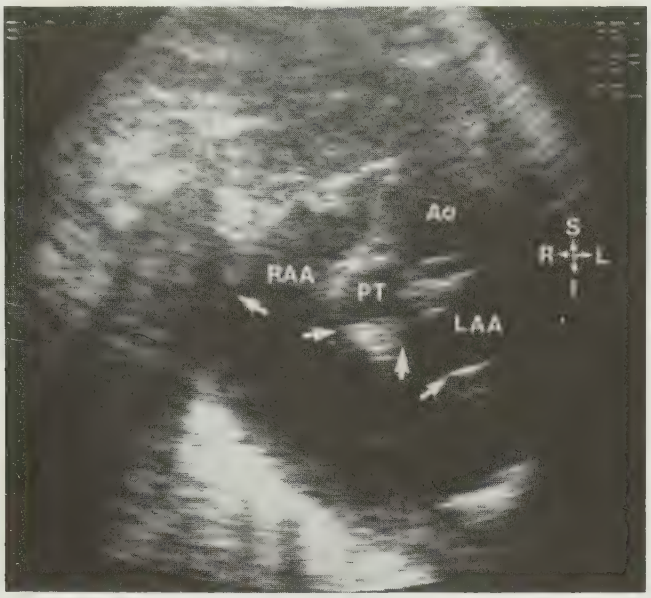

Fig. 46–1. High parasternal imaging of the great arteries (aorta-Ao and pulmonary trunk-PT) showing the normal morphology of the right (RAA) and left (LAA) atrial appendages. I = inferior; L = left; R = right; S = superior; Ao = aorta.

Fig. 46–2. High parasternal imaging of bilateral right atrial appendages (RAA) resembling "dog ears" in a neonate with pulmonary atresia. Ao = aorta. (Reproduced with permission from Huhta, J.C.: Pediatric Imaging/Doppler Ultrasound of the Chest. Philadelphia, Lea & Febiger, 1986, p. 172.)

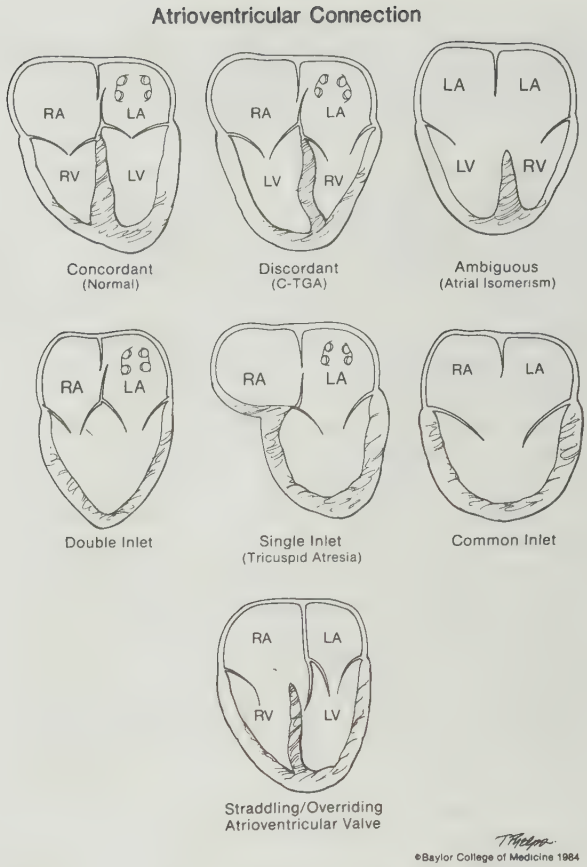

Fig. 46–3. From an apical approach the diagnosis of the atrioventricular connection can be made. *Top row:* In normal (concordant) atrioventricular connection the right atrium (RA) connects normally to the right ventricle (RV). The morphologic left atrium (LA) connects to the morphologic left ventricle (LV). Discordant atrioventricular connection is found in corrected transposition of the great arteries (C-TGA). The right atrium connects to the left ventricle and the left atrium to the right ventricle. In such patients, there is also ventriculoarterial discordance (see below). Ambiguous atrioventricular connection occurs when bilateral left or right atria are present and there are two ventricles. *Middle row:* Univentricular atrioventricular connection is where all the atrial connection is to one ventricle. This abnormal connection may be via two valves (double inlet) (left figure), single inlet with mitral or tricuspid atresia (middle figure), or common inlet where the left and right atria drain to one ventricle via a common AV valve. In rare anomalies with severe straddling or an overriding of an atrioventricular valve, one atrium may drain to more than one ventricle. (Reproduced with permission from Huhta, J.C., et al.: Segmental analysis of congenital heart disease. Dynamic Cardiovasc. Imag. J., *1*:119, 1987.)

There are four possibilities for atrioventricular connection: 1) concordant; 2) discordant; 3) univentricular: single inlet (tricuspid or mitral atresia), double inlet (Fig. 46–4), and common inlet; and 4) ambiguous (in the case of two ventricles with atrial isomerism). When the morphologic right atrium connects normally to the morphologic right ventricle and the left atrium connects to the left ventricle, there is atrioventricular concordance (normal). When this connection is reversed and the morphologic right atrium connects to the morphologic left ventricle, there is atrioventricular discordance, sometimes referred to as ventricular inversion.[13] Pa-

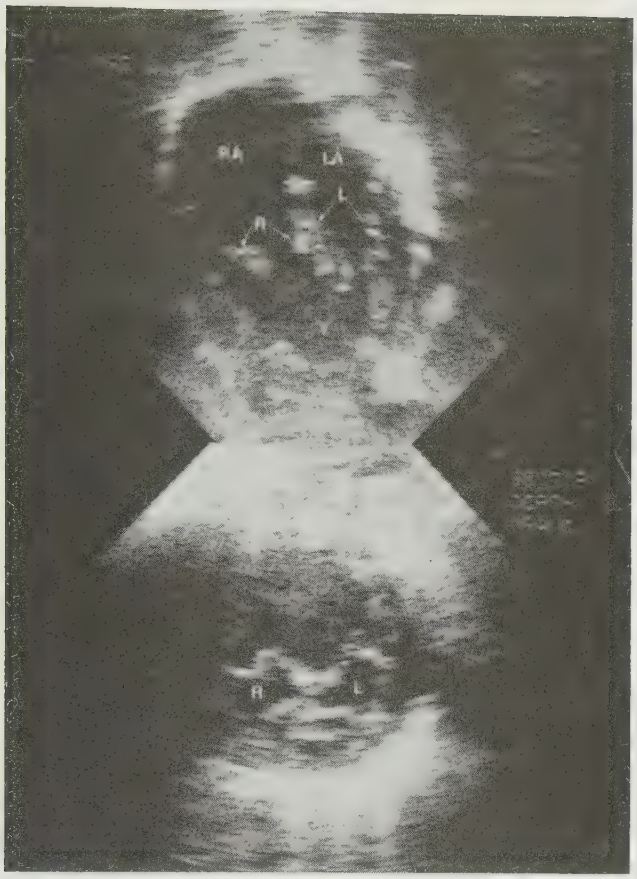

Fig. 46–4. Double inlet ventricle (V) from an apical (upper panel) and short axis scan (lower panel). Both the left (LA) and the right (RA) connect to the same ventricle.

tients with such abnormalities may present with complete AV block and have a high incidence of associated congenital cardiac malformations such as ventricular septal defect and pulmonary stenosis and usually also have ventriculoarterial discordance (see below). Rarely, atrioventricular discordance may occur while the ventriculoarterial connection is normal. When the majority of atrioventricular connection is to one ventricle, the connection is univentricular via either one valve (single inlet with atresia of the other valve), double inlet (two atrioventricular valves), or common inlet (via a common atrioventricular valve). Common inlet ventricle is part of one end of the spectrum of atrioventricular septal defect (AV canal) where there is hypoplasia of one of the ventricular chambers and atrioventricular connection is predominantly to the other.[14]

The accuracy of echocardiographic imaging in the diagnosis of atrioventricular connection is unsurpassed by other modalities.[15,16] Occasionally, an inexperienced observer may observe a common inlet that has a common (four leaflet) valve and confuse it with a single inlet. After experience with imaging the variations of atrioventricular septal defect this should not present problems.[17] Identification of the lower atrial septum unequivocally identifies the crux of the heart and points to a single inlet with atresia of the other valve.

Ventriculoarterial Connection

Ventriculoarterial connection is the manner in which the great arteries and semilunar valves connect to the ventricular outflow tracts (Fig. 46–5). There are four possibilities: concordant (normal), discordant (right ventricle to aorta and left ventricle to pulmonary trunk), double outlet (usually right ventricle), or single outlet (with aortic or pulmonary atresia or truncus arteriosus). Normally the morphologic right ventricle connects to the pulmonary valve and the morphologic left ventricle connects to the aortic valve.

Ventricular Morphology

Determination of the atrioventricular and ventriculoarterial connections requires a knowledge of ventricular morphology and this

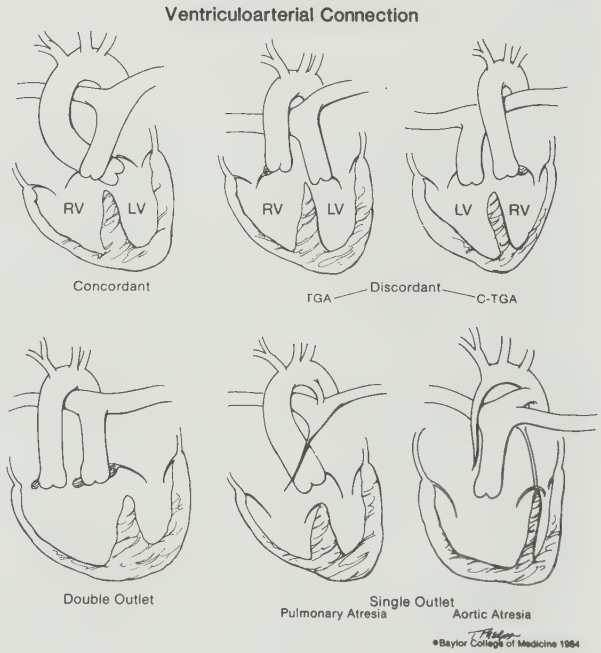

Fig. 46–5. Diagnosis of ventriculoarterial connection. Normal (concordant) ventriculoarterial connection connects the left ventricle to the aorta and the right ventricle (RV) to the pulmonary artery. Discordant ventriculoarterial connection may occur with transposition such that the right ventricle connects to the aorta and the left ventricle to the pulmonary artery. Both great arteries may arise from either ventricle but most commonly, a double outlet ventricle is a double outlet right ventricle (left lower figure). Single outlet hearts include those with truncus arteriosus but also those with pulmonary or aortic atresia (middle and right lower figures). (Reproduced with permission from Huhta, J.C., et al.: Segmental analysis of congenital heart disease. Dynamic Cardiovasc. Imag J., *1*:120, 1987.)

should be one of the first steps in noninvasive diagnosis. Criteria for a morphologic left ventricle by echocardiography includes insertion of the mitral valve at the base of the heart farther from the cardiac apex than the tricuspid valve (so-called "offsetting" of the valves), two normally placed left ventricular papillary muscles, mitral semilunar continuity, typical elliptical shape, smooth wall septum, and fishmouth appearance of the mitral valve with two commissures. In the absence of typical offsetting of the atrioventricular valves and with cardiac malposition, the trabecular pattern of the ventricles can sometimes be recognized, i.e., smooth-walled in the left ventricle and coarser, more heavily trabeculated, in the right ventricle. The appearance of the ventricular outflow tracts may aid in ventricular morphology diagnosis and should be noted as part of the segmental approach. There is normally continuity between the mitral valve of the left ventricle and the aortic valve, whereas there is muscle separating the tricuspid and the pulmonary valve in the right ventricular outflow tract.

The most common type of abnormality of ventriculoarterial connection is transposition of the great arteries (TGA) where the morphologic right ventricle gives rise to the aorta and the morphologic left ventricle gives rise to the pulmonary trunk (ventriculoarterial discordance) (Fig. 46–6). In order to diagnose this abnormality, it is necessary to identify the great vessels. The pulmonary artery is identified by its branching pattern into left and right pulmonary arteries and ductus arteriosus, and the aorta is identified by the carotid and subclavian arteries. Both great vessels may originate from either ventricle (usually the morphologic right ventricle) creating double-outlet right ventricle. If the aortic or pulmonary valve is atretic, then a single-outlet ventricle is the result. Another example of single outlet is truncus arteriosus where there is a single trucal valve originating from the ventricular mass but overriding of the ventricular septum. The ventriculoarterial connection is designated single outlet with overriding truncal valve. In complex malformations including right atrial isomerism with the asplenia syndrome, atrioventricular septal defect is often associated with double-outlet right ventricle (Fig. 46–7). With tetralogy of Fallot there is often overriding of the aortic valve so

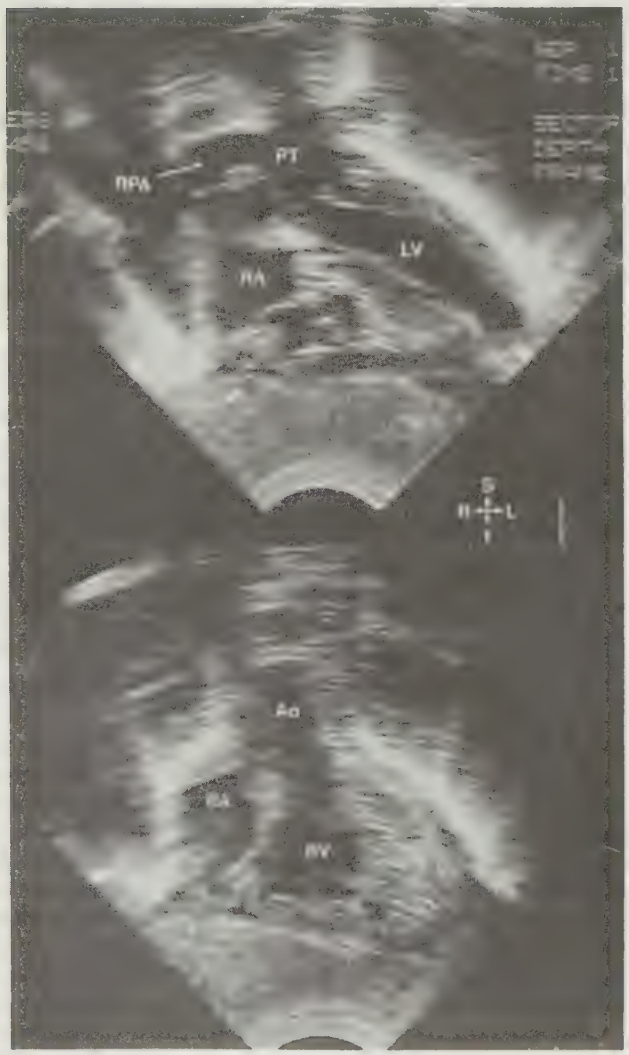

Fig. 46–6. Subcostal imaging of a neonate with transposition of the great arteries. The left ventricle (LV) connects to the pulmonary trunk (PT) (upper panel) and the right ventricle connects to the aorta (Ao). RA = right atrium.

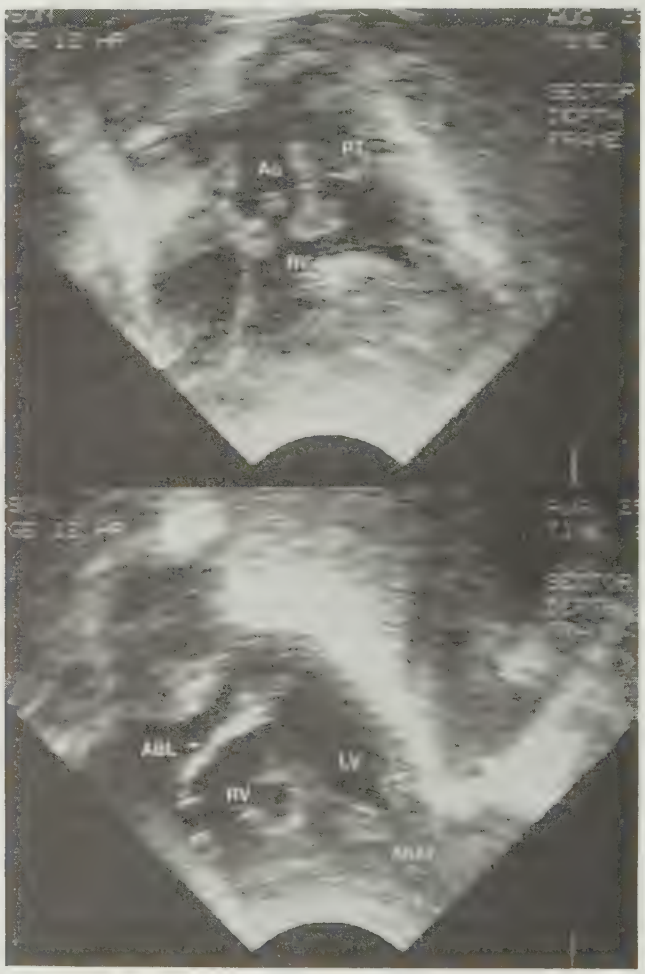

Fig. 46–7. Subcostal scanning of a neonate with double outlet right ventricle with the aorta (Ao) to the right of the pulmonary trunk (PT). The ventricular anatomy is complete atrioventricular septal defect with a freefloating anterior bridging leaflet (ABL). LV = left ventricle.

that nearly half of the aortic valve anulus appears to arise from the right ventricle. There is mitral aortic continuity and, except for the rare circumstance where there is more than 50% overriding of the aortic valve, the ventriculoarterial connection in tetralogy of Fallot is concordant.

Reports in neonates with abnormalities of ventriculoarterial connection and in children with transposition of the great arteries show that echocardiography is highly accurate in this type of abnormality.[18,19,20] Consequently, a newborn with cyanosis due to transposition should virtually never be discovered during the catheterization and some such neonates have had surgery without catheterization.

Ventricular and Atrial Septae

Atrial Septum

Prior to birth the atrial septum usually bows toward the morphologic left atrium due to the significant blood flow to the left heart via the fossa ovalis (Fig. 46–8). Such aneurysmal bowing of the atrial septum after birth may be a clue to right-to-left intra-atrial shunting (or left-to-right if it is bowing toward the right atrium). Results by imaging alone in detection of atrial septal defect are good.[20] The presence of a thin strand of septal tissue in what appears to be a common atrium is highly suggestive of right atrial isomerism. The upper atrial septum where a sinus venosus defect may occur can be difficult to evaluate in the older child but color flow mapping has improved the results in all forms of atrial septal defect.[21] In the prospective study of Gutgesell there was one false positive and one false negative for sinus venosus defect.[6] One practical application of echocardiography is evaluation of the results of creation of an atrial defect by balloon atrial septostomy or blade and balloon techniques (Fig. 46–9).

Ventricular Septum

Defects of the ventricular septum can be analyzed using multiple tomographic imaging approaches and defects can be separated into those which are perimembranous, muscular, and subarterial (see Fig. 46–4).[22] An inlet perimembranous defect (AV canal-type defect) can be distinguished from AV canal by the presence of the central fibrous crux (Fig. 46–10). Small muscular ventricular septal defects and even a significant defect in the perimembranous region may be missed by imaging alone (Fig. 46–11); color Doppler has substantially improved the ability to detect muscular defects, but the sensitivity in detection of a muscular defect in older children with another large VSD was only 72% in one study.[23] The details of interventricular communications in the trabecular septum require angiographic definition. At present, echocardiography with color Doppler appears adequate only to detect the defect rather than provide details.

Valves

Atrioventricular Valves

A wide variety of malformations may involve the left or right atrioventricular valves. From an anatomic perspective, either the

Fig. 46–8. Five different types of atrial septal morphology. Intact and secundum defect (top) and common atrium (CA), primum defect and atrial strand (S) (lower). LA = left atrium; RA = right atrium. mitral or tricuspid valve may be abnormal in position, stenotic, regurgitant, have a cleft, be hypoplastic, exhibit prolapse, straddling, or Ebstein's malformation. The pattern of opening on real-time imaging is augmented by the Doppler or M-mode functional assessment. Virtually all forms of congenital anatomic abnormality of the mitral valve can be recognized immediately by imaging alone with the possible exception of supravalvar mitral ring where the ring may be adherent to the valve tissue. The presence of normal papillary muscles in supravalvar mitral ring differentiates it from most other congenital forms of mitral stenosis. Color flow mapping and continuous-wave Doppler can effectively evaluate the hemodynamics of AV valve stenosis better than invasive techniques. Regurgitation of AV valves can be detected with excellent sensitivity and progress is being made with color Doppler at grading the severity of regurgitation of AV and semilunar valves.[24]

Semilunar Valves

Semilunar valve assessment is aimed at detecting obstruction or regurgitation at either the aortic or pulmonary valve. Because the size of a valve anulus will normally reflect the flow through it, hypoplasia of the valve anulus usually is present with severe stenosis and imaging echocardiography may detect this or the doming of a stenotic valve or muscular hypertrophy of infundibular

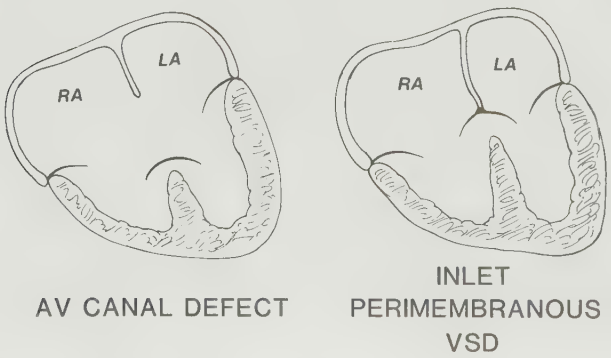

Fig. 46–10. Comparison of atrioventricular (AV) canal defect and inlet perimembranous ventricular septal defect (VSD). In the latter defect the fibrous crux is present.

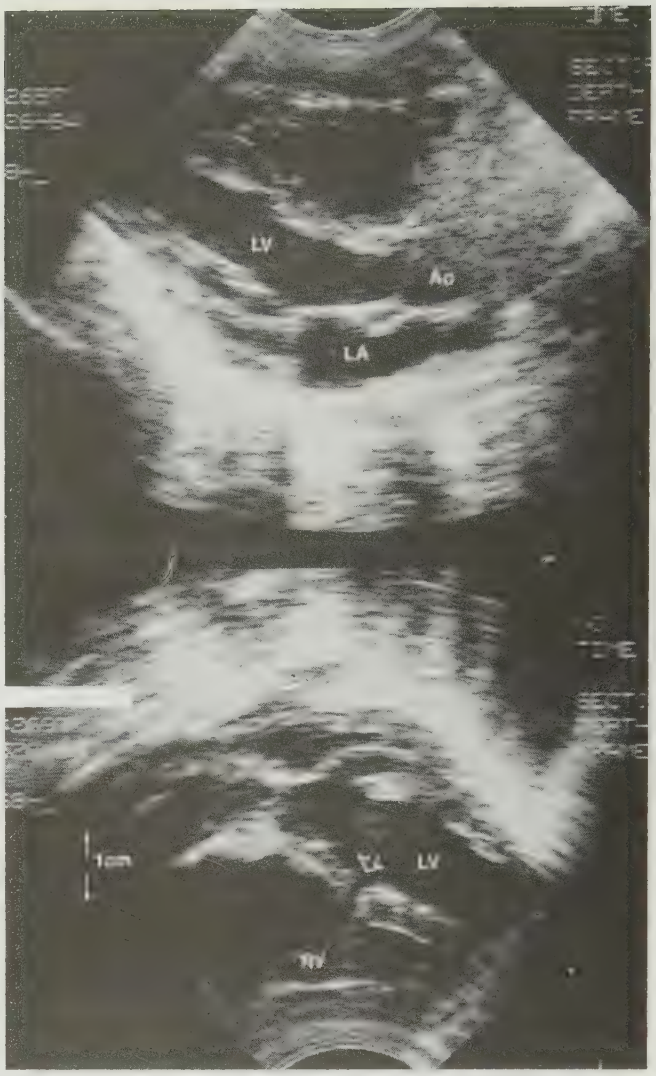

Fig. 46–11. Parasternal (upper) and subcostal (lower) imaging of a small muscular septal defect above the insertion of the moderator band. Ao = aorta; LA = left atrium; LV = left ventricle.

stenosis. Likewise, the abnormal coaptation of semilunar valve cusps indicate regurgitation (Fig. 46–12). In congenital heart disease there was a 77% sensitivity of pulmonary stenosis detection with a specificity of 97%.[6] Both of these numbers are now approaching 100% by application of pulsed and continuous wave techniques.[25] Because of the variability of cardiac output through a stenotic valve, the flow-independent method of the continuity equation looking at the mean velocity may be more useful.

Systemic Veins

Systemic Venous Connections

Normal inferior and superior vena cavae connecting to the right atrium are highly indicative of normal systemic venous connection to the morphologic right atrium. It is important to identify the inferior vena cava connecting to the heart and extending into the abdomen so that hepatic veins connecting separately are not mis-

Fig. 46–12. Abnormal aortic valve coaptation (open arrow in the lower panel) with aortic regurgitation secondary to subacute bacterial endocarditis. AAo = ascending aorta; LV = left ventricle.

taken for it. Systemic venous return which is abnormal in situs solitus may be normal or "usual" in cases where the situs is not solitus. Systemic venous return may be typical of the atrial situs (for example, azygous continuation with left atrial isomerism). Each of the systemic venous segments, including the right superior vena cava, the left superior vena cava, the inferior vena cava, coronary sinus, and hepatic veins should be examined individually. A prospective assessment of this approach showed a sensitivity of over 95% for each segment with the exception of the smaller bridging innominate veins.[26]

Systemic Venous Anomalies

A persistent left superior vena cava (Fig. 46–13) can be detected by echocardiography and confirmed by contrast studies; however, if it appears that the superior vena cava may connect to the left atrium or drain to this site due to unroofing of the coronary sinus, then angiographic confirmation is useful (see Chapter 84 on Systemic Veins).

Pulmonary Veins

Each pulmonary vein must be imaged in a sequential fashion. A four-chamber view will often reveal at least two pulmonary

Fig. 46–13. Persistent left superior vena cava (LSVC) passing anterior to the left pulmonary artery (PA) in a child with corrected transposition.

veins connecting to the left-sided morphologic left atrium, and the right veins can be seen individually from suprasternal scans. Total anomalous pulmonary venous connection can be detected with 85 to 97% sensitivity depending on the experience of the examiner.[6,27] Although accurate diagnosis of isolated total anomalous pulmonary venous connection can be made in neonates and infants, the ability of any noninvasive tool to exclude isolated partial anomalous connection of one vein has not been tested. Color Doppler adds a significant increment in confirming the presence of pulmonary venous flow in the location where the vein is thought to be connecting and the detection of pulmonary venous obstruction is dependent on Doppler.[28]

Direct visualization of all four pulmonary veins is mandatory prior to corrective surgery for any defect but especially those associated with anomalous pulmonary venous connection such as atrial septal defect. Any deviation from usual should prompt complete angiographic study. Patients with atrial isomerism usually have abnormalities of pulmonary venous connection and often require angiography prior to palliative surgery.

Coronary Arteries

A segmental approach is necessary for evaluation of the coronary arteries.[29] With the exception of aneurysm detection in the proximal coronary arteries in Kawasaki disease, the detection of the origin of the common left or right coronary artery, ultrasonography is limited in the definition of abnormalities of the coronary circulation. In the presence of a coronary artery fistula, the enlargement of one of the coronaries can usually be detected. In our experience, an isolated coronary fistula can be repaired without bypass and the entry site can be defined with color Doppler.

Anomalous origin of one or both coronaries from the pulmonary trunk can be detected with high specificity, especially in combination with Doppler,[30] but the sensitivity is not adequate in neonates. The use of 7.5 and 10 MHz transducers can improve these results. Any electrocardiographic evidence of coronary insuffi-

ciency should prompt immediate coronary angiography if surgical intervention is contemplated in anomalous coronary artery.

All patients with tetralogy of Fallot should have definition of the coronaries to define the origin of the left anterior descending branch prior to a right ventriculotomy. Future work in imaging the coronary artery anatomy in tetralogy of Fallot and transposition may help to define the coronaries without need for angiography.

Aorta

Segmental analysis of the aorta includes assessment of the ascending aorta, aortic arch branching, the aortic isthmus, and the descending aorta. Echocardiography is highly accurate in the diagnosis of abnormalities of the aorta in neonates, infants, and children (sensitivity 95%, specificity 99%). Each segment of the aorta is in a slightly different tomographic plane requiring a sequential, segmental approach.[31] Normal branching of the right innominate artery indicates a left aortic arch with normal branching (Fig. 46–14). Such branching of an innominate artery to the left indicates a right aortic arch with mirror image branching (Fig. 46–15). A patent ductus arteriosus is the most common abnormality detected in examination of the aorta and the morphology of the ductus may be helpful. For example, in pulmonary atresia, the ductus is horizontal, unlike normal (Fig. 46–16). The sensitivity of two-dimensional imaging alone in detection of ductus is only 83%.[6]

Coarctation of the aorta, which has a typical appearance in the

Philadelphia, Lea & Febiger, 1986, p. 115.)

neonatal period including hypoplasia of the transverse aortic arch, may be diagnosed by echocardiography.[32] This appearance plus the presence of right ventricular enlargement make the diagnosis of coarctation of the aorta possible. The typical Doppler pattern will confirm the diagnosis. In patients with a large ventricular septal defect, the status of the aorta should always be investigated to exclude coarctation. In adults, the segmental analysis of the aorta is less reliable[33] so that Doppler techniques have significantly improved the detection of coarctation in cases where imaging is poor.

Systemic Arteriovenous Fistulae

Systemic arteriovenous fistulae cause enlargement of the artery feeding the fistula and generalized enlargement of the aorta. Pulmonary sequestration and hepatic and cerebral fistulae are the most common systemic fistulae. Sequestration of the lung and other fistulae causing an obligatory shunt can be detected by careful technique and may simulate coarctation of aorta due to the aortic isthmus morphology. Angiography is required for definition of the small vessel anatomy of the fistula before surgery.

Pulmonary Arteries

The most common abnormality of the pulmonary arteries that is indicative of congenital heart disease is pulmonary artery hypoplasia (Fig. 46–17). The pulmonary arteries normally are confluent in the midline and this detail of anatomy has importance in planning a palliative approach to cyanotic congenital heart disease.[34,35] Abnormalities of origin of the pulmonary arteries as well as their size may occur. In severe right ventricular outflow tract obstruction in neonates, pulmonary artery hypoplasia is associated with a reciprocal increase in the size of the aorta so that the ratio of size of the pulmonary arteries to the aorta may be useful in the diagnosis of this abnormality (Fig. 46–18). Diagnosis of the details of the distal pulmonary arteries requires angiography. Magnetic resonance imaging may be helpful in this area. A pulmonary arteriovenous fistula presents with cyanosis and enlargement of the pulmonary arteries and veins on echocardiography and should be confirmed by angiography.

Pulmonary atresia-VSD with major aortopulmonary artery collaterals may be difficult to evaluate. The neonate with pulmonary atresia and ventricular septal defect with collaterals can be differentiated from one with ductus-dependent pulmonary supply by imaging the ductus and well-developed confluent pulmonary arteries. All patients with collateral arteries and multifocal pulmonary supply must have complete angiography prior to any operation.

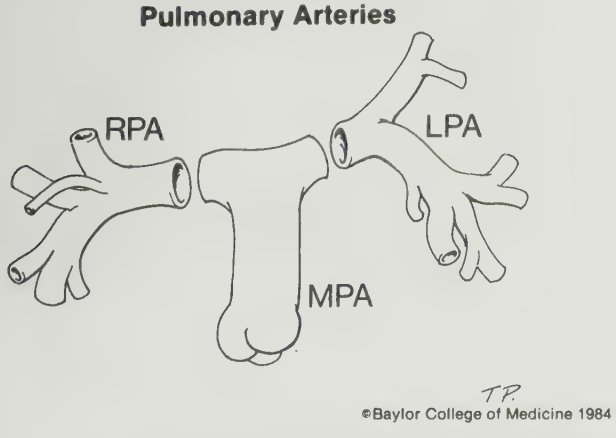

Fig. 46–17. Schematic of the segmental approach to the pulmonary arteries. The main, left and right pulmonaries can be imaged in turn from parasternal and suprasternal scans.

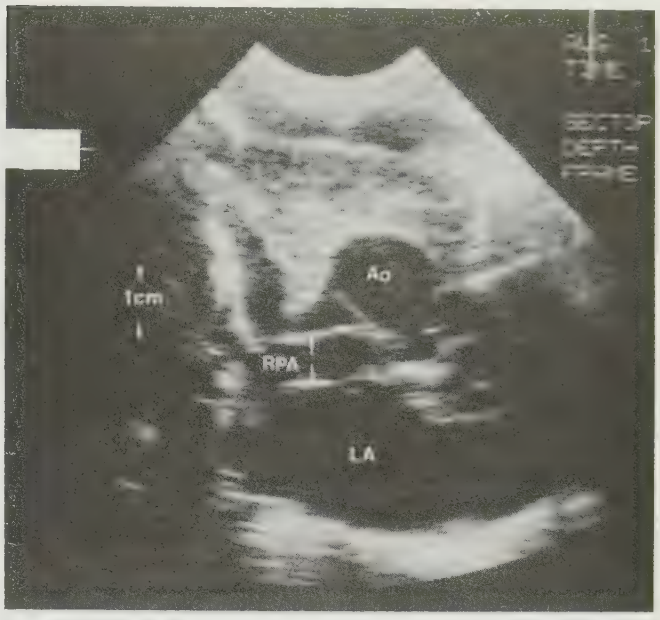

Fig. 46–18. Suprasternal imaging of the right pulmonary artery (RPA) in a neonate with pulmonary stenosis. The artery passes above the left atrium (LA) and posterior to the superior vena cava.

Example of a Clinical Examination

A 26-month-old child was noted to have a heart murmur and the electrocardiogram was "unusual." An echocardiogram was ordered to exclude congenital heart disease. The imaging examination was performed in segmental fashion beginning with the atrial situs determination (Fig. 46–19). The aorta was on the left in the abdomen and the inferior vena cava was on the right connecting normally. The right atrial appendage appeared to be broad-based and normal, suggesting situs solitus, and the position of the aorta and pulmonary trunk were reversed (Fig. 46–20). The atrioventricular connection was abnormal with the left atrium connecting to the left-sided morphologic right ventricle (Fig. 46–21). The right atrium connected to the morphologic left ventricle, which then connected to the pulmonary artery (Fig. 46–22). The aortic valve arose from the morphologic right ventricle (Fig. 46–23) so the atrioventricular and ventriculoarterial connections were discordant ("corrected" transposition). The ventricular septum appeared intact but there was dropout in the fossa ovalis region of the atrial septum (Fig. 46–24), implying an atrial septal defect. Pulmonary veins connected to the left atrium, and the superior vena cava connected to the right atrium. Imaging of the great arteries showed a normal left aortic arch and pulmonary arteries (Fig. 46–25). Doppler evaluation of the left atrioventricular valve (tricuspid valve) showed that the murmur was caused by tricuspid regurgitation (Fig. 46–26). The final diagnosis was "corrected" transposition with systemic atrioventricular valve regurgitation.

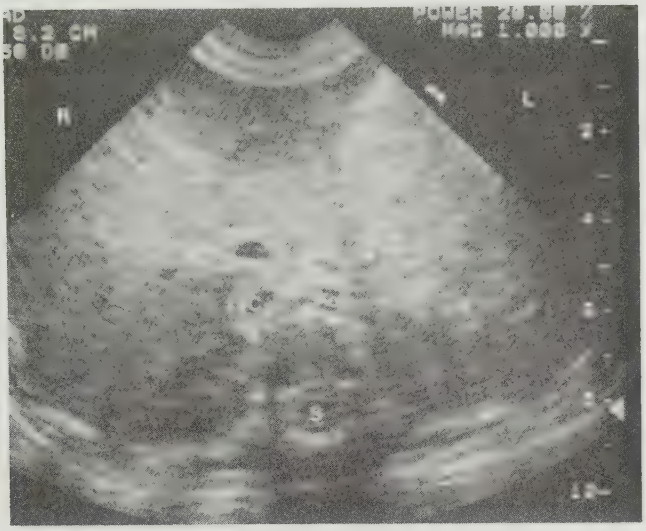

Fig. 46–19. Echocardiographic determination of atrial situs. A subcostal transverse scan of the abdomen immediately below the diaphragm shows the inferior vena cava (IVC) on the right and the descending aorta (Ao) on the left symmetrically related with respect to the spine (S). The liver is normally predominately right-sided at this level of the abdomen.

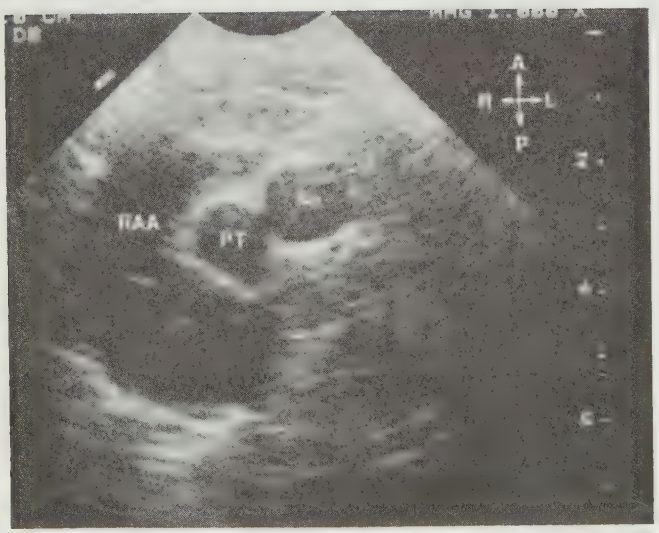

Fig. 46–20. High parasternal transverse scan of the broad-based right atrial appendage (RAA) on the right confirming the normal atrial situs. Note that the aorta (Ao) is anterior and to the left of the pulmonary trunk (PT).

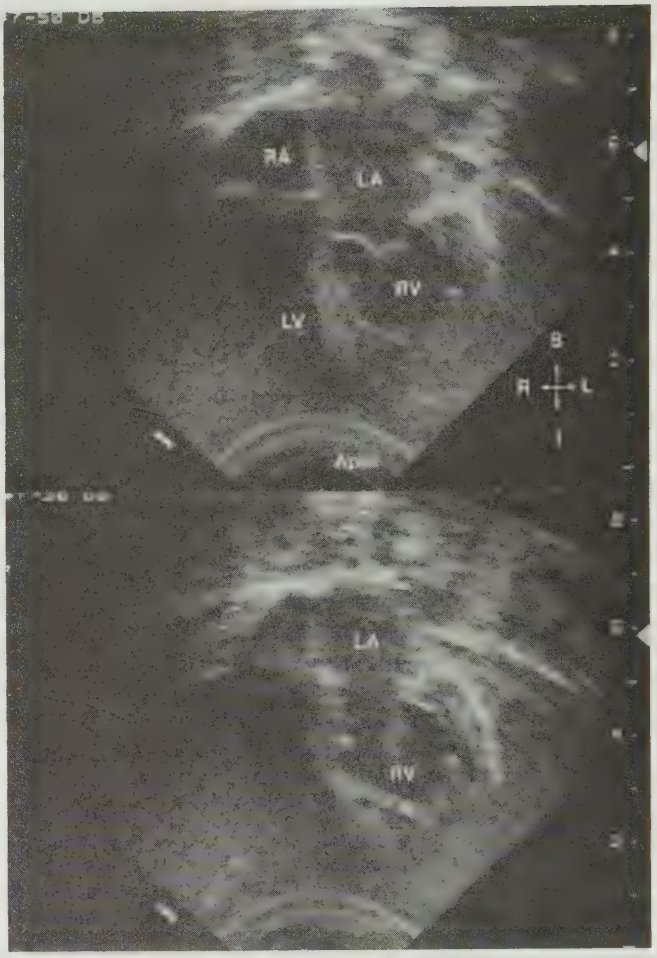

Fig. 46–21. Atrioventricular connection is determined from the apical four-chamber view. The atria are normally related with the morphologic right atrium (RA) on the right and the morphologic left atrium (LA) on the left (further identified by the connection of pulmonary veins). The atrioventricular connection is abnormal (discordant): the right atrium connects to the right-sided left ventricle and the left atrium connects to the left-sided right ventricle. The atrioventricular valve always goes with its ventricle and, in this systolic frame (upper panel), the left-sided tricuspid valve is identified further by its inferior displacement with respect to the right atrioventricular valve. The opening pattern of the left atrioventricular valve in diastole (lower panel) is toward the apex of the ventricle with septal chordal insertions, typical of a morphologic tricuspid valve.

Fig. 46–22. Determination of the ventriculoarterial connection is shown in two subcostal scans. Top: The morphologic left ventricle (LV) receives blood through the mitral valve from the right atrium (RA). The abnormal ventriculoarterial connection (discordant) is recognized by the connection of the left ventricle to the pulmonary artery (PA) which is identified by its continuation to the right pulmonary artery. The continuity of the right atrioventricular (mitral) valve and the pulmonary valve and the smooth-walled appearance of the right side of the ventricular septum confirm this as the left ventricle. Bottom: The connection of the right ventricle (RV) to the left-sided aortic valve (AV) can be seen by scanning more anteriorly.

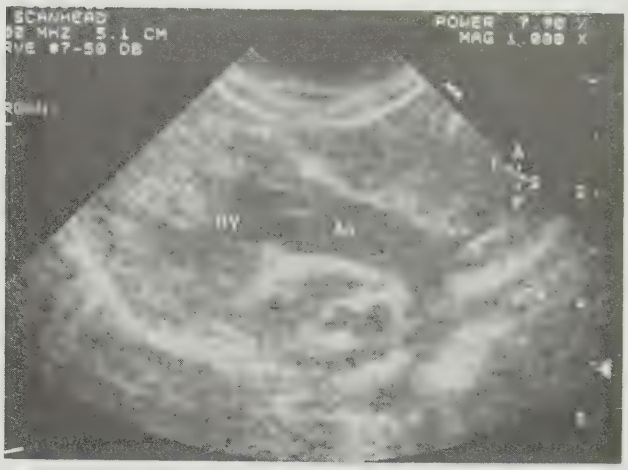

Fig. 46–23. The connection of the morphologic right ventricle (RV) to the aorta (Ao) is confirmed in a high left parasternal scan. There is infundibular muscle under the aortic valve and no continuity with an atrioventricular valve, typical of a right ventricle. The aorta is identified by the origin of the brachiocephalic arteries including the left carotid artery (LCA) from it.

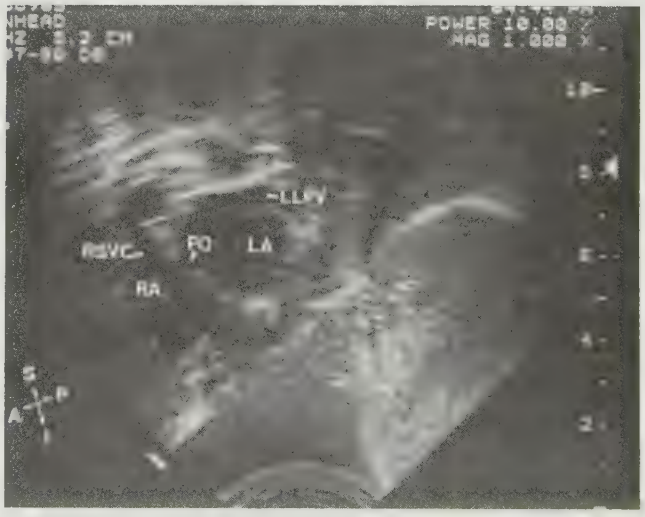

Fig. 46–24. Subcostal examination of the atrial septum. The left (LA) atrium receives connection of the left lower pulmonary vein (LLPV) in this scan and the right superior vena cava (RSVC) is seen entering the right atrium (RA) atria. Dropout in the region of the fossa ovalis (FO) is a normal finding.

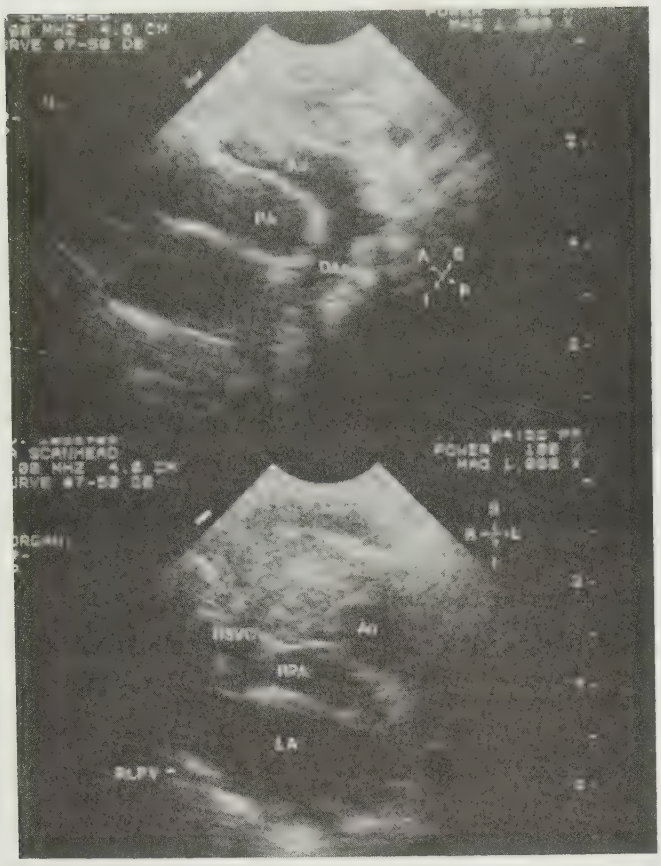

Fig. 46–25. (Upper panel) High parasternal scanning of the aortic arch (Ao) and pulmonary artery (PA). The origin of the left subclavian artery (LSA) is well visualized. (Lower panel) Suprasternal scanning of the aorta (Ao), the right pulmonary artery (RPA), and the left atrium (LA). The connection of the right lower pulmonary vein (RLPV) to the left atrium (LA). The right superior vena cava (RSVC) passes in front of the pulmonary artery.

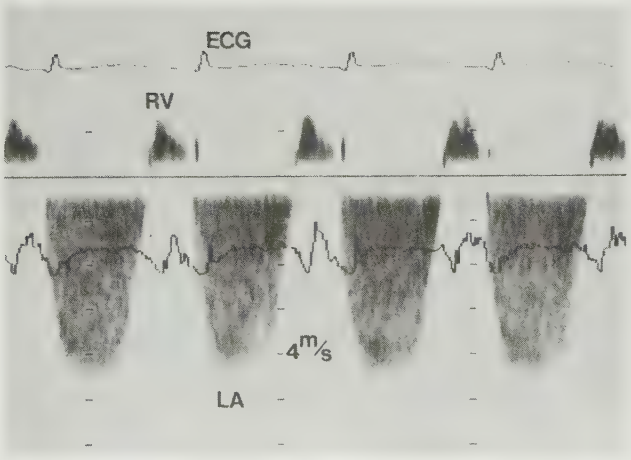

Fig. 46–26. Continuous-wave Doppler of left atrioventricular valve (tricuspid) regurgitation from the right ventricle (RV) to the left atrium (LA) in corrected transposition. The peak velocity is 4.5 meters per second (m/s).

Such a step-by-step evaluation led to the diagnosis by excluding abnormalities of each segment and synthesizing the individual findings.

VENTRICULAR FUNCTION ASSESSMENT

The temporal resolution of two-dimensional echocardiography is limited by the scanning rate limits of the equipment. M-mode techniques interrogate the heart at a much higher rate (800 to 1500 times per second) and allow tracking of the ventricular wall and valves at rapid rates of movement. Factors such as the rapidity of the pulse repetition frequency and the depth of the scan alter the maximum rate of ultrasonic sampling. M-mode echocardiography has been used for the diagnosis of congenital heart defects in the past,[36] however, it has been completely supplanted by two-dimensional imaging for this purpose. The most useful application of M-mode echocardiography is the measurement of absolute cardiac chamber dimensions and wall thicknesses and their dynamic changes. Normal values for the systolic and diastolic dimensions of the left atrium and ventricle increase with increasing age and body size. M-mode parameters from the left ventricle can be used to estimate the wall stress of the left ventricle and its dynamic changes. Systolic function can be estimated using the concept of shortening fraction. In the presence of normovolemia, the dimensional shortening of the left ventricular endocardial cavity relates well to the stroke volume.

The first attempts at noninvasive measurement of pulmonary artery pressure were made possible by M-mode echocardiography. Systolic time intervals of the pulmonary valve (preejection period divided by the ejection time) (Fig. 46–27) correlate with the peak systolic pulmonary artery pressure.[37] In transposition of the great arteries, the pulmonary artery pressure can be estimated by the systolic intervals of the left ventricle.[38]

Changes in the pattern of the opening of the pulmonary valve on M-mode were used to detect pulmonary stenosis[39] but have been supplanted by Doppler techniques (see Chapter 47).

CONTRAST ECHOCARDIOGRAPHY

An ultrasonic contrast agent is a substance with stable microbubbles in solution; these microbubbles are large enough to reflect ultrasound but small enough that they disappear rapidly and are safe.[40] Such an agent may be as simple as saline or as complex as precision engineered microbubbles of polysaccharide that dissolve in the circulation after injection. A contrast injection can be useful in defining the identity of a structure that is imaged but may be unusual.[41] For example, a structure near the aortic arch may be confusing but can be confirmed to be the innominate vein by an echocardiographic contrast injection in a left arm vein (Fig. 46–28). In congenital heart disease the major application of contrast echocardiography is in the postoperative patient with residual shunts or in excluding congenital heart disease.[42] Systemic venous injection of contrast fills the right heart sequentially and the site of residual right-to-left shunting can be defined.[43] A catheter can be advanced retrogradely into the left ventricle after closure of a ventricular septal defect and a contrast injection can be used to diagnose the presence and severity of residual left-to-right shunts. There are concerns about the use of new agents designed to enter the left heart circulation and their effect on developing children.

SAFETY OF ULTRASOUND—TWO-DIMENSIONAL/ M-MODE

At the present time, significant adverse effects from the use of ultrasound for imaging or M-mode evaluation have not been reported. The potentially negative bioeffects of ultrasound can be classified into those caused by cavitation and those from heating. Cavitation refers to the development of tiny gas-filled bubbles that resonate at the ultrasonic frequency and induce neighboring particles of liquid to vibrate, thereby potentially damaging the ultrasound-transmitting medium. Practically, the intensities now used (typically 10 Watts per centimeter squared) are nearly an order of magnitude less than those known to produce cavitation. Thermal effects could result from heat generated in the tissue. In order to reach the thermal threshold for damage using modern ultrasonic intensities for imaging and M-mode, an average intensity of 1000 Watts per centimeter squared (100 times the usual intensity) would be necessary for many hours.[29]

The evidence thus far supports the statement that diagnostic ultrasound used at current pulse intensity levels does not constitute a risk or hazard to the patient. Higher intensities with pulsed Doppler have the potential to cause cavitation, and concerns about the use of Doppler in the fetus are currently being investigated.

COST AND BENEFITS

One of the major reasons that ultrasound is proliferating so rapidly in pediatrics is that it is noninvasive. Ultrasound equipment is less expensive than x-ray equipment, for example, and there is a natural process of reassessment going on now of the indications for cardiac catheterization. The development of echocardiography as an extension of the clinician's other assessment skills has led to some decrease in utilization of the catheterization laboratory, especially in neonates. If a catheterization can be completely avoided, then echocardiography has the potential to decrease the cost of medical care for these patients.

For the most effective application of ultrasound in the cardiovascular system, the involvement of a physician during performance of the study, as well as in the interpretation, is important. A more physician-intensive diagnostic process may benefit the patient, but may become more expensive than a test involving only a technician.

FUTURE DIRECTIONS

Technology has been changing so rapidly in this area that it is difficult to predict which technique will be optimal for a given lesion in five years time. The rapid development of nuclear magnetic resonance for imaging and spectroscopy will have a major impact on the field (see Chapter 51). Echocardiography is advancing at a rapid pace. The emerging areas include 1) the development of contrast agents some of which will allow myocardial blood flow assessment by ultrasonography, 2) tissue characteri-

Philadelphia, Lea & Febiger, 1986, p. 182.)

zation techniques, 3) color Doppler blood flow measurement, 4) invasive ultrasonic imaging probes for intracardiac imaging, 5) transesophageal ultrasonic imaging in neonates for intraoperative functional assessment, and 6) three-dimensional reconstruction of cardiac images from ultrasound data. One thing is certain: a nearly constant re-evaluation of the relative roles of various diagnostic modalities in congenital heart disease will be needed.

CHAPTER 47

Doppler Echocardiography

Daniel J Murphy, Jr

Although Doppler ultrasound was developed prior to M-mode and two-dimensional echocardiography, its use remained limited prior to the late 1970s. At that point, newly introduced systems combined two-dimensional imaging with pulsed Doppler ultrasound. This use of two-dimensional echocardiography (2DE) as a guide for the placement of a Doppler sample volume allowed confirmation of findings previously made by "blind" continuous wave and pulsed Doppler ultrasound; 2DE also simplified the examination of individual locations within the vascular system and paved the way for Doppler ultrasound to become an integral part of the echocardiographic evaluation. Whereas 2DE is used to obtain information regarding the structure of the heart, Doppler is used to detect the disturbances in flow that result from abnormalities of structure. In addition, Doppler augments the M-mode and two-dimensional evaluation of systolic and diastolic function. Finally, through the use of Doppler, it is possible to estimate intracardiac pressure gradients and flow areas.

The goals of the Doppler echocardiographic examination are: 1) to document the presence of normal flow patterns; 2) to detect the presence of flow disturbances or abnormal patterns; 3) to measure the velocity of flow at each point within the vascular system; and 4) to estimate the flow volume at each point in the heart and great vessels. Although not all of these aspects are necessarily addressed during each examination, they represent the potential information available on each occasion.

In general, the Doppler echocardiographic examination should be complementary to a complete 2DE evaluation. The segmental anatomy and the intracardiac and extracardiac connections should be established prior to Doppler interrogation. Once the structural information is obtained, a complete Doppler examination at each location within the great vessels or intracardiac chambers should be performed. Information is obtained regarding the pattern of blood flow, the velocity of blood flow, and the volume of blood flow. These data can be obtained using pulsed Doppler, continuous wave Doppler, or two-dimensional color Doppler. It is advisable to use single sample volume pulsed Doppler or color Doppler for routine screening at various sites. Continuous wave Doppler is generally reserved for determination of peak velocities when aliasing or flow disturbance is noted on the pulsed Doppler display.

TYPES OF DOPPLER EQUIPMENT

Doppler echocardiography is generally performed using one of three formats: 1) pulsed Doppler; 2) continuous wave Doppler, and 3) two-dimensional color Doppler. Doppler equipment includes the transducer, the signal processing unit, and the information outputs. Doppler instrumentation can be free-standing—that is, without any other echocardiographic imaging capability—or it can be part of an ultrasound system that contains other ultrasonic features such as two-dimensional imaging or other Doppler formats.

The configuration of Doppler transducers depends on the type of Doppler and whether the system is shared with an imaging system. Single crystal nonimaging transducers are compact with a small contact face. Such transducers are particularly useful for accessing small ultrasound windows such as intercostal spaces or the suprasternal notch. Transducers that function for imaging and Doppler are larger and available in a variety of configurations (Fig. 47–1). The ultrasound beam may emerge in line with the

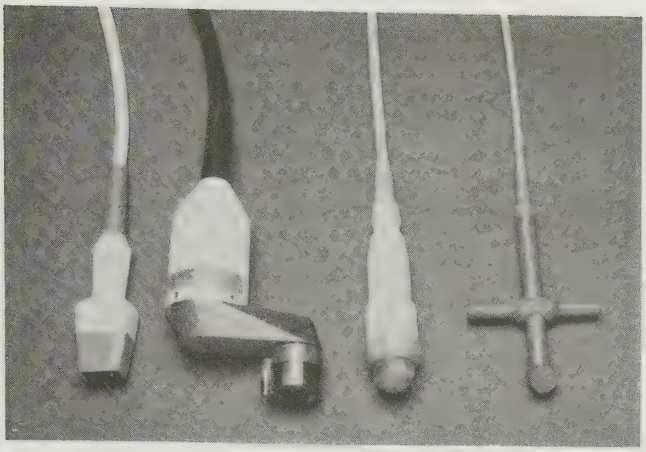

Fig. 47–1. Doppler echocardiographic transducer configurations. From left to right, the following types of transducers are pictured: 1) a phased array transducer that combines imaging with pulsed and continuous wave Doppler; 2) a mechanical sector scanner that combines imaging with pulsed and high-pulse repetition frequency Doppler; and 3) an annular array transducer that combines imaging with pulsed, high-pulse repetition frequency pulsed, continuous wave, and color Doppler. Finally, the transducer to the right is a nonimaging transducer with pulsed and continuous wave capability.

axis of the transducer, or it may be offset by as much as 90° to facilitate access to particular areas. Each transducer has a different "footprint"—that is, the ultrasound beam emerges with a specific width and orientation. Difficulties in imaging or Doppler interrogation may be alleviated by changing to a transducer of a different configuration.

Pulsed Doppler capability is available now on nearly all 2DE machines. In addition, color Doppler and continuous wave Doppler are available on many systems with linear, phased, or annular array systems. Another difference among the imaging systems with Doppler is related to the ability to direct the Doppler beam using the two-dimensional image for guidance. Some systems have a fixed Doppler path, and the operator must angle the scan plane so that the Doppler beam intersects the area of interest. With steerable Doppler systems, the Doppler beam can be maneuvered by means of a joystick or trackball into the desired location.

DOPPLER SIGNAL PROCESSING

Doppler ultrasound units employ a variety of signal processing methods (see Chapter 36). While the simplest Doppler units produce only an audio signal, most systems designed for examination of the heart and great vessels use a more sophisticated form of signal processing in an attempt to display information regarding the velocities encountered. The older and simpler units used zero crossing counters to produce a time-interval histogram. However, these units have been replaced by those containing fast Fourier transform analysis units. Even among systems with FFT capability, there are differences in sampling rate. Faster sampling rates allow for less time delay between signal acquisition and display. They also produce more reliable point-to-point temporal resolution of recorded velocities.

All Doppler units have an audio output. This is due in part to the fact that the Doppler frequency shifts produced by blood flowing at physiologic velocities are in the audible range. Most ultrasonographers rely on the characteristics of the audio signal for information regarding the nature and velocity of the flow. For example, higher-pitched sounds indicate faster blood velocities. An audio signal with a pure tone (a whistling sound) indicates a narrow band of velocities suggesting laminar flow. Conversely, areas of disturbed flow contain a range of velocity components, and the resultant audio signal has a harsh quality.

In addition to the audio output, spectral information from the Doppler interrogation is generally displayed on a video screen as a time-velocity plot. By convention, signal produced by flow toward the transducer is displayed above the zero line and flow away is displayed below. An ECG trace is usually present on the display and allows timing of Doppler signals in relation to the cardiac cycle.

As well as the video display, Doppler output is often available in a hardcopy or paper format. This can be a stripchart recorder or a video screen page printer. Frequently, the Doppler output provides information regarding the specific conditions under which the Doppler system is operating. These parameters include calibration lines for velocity and time, sample volume size and carrier frequency of the transmitted ultrasound beam, depth of sampling, and wall filter settings. Each of these factors is important in obtaining the best possible Doppler recording.

With a wide variety of Doppler echocardiographic equipment available, there is no simple answer to the question "which echocardiographic equipment is appropriate for one's clinical needs." In fact, the simplest generalization is that no echocardiographic equipment with or without Doppler capability is perfect for every situation. For this reason, many clinical noninvasive imaging laboratories are equipped with several ultrasound systems with different features. The strength of any diagnostic ultrasound system should be its imaging capability. Structural diagnosis is the centerpoint of echocardiographic evaluation. Some systems with high frequency (7.5 to 10 MHz) transducers are exceptional for their ability to image the heart of the premature or newborn infant. However, the same system may be inadequate for examining larger patients. Conversely, many phased-array systems have either poor near-field resolution or a transducer shape that is inappropriate for a small infant.

Any echocardiographic system should include high-quality pulsed and continuous wave Doppler. Both should be steerable using the two-dimensional image. Standard features include a variable size sample volume and high pulsed repetition frequency on the pulsed Doppler. In addition, the audio quality of the signal should be adequate to allow the examiner to incorporate it into the interpretation of the examination.

Color Doppler is rapidly becoming an integral part of the Doppler examination and should be available in every pediatric echocardiographic laboratory. However, not every ultrasound system in the laboratory must include color Doppler. There is also a need for smaller systems with excellent imaging, pulsed Doppler, and continuous wave Doppler. When purchasing equipment that includes color Doppler, one must not sacrifice image quality or the quality of pulsed and continuous wave Doppler for the sake of the color display. Current color systems are evolving rapidly. Therefore, another desirable feature is that the system be upgradable as new advances are made. Any system is more desirable if hardware or software changes can be made to improve it or add new features to the existing color display.

Hardcopy format is desirable on all echocardiographic systems.

Any systems with color Doppler should be equipped with a color printer or Polaroid camera. A black-and-white page printer or stripchart recorder is also essential.

When purchasing an ultrasound system, one must get transducers that provide adequate imaging and Doppler for the range of patients to be studied. In a pediatric laboratory, this frequently includes the entire range of available transmission frequencies from 2.25 MHz to 7.5 MHz. It also may include probes with different types of crystals (e.g., phased array, annular array, and single crystal continuous wave Doppler).

Finally, when purchasing any new echocardiographic equipment, one should consider the availability of trained service personnel. New systems have become increasingly complex and technologically sophisticated. That, coupled with the increasing clinical dependence placed upon echocardiographic information, makes the reliability and serviceability of any echocardiographic system crucial.

Doppler Signals

Doppler information is produced as a spectral display and as an audio signal, and the examiner must interpret the output and relate it to the qualities of the area of blood flow being examined. First, the Doppler signal identifies the presence of flow. With the exception of low-frequency wall-motion artifacts and higher-frequency valve clicks, the presence of any Doppler signal indicates blood flow. The absence of Doppler output does not necessarily imply the absence of flow. Rather, it might result from a technical problem in the performance or the analysis of the examination. For example, placement of the sample volume outside the vascular system will not produce a Doppler signal. This can occur when the operator activates the Doppler apparatus but does not update the sample volume position using the two-dimensional image. More commonly, lack of Doppler signal results from an attempt to sample at too great a depth, with a high-frequency transducer, or with inadequate or improper power and/or gain settings.

Normal Flow

Once flow has been detected, the direction of flow is assessed. Flow toward the transducer is displayed above the zero line, and flow away from the transducer is displayed below. If the ultrasound beam is aligned relatively perpendicular to the axis of flow, flow will either appear to be of low velocity or bidirectional. Another cause for apparent bidirectional flow is spectral mirroring, which occurs when the Doppler gain settings are inappropriately high. Doppler sampling in a stream with laminar flow will produce a spectral pattern with a narrow range of frequencies throughout the period of flow. Movement of the sample volume toward a vessel wall where viscous drag results in broader range of velocities will also result in a wider Doppler display. This phenomenon is referred to as "spectral broadening." The Doppler patterns then depend on the nature of the blood flow in the area sampled, the size and location of the sample volume, and the precise adjustments and settings of the Doppler apparatus. A thorough familiarity with the normal patterns is essential before one can confidently recognize and identify the cause of abnormal patterns.

Disturbed Flow

Disturbed flow and turbulence are easily recognized and distinguished from normal laminar flow by their Doppler signals. Flow disturbance results in a change in direction of many of the blood cells in the stream of flow. This changes the angle between the path of the individual cells and the ultrasound beam, resulting in a change in the apparent velocity components. Interrogation of an area in which individual blood cells are moving in a number of different directions results in a spectral output that contains a wide range of velocities at that particular instant. The Doppler output appears wider due to spectral broadening. As the flow disturbance becomes more severe, spectral broadening becomes more pronounced and velocity components may be observed moving both toward and away from the transducer simultaneously (Fig. 47–2). Disturbed flow alters the color Doppler output as well. Spectral broadening results in a greater variance in the sampled frequencies, producing a green or yellow color on the display.

Flow through a stenotic valve has a characteristic pattern (see Chapter 34). There is acceleration of the blood immediately proximal to the obstruction. Flow through the obstruction itself occurs as a high-velocity laminar jet. However, this laminar quality to the flow is immediately lost as the poststenotic eddies and vortices develop in the poststenotic region. Doppler sampling proximal to, in, and distal to the obstruction will reveal each of the components of this flow disturbance.[1–3]

THE DOPPLER EXAMINATION

The Doppler examination generally is performed as an integral part of a complete echocardiographic evaluation. As with any echocardiographic examination, it is advisable to examine all cardiac structures, and each Doppler examination should be as complete as possible. The Doppler examination may require from 5 to 60 minutes to perform; the patient must be comfortable and clinically stable. In addition, a fairly constant heart rate is useful. In the case of infants and small children, it may be necessary to perform the study during sleep or with the use of a sedative. Agitation not only makes the examination difficult but can also result in erroneous information due to improper sample volume location and patient motion during the examination. Flow velocities across both normal and stenotic valves differ between the awake and sedated states.[4,5]

The specific order in which the Doppler examination is performed is unimportant. In addition, it does not matter whether the 2DE examination is performed before or after the Doppler study. However, the two-dimensional information must be integrated with the Doppler assessment into an overall diagnostic picture. Frequently, this means that after an initial assessment, the study is reviewed and the need for further information is noted. Therefore, it is not unusual for more than one two-dimensional and Doppler examination to be performed on the same patient before complete diagnostic information is available.

Several strategies are acceptable for pursuing the Doppler examination. One is a "view-oriented approach," through which Doppler information is obtained in each of the standard echocardiographic views. This has the advantage of shortening the examination and does not require frequent repositioning of the patient. It has the disadvantage that blood flow is sampled at the same time in a variety of locations unrelated to each other. The examiner must mentally catalog the information as it is obtained and unify it at the end of the examination. An alternative approach is to sample flow in a physiologic fashion—that is, to follow the

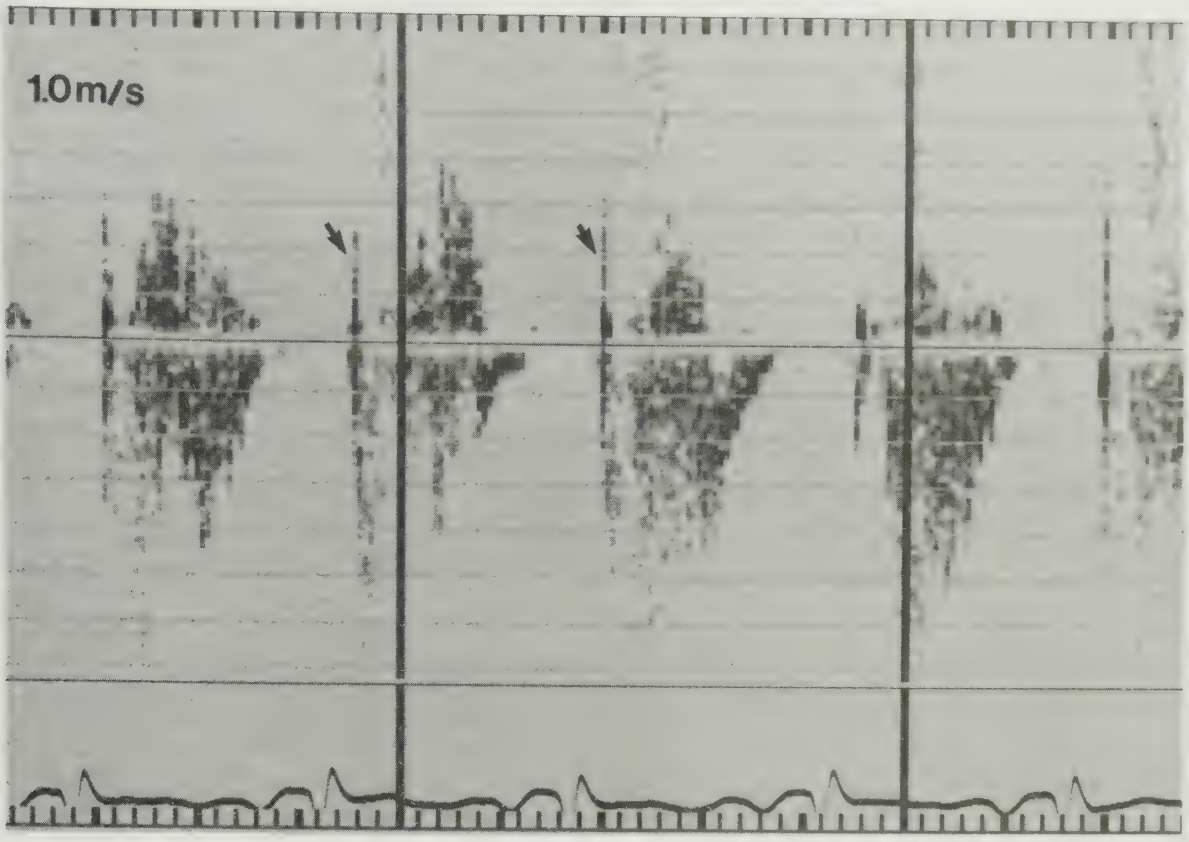

Fig. 47–2. Disturbed flow. A pulsed Doppler sample volume has been placed in the main pulmonary artery just distal to the valves. Doppler signals from valve opening are noted (arrows). The Doppler flow pattern consists of a wide range of velocity components. The occurrence of signals above and below the zero line suggests flow in multiple directions. This is due to the presence of eddies in the parajet flow disturbance.

venous flow as it enters the heart and sequentially sample flow patterns following the flow of blood through the right side and then the left side of the heart. This approach is somewhat inconvenient and impractical. However, the concept is sound and forces the examiner to acquire Doppler information at all possible sites.

What type of Doppler should be used in a routine examination? In general, pulsed Doppler should be used for the detection of flow disturbances and for the measurement of velocities within the normal range. This can be done either with single sample volume pulsed Doppler or with color Doppler display. Using the single sample volume equipment, the sample volume must be moved sequentially from one area of the heart to the other during recording of the Doppler output. This approach is somewhat tedious and time-consuming. However, done carefully it is exquisitely sensitive and provides a large amount of information. Theoretically, the same capability exists using color Doppler; color Doppler shortens the examination time by allowing the examiner to view larger areas of Doppler information simultaneously. Early generation color Doppler systems had poor sensitivity and low pulse repetition frequency. Thus, it was possible to miss small flow disturbances or areas of low flow velocity. This was particularly true in children with fast heart rates or in adults at a greater depth of sampling. As the quality of color Doppler systems improves, it is likely that this will become the modality of choice for routine Doppler screening examination. Using these systems, one sequentially interrogates each area of the heart from a variety of views looking for the presence of high-velocity flows or areas of disturbed flow. Continuous wave Doppler is generally reserved for the examination of areas with higher-flow velocity or a great distance from the transducer. It is most useful to perform continuous wave Doppler sampling after prior pulsed or color Doppler examination.

Goals

The Doppler examination is intended to characterize flow in each of the cardiac chambers as well as in the great vessels. This allows the detection of any flow disturbance. In addition, the complete Doppler examination includes estimation of flow velocity in each of the locations sampled and, frequently, estimation or calculation of flow volume in certain sites. This information is obtained from a variety of echocardiographic windows at various times during the patient examination. In fact, it is advisable to interrogate each area of interest from as many windows as possible. It is also useful to identify structural abnormalities using two-dimensional imaging prior to the performance of the Doppler examination. This alerts the examiner to areas which require special attention during the Doppler examination. In the following sections, flow patterns are described following the pathway of blood flow into and through the heart.

Systemic Venous Flow

The pattern of systemic venous flow is biphasic. There is a portion of venous flow that occurs during ventricular systole (atrial filling). This is followed by a second period of flow during atrial diastole (following atrial contraction) (Fig. 47–3). Flow velocities range from 30 to 80 cm per second, and there is generally a noticeable respiratory variation with increased velocities occurring during inspiration.[6]

Abnormalities of venous flow can be characterized by: 1) increased flow volume and velocity (increased flow due to anomalous pulmonary venous return[7] or arteriovenous malformations); 2) increased velocity, flow disturbance, and loss of normal phasic pattern due to stenosis, which could be due to obstruction of the veins themselves or due to obstruction due to a baffle following intra-atrial correction of transposition of the great arteries; and 3) flow reversal during systole due to tricuspid regurgitation[8,9] or restrictive ventricular physiology.[10]

Flow in the superior vena cava is examined best from the suprasternal notch. From this window, blood flows away from the transducer. The subcostal window can also be used. Flow in the inferior vena cava should be examined from the subcostal location.

Right Atrium

Normal flow in the right atrium represents a convergence of flow from the superior vena cava and the inferior vena cava.[11] As flow approaches the tricuspid valve, the velocities increase slightly but retain the biphasic pattern: there is a prominent early filling phase during early diastole and a less pronounced late filling phase following atrial contraction.

Normal flows in the right atrium can be disturbed by additional flow entering through an atrial septal defect,[12,13] or from anomalous pulmonary venous drainage[7,14] by a systolic jet from tricuspid regurgitation.

Flow in the right atrium is best examined from the apical or subcostal windows. Normally, all flow occurs toward the transducer from these locations. Any flow detected away from the transducer likely represents tricuspid regurgitation.[15,16] The distinction between normal flow and flow through an atrial septal defect can be difficult. This is due to the fact that flow normally occurs along the atrial septum from the inflow of the superior vena cava. Separation of the two streams of flow is most easily accomplished with the use of color Doppler.[17–21]

Tricuspid Valve and Right Ventricular Inflow

The biphasic flow into the right ventricle produces a characteristic M-shaped pattern on the Doppler tracing. The early filling phase occurs during early diastole; then, velocities are slightly higher and volumes are slightly larger than during the late filling phase (Fig. 47–4). Normal velocities range from 30 to 80 cm per second. Abnormalities of tricuspid inflow include: 1) increased velocity due to increased venous return or left-to-right shunt at the atrial level; 2) increased velocities and flow disturbance due

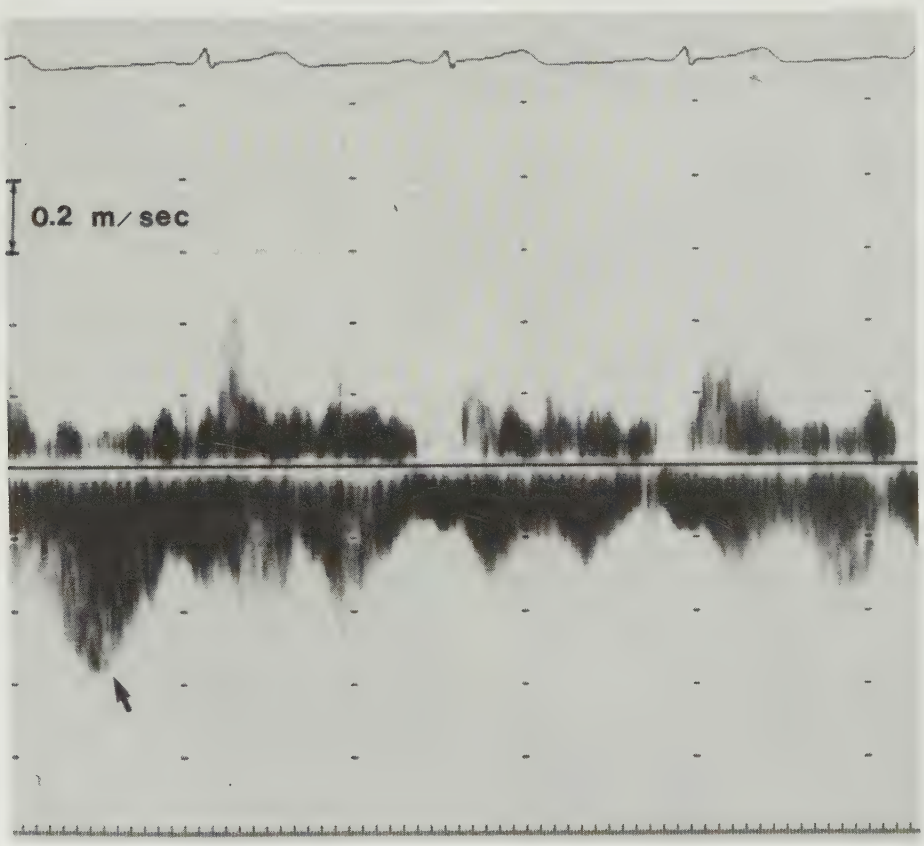

Fig. 47–3. Flow in the superior vena cava. Venous inflow is typically biphasic with a prominent systolic component followed by an early diastolic phase. In the superior vena cava, flow is also affected by the respiratory cycle with an accentuation of inflow during inspiration (arrow).

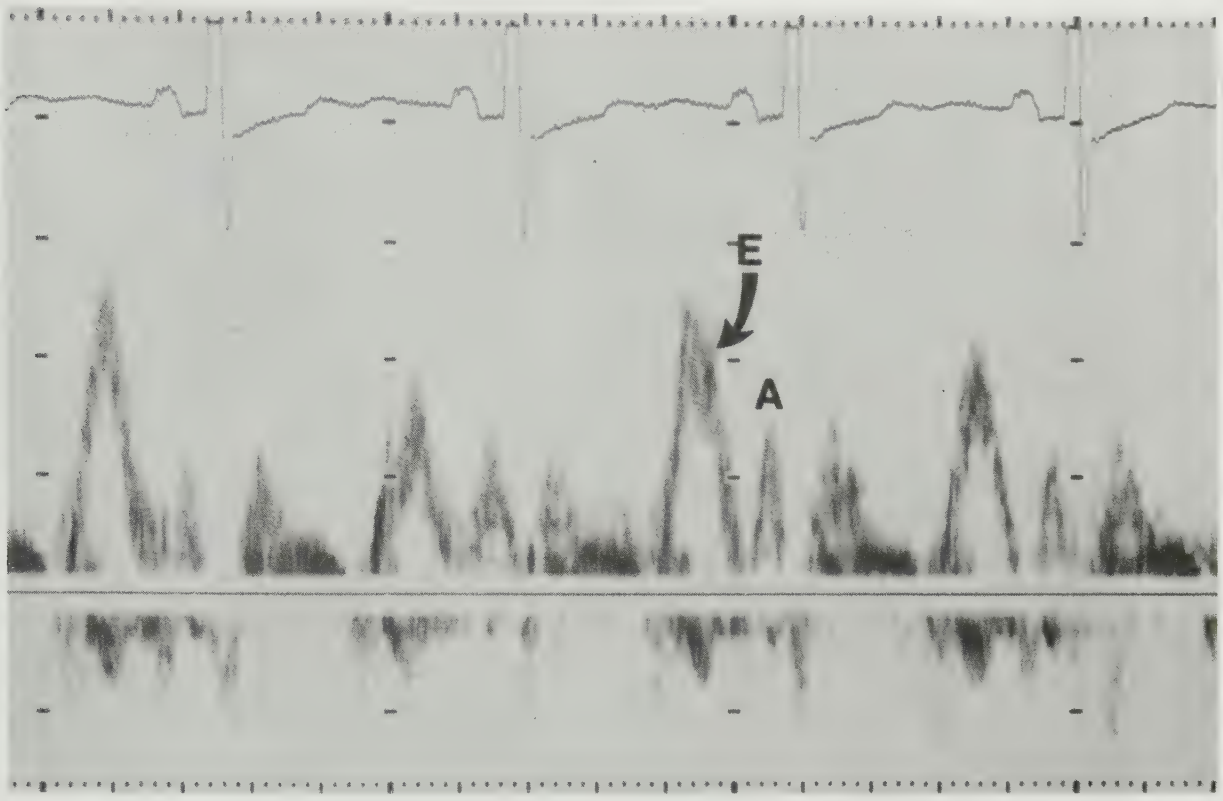

Fig. 47–4. Normal tricuspid inflow. Tricuspid inflow has a biphasic pattern with a prominent early filling phase (E) and a less prominent late filling phase that follows atrial contraction (A). Tricuspid inflow velocities and time velocity integrals vary with position and respiratory cycle.

to tricuspid stenosis; and 3) systolic flow reversal due to tricuspid regurgitation. Flow reversal must be holosystolic to establish the presence of true tricuspid regurgitation.[16] Short, early systolic flow reversal occurs in normal individuals.[22] This jet is not pathologic, but can be useful in estimating right ventricular pressure.

Flow through the tricuspid valve and into the right ventricle is best sampled from the apical window. An alternative is to sample the right ventricular inflow from the parasternal window.

Right Ventricular Outflow and Pulmonary Valve

Flow in the right ventricular outflow tract occurs primarily during systole, although some low-velocity forward flow can be detected in diastole.[23] Flow is laminar and produces a clean systolic signal with velocities ranging from 40 to 100 cm/second. As the sample volume is moved into the pulmonary valve region, valve clicks are detected on the Doppler tracing and the audio signal. A normal pulmonary artery Doppler signal has a rounded contour with the peak velocity occurring in midsystole. Normally, there is no forward diastolic flow detectable in the right ventricular outflow tract or main pulmonary artery. However, an early diastolic signal produced by trivial pulmonary regurgitation is commonly present in normal individuals (Fig. 47–5).[15,22,24]

A variety of structural lesions can account for flow disturbances in the right ventricular outflow tract. Perimembranous and muscular ventricular septal defects are accompanied by jets from left ventricle to right ventricle that produce flow disturbances in the right ventricular outflow tract (Fig. 47–6). Such jets are usually holosystolic[25–28] and are easily identified on color Doppler examination.[18,19,21,29–31] The orientation of the jet depends on the location of the defect. Anomalous muscle bundles such as those in double chamber right ventricle, tumor,[32,33] and aneurysm of the ventricular septum[34] can all produce flow disturbances in the right ventricular outflow tract. Infundibular pulmonary stenosis also results in an acceleration of blood and a flow disturbance proximal to the pulmonary valve. In pulmonary valve stenosis, there is a slight acceleration of blood immediately proximal to the valve, but the Doppler pattern is undisturbed until the sample volume is moved distal to the valve leaflets themselves. True pulmonary regurgitation produces a Doppler signal throughout diastole and is detectable more than several millimeters proximal to the valve leaflets.[22] In addition to flow disturbances caused by structural disturbances, it is also possible for flow velocities to be increased in any situation in which return to the right heart is abnormally high. Therefore, conditions such as atrial septal defect or increased cardiac output may produce increased velocities for other reasons. Only rarely will such conditions lead to flow disturbances.

Flow in the right ventricular outflow tract and main pulmonary artery can be sampled from the parasternal window in the short axis view or from the subcostal location. The parasternal location has the advantage of placing the transducer closer to the right ventricular outflow tract. However, the Doppler sample volume is better aligned with the axis of flow from the subxiphoid position. Therefore, qualitative studies particularly using color Doppler may yield more information from the parasternal window[35] whereas the maximal peak velocity may be obtained from another transducer position.[36]

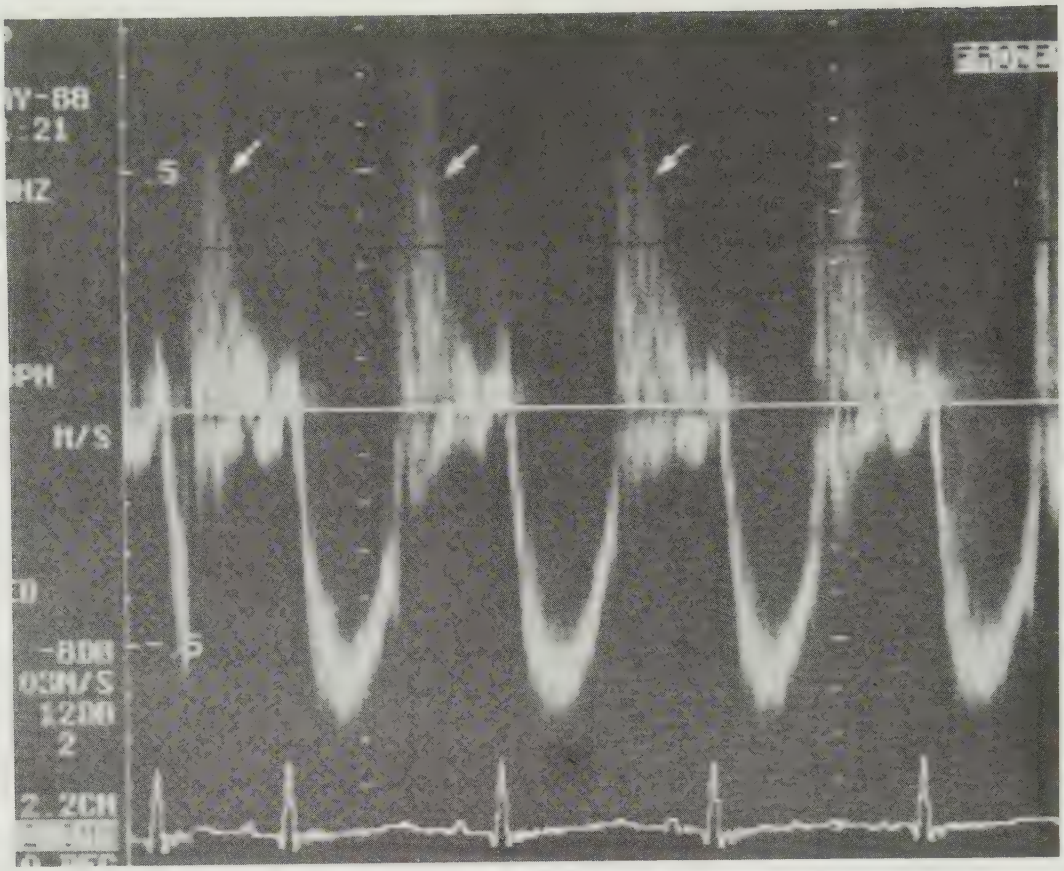

Fig. 47–5. Normal pulmonary flow with pulmonary regurgitation. The sample volume is placed in the main pulmonary artery at the level of the pulmonary valve. Flow occurs during systole away from the transducer (downward), and a narrow envelope is present. Compared to aortic flow, pulmonary peak velocity occurs during midsystole with a more gradual acceleration. In this tracing, mild pulmonary regurgitation is present (arrows) that appears as diastolic flow toward the transducer. This pattern of pulmonary regurgitation is normal particularly when detected close to the pulmonary valve leaflets.

Pulmonary Arteries

Flow in the pulmonary arteries occurs normally only during systole with the exception of low velocity early and late diastolic forward flows related to right ventricular filling and atrial contraction[37] and low velocity diastolic forward flow in the distal pulmonary arteries. Whereas normal velocities in the main pulmonary artery rarely exceed 120 cm/sec, normal velocities in the left pulmonary artery are considerably higher. In the newborn infant, the left and right pulmonary arteries are small compared to the main pulmonary artery, and blood accelerates as it enters the branch pulmonary arteries. This phenomenon, which is responsible for the physiologic murmur of peripheral pulmonary stenosis in such infants, can result in systolic velocities as high as 220 cm/sec, and may cause continuation of flow into diastole in the pulmonary artery branches.

Flow disturbances in the pulmonary artery can be due to stenosis at or above the pulmonary valve. In addition, proximal flow disturbances (e.g., those produced by ventricular septal defects or infundibular pulmonary stenosis) can be transmitted downstream and result in disturbed flow well into the branch pulmonary arteries. True peripheral pulmonary stenosis produces a pattern of undisturbed flow in the main pulmonary artery with acceleration and flow disturbance in one or both of the branches.[38] Additional sources of flow disturbance in the pulmonary arteries include flow reversal due to severe pulmonary regurgitation and diastolic flow due to left-to-right shunting from an aortopulmonary window, patent ductus arteriosus,[21,39–46] surgically created systemic to pulmonary artery shunt,[47,48] or anomalous coronary artery originating from the pulmonary artery.[49] The source of any of these flow disturbances can be identified by careful two-dimensional imaging as well as Doppler interrogation of the pulmonary artery to detect a point of flow entry. Pulsed,[39,40,43] continuous wave,[45] and color Doppler[19,21,50] have increased the sensitivity of echocardiographic identification of patent ductus arteriosus (Fig. 47–7).

Doppler sampling in the main and left pulmonary arteries is best performed from the subcostal location. Sampling in the right pulmonary artery can be performed from the parasternal or suprasternal view. Unfortunately, from these locations the Doppler sample volume is aligned nearly perpendicular to the direction of flow, and good Doppler records are difficult to obtain. Color Doppler can frequently be used from the suprasternal notch to detect a flow disturbance in the right pulmonary artery.

Pulmonary Venous Return

Pulmonary venous flow produces a pattern similar to that seen in systemic veins. It is biphasic with an early phase during systole

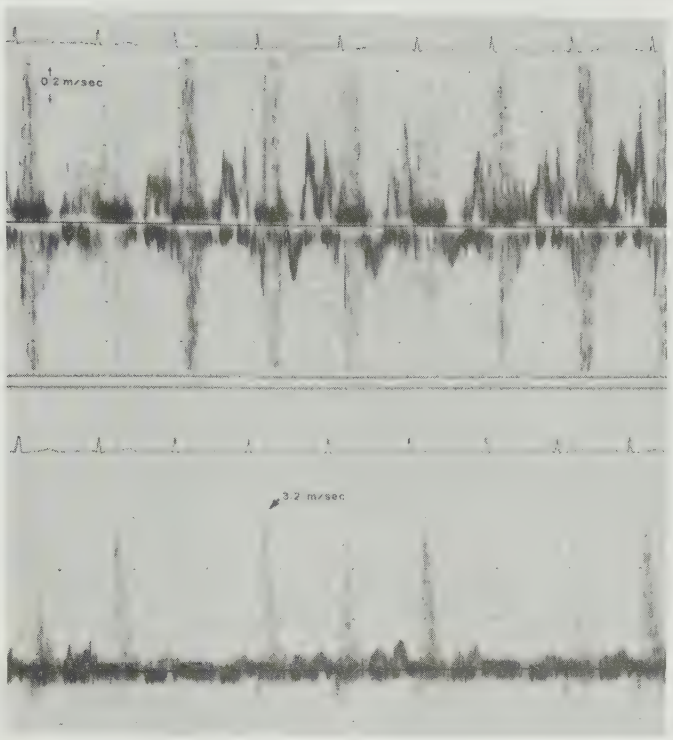

Fig. 47–6. Ventricular septal defect. In the upper panel, a pulsed Doppler sample volume is placed in the right ventricular inflow tract. Normal tricuspid inflow pattern is present during diastole. During systole, there is a signal of disturbed flow that exceeds the Nyquist limit. Flow occurs throughout systole. In the lower panel, a continuous wave beam has been directed toward the area of flow disturbance. A high-velocity systolic jet is present. Flow toward the transducer produces the Doppler signal above the zero line.

and a second phase in diastole.[51–53] Pulmonary venous flow is somewhat less affected by respiratory variation. Normal pulmonary venous velocities range from 20 to 80 cm/sec. Doppler tracings with velocities in excess of 2 m/sec, particularly if accompanied by a loss of the normal phasic pattern,[53–55] suggest pulmonary venous obstruction. Pulmonary venous flow is best sampled from the apical and subcostal windows.

Left Atrium

Flow in the left atrium has a low velocity and is similar to flow in the right atrium. Doppler velocities increase to 40 to 100 cm/sec as sample volume is moved closer to the mitral valve. Disturbances in flow can be produced by right-to-left atrial shunting, obstructed pulmonary venous return (e.g., cor triatriatum or baffle obstruction following intra-atrial correction of transposition of the great arteries),[55] or mitral regurgitation. In the presence of mitral regurgitation, there is holosystolic flow disturbance in the left atrium near the mitral valve leaflets.[56] Color Doppler displays a green or yellow jet that originates at the mitral valve and extends into the left atrium. Attempts have been made to estimate the severity of mitral regurgitation using pulsed Doppler mapping[57–60] or color Doppler jet area.[61–67] These methods are at best a semiquantitative "grading" of severity. Combining mapping with estimates of regurgitant fraction[68,69] may improve accuracy. In normal individuals, a short early systolic signal is detectable in the left atrium immediately adjacent to the mitral valve. This represents a normal finding.[22,56]

Flow in the left atrium is best sampled from the apical window. The mitral valve flow also can be examined using a parasternal long axis view.

Left Ventricular Inflow

As the sample volume is moved into the funnel of the mitral valve, inflow velocities increase, but the Doppler signal retains its characteristic M-shaped pattern (Fig. 49–8). As sampling proceeds toward the apex of the left ventricle, velocities decrease slightly and there is a disturbance of flow due to the eddies normally present at the apex.

The major abnormality detectable in this region is disturbed flow due to mitral stenosis. Mitral stenosis results in increased inflow velocities and a change in the characteristic Doppler pattern. The time of early filling is prolonged because left atrial pressure exceeds left ventricular pressure throughout diastole. Estimation of the severity of mitral stenosis can be made based on the peak velocity of the inflow jet or on the slope of the inflow velocities. Color Doppler examination of normal mitral inflow reveals a homogeneous red signal.[70,71] Mitral stenosis produces a pattern of aliasing and increased variance due to the flow disturbance at the narrowed valve orifice.[35,72] Left ventricular inflow is best sampled from the apical window.

Left Ventricular Outflow

Flow in the left ventricular outflow tract occurs in systole and moves away from the transducer when sampled from the apical window. As the sample volume is moved toward the aortic valve, velocities increase slightly and there is narrowing of the spectral width. At the aortic annulus, the valve leaflets create clicks on the Doppler tracing. As the sample volume is advanced to the proximal aorta, the pattern remains essentially unchanged. Color flow mapping reveals a homogeneous signal during systole throughout the left ventricular outflow tract.[70,73]

The most common lesions that produce flow disturbance in the left ventricular outflow tract are subaortic stenosis, valvar aortic stenosis, and aortic regurgitation (Fig. 47–9). A careful pulsed Doppler examination or a two-dimensional color examination can be useful in localizing the site of flow disturbance. When combined with the anatomic appearance of the left ventricular outflow tract and aortic valve, it simplifies detection of the location of stenosis.[35,74–76] Doppler has also proven useful in the identification and characterization of flow disturbances caused by dynamic subaortic obstruction in hypertrophic cardiomyopathy.[77–81]

The presence of any diastolic flow in the region of the aortic valve is abnormal and likely represents the presence of aortic insufficiency. Other courses of diastolic flow in the left ventricular outflow tract include aortico–left ventricular tunnel.[82,83] Pulsed Doppler and color Doppler are extremely sensitive in the detection of aortic regurgitation.[62,84–87] Careful pulsed Doppler mapping or two-dimensional color flow can be used to examine the location and extent of the regurgitant area. Such mapping correlates well with angiographic grading of severity of aortic regurgitation.[67,88–90] Additional estimates of severity can be obtained by applying the pressure half-time concept to the aortic regurgitation jet.[91,92]

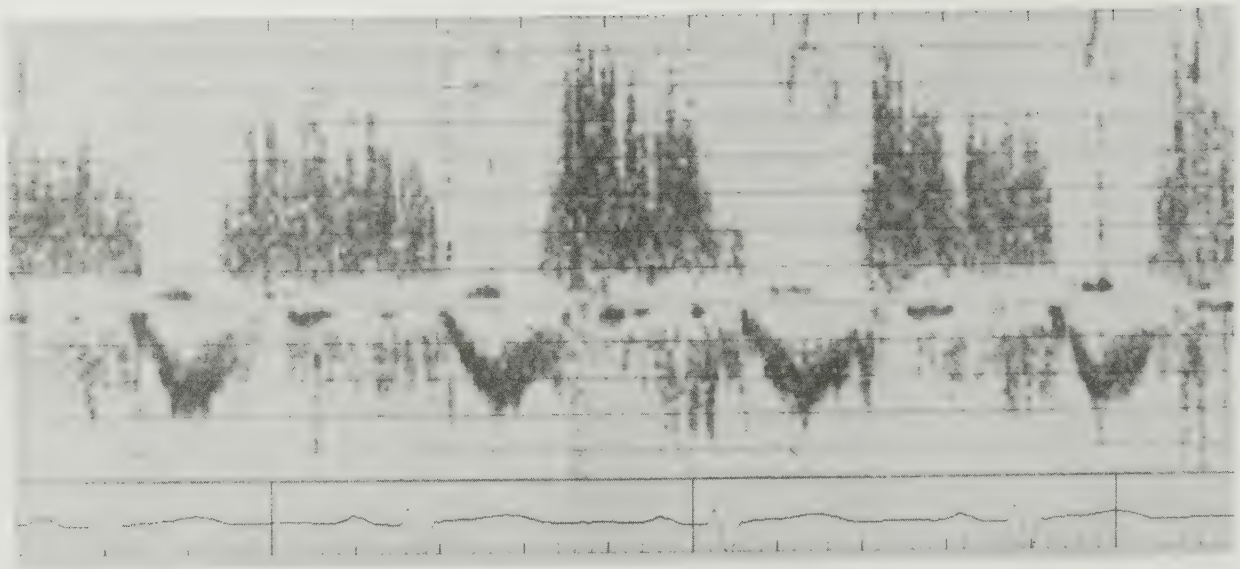

Fig. 47–7. Patent ductus arteriosus. A pulsed Doppler sample volume has been placed in the main pulmonary artery just distal to the pulmonary valve. A normal pattern of systolic flow away from the transducer is noted. In addition, there is diastolic signal toward the transducer, produced by blood that has entered the pulmonary artery through the patent ductus. Flow in the ductus is usually continuous throughout the cardiac cycle.

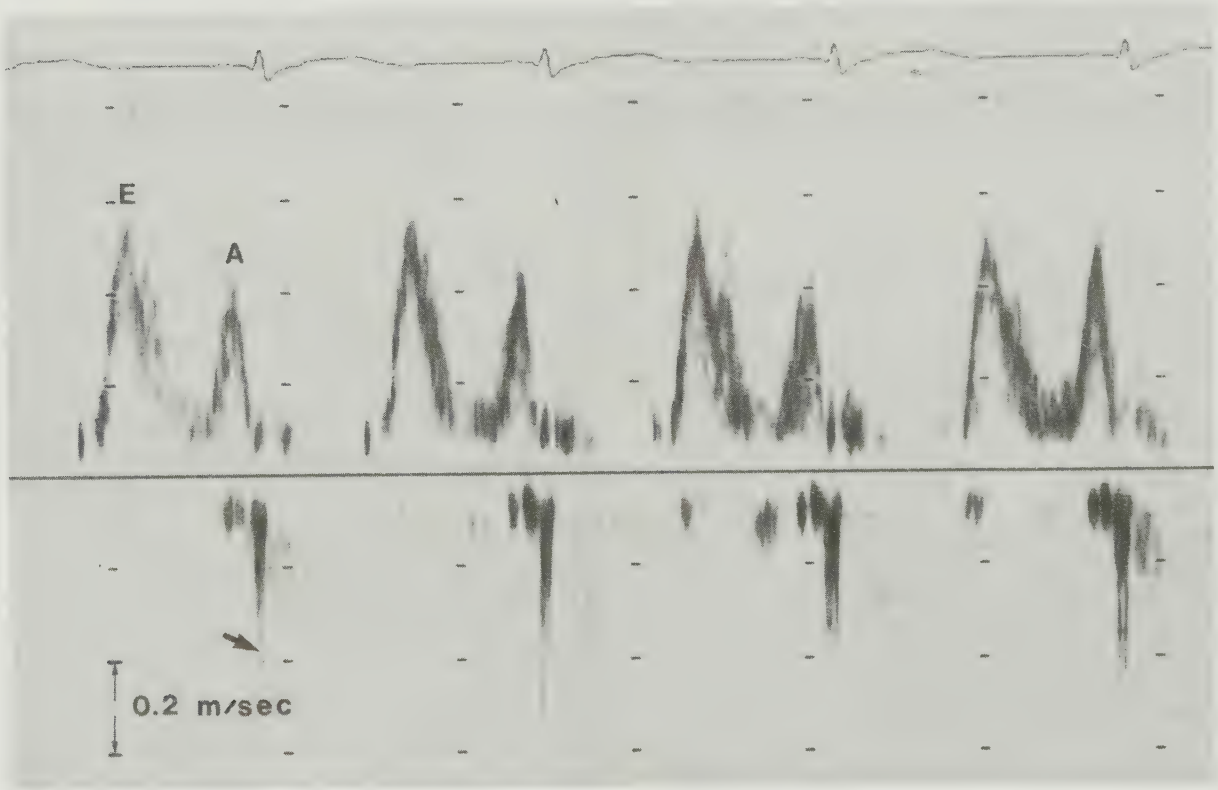

Fig. 47–8. Normal mitral inflow. Flow across the mitral and tricuspid valves is similar, characterized by a prominent early diastolic filling phase (E). Later in diastole a second filling phase (A) follows atrial systole. The onset of ventricular systole is marked by a Doppler signal produced by closure of the mitral valve (arrow).

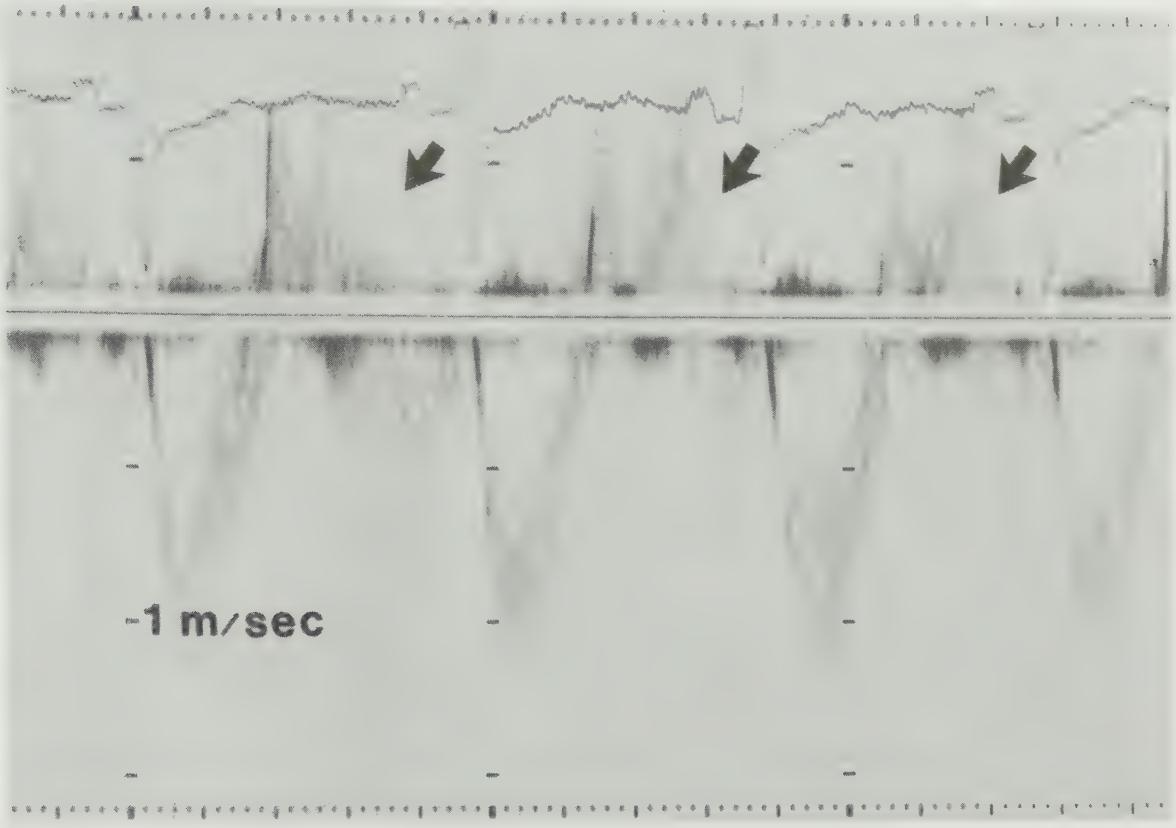

Fig. 47–9. Aortic regurgitation. A Doppler sample volume is placed in the left ventricular outflow tract immediately beneath the aortic valve leaflelts. Normal ventricular outflow pattern is present during systole. However, a signal of disturbed flow is present throughout diastole. Ordinarily, there is no diastolic flow in the subaortic region; therefore, this represents signal from an aortic regurgitation jet. The appearance of bidirectional diastolic flow is created by a circular movement of red blood cells in eddies surrounding the regurgitation jet.

Doppler sampling of flow in the left ventricular outflow tract is best performed from the apical window. The subaortic region also can be examined from the parasternal location.

Aorta

Flow in the aorta occurs almost exclusively in systole, and normal velocities range from 60 to 150 cm/sec. The brief amount of diastolic flow that enters the coronary arteries is generally undetectable during the normal Doppler examination (Fig. 47–10). Flow reversal in the aorta indicates significant runoff either due to aortic regurgitation[93] or to systemic runoff into a low pressure system through a patent ductus arteriosus aortopulmonary window or atrioventricular malformation.[94] Increased velocities in the aorta may reflect increased cardiac output such as occurs with anemia. Higher aortic velocities may be associated with Still's murmurs in normal children.[95,96]

Disturbances due to localized stenosis can occur in the ascending aorta due to aortic valve abnormalities[1,2,75] or supravalve stenosis. In the proximal descending aorta, the pattern found in coarctation of the aorta is pathognomonic (Fig. 47–11) when obstruction is present. The Doppler pattern consists of a continuation of forward flow throughout diastole. In addition, there is an acceleration of blood through the stenotic area and a high-velocity jet detectable at the point of obstruction.

Although flow in the proximal ascending aorta can be examined from the apical window, flow in the remainder of the aortic arch is best sampled from the suprasternal notch, or the high right parasternal location.

QUANTITATIVE DOPPLER METHODS

Measurement of Flow

The relationship between mean velocity, cross-sectional area, and volume of flow is discussed in Chapter 34. Based on that relationship, it is possible to estimate cardiac flow if one can measure the mean velocity and cross-sectional area at a given point. This provides the Doppler echocardiographer with a powerful quantitative tool, but certain conditions must be met for the Doppler estimates of flow to reflect true flow volumes: 1) flow must be laminar, and 2) the spatial velocity profile across the orifice must be relatively flat.[97–101] These criteria are necessary because the Doppler echocardiographer uses data from a single sampling point to represent mean velocities for the entire area of flow. Other assumptions include the fact that the angle of incidence between the ultrasound beam and the direction of flow must be known or nearly zero degrees. Also, the flow area is assumed to be constant during the period of flow (except when using the modified mitral flow method).[102]

Flow is the product of cross-sectional area and mean velocity.

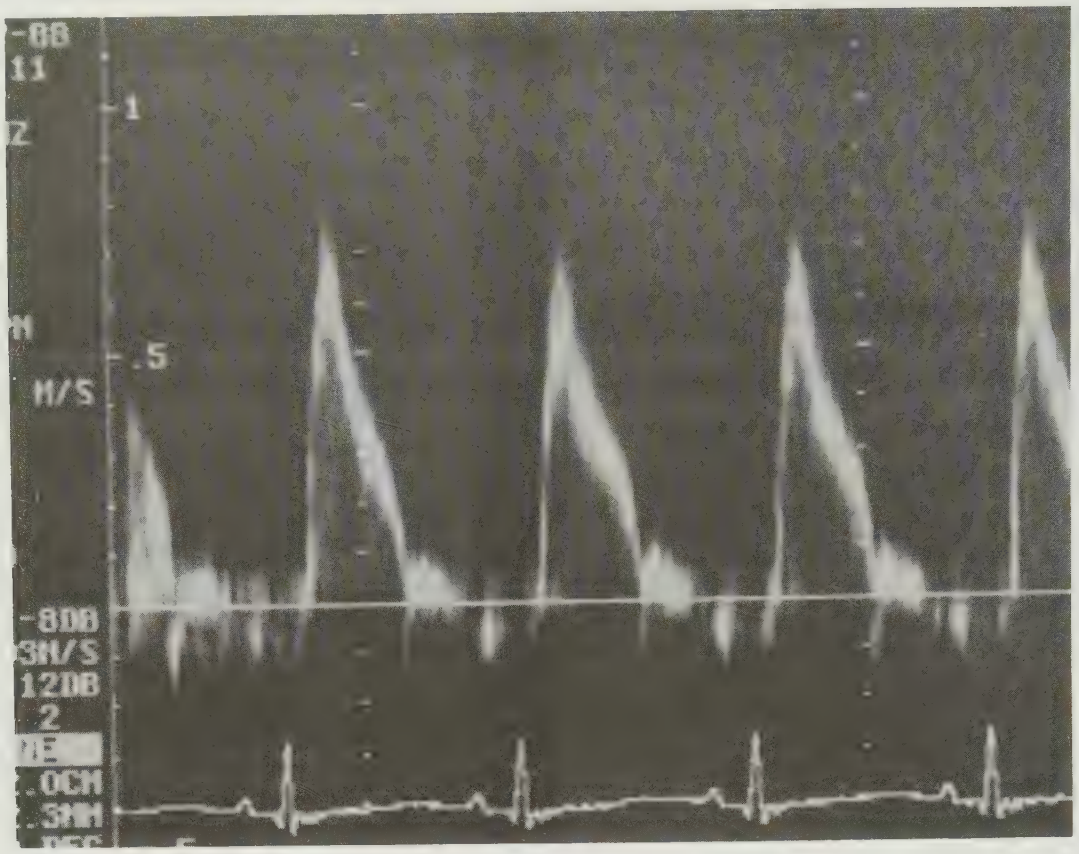

Fig. 47–10. Normal aortic flow. The Doppler sample volume is placed in the ascending aorta from the suprasternal notch. The flow occurs during systole toward the transducer (upward). A narrow range of velocities is present that produces a discrete spectral envelope. Aortic acceleration is relatively rapid with peak velocity occurring early in the ejection phase. As the flow decelerates, red cells move at different rates creating a broader deceleration envelope.

Cross-sectional area is generally obtained from the two-dimensional or M-mode echocardiogram as discussed below. Mean velocity can be obtained either for a single beat (time velocity integral) over a complete cardiac cycle, or over an arbitrary period of time. If the time velocity integral is used, then the formula for calculation of flow is:

$$\text{Flow} = \text{cross-sectional area} \times \text{TVI} \times \text{heart rate}$$

If mean velocity is measured for the complete cardiac cycle or over a specific period of time, then heart rate is not taken into account, and flow is simply the product of cross-sectional area and mean velocity. The Doppler signal used to calculate mean velocity can be from pulsed or continuous wave interrogation. When a pulsed output is obtained, the mean velocity is calculated by tracing the darkest part of the spectral display (modal velocity). When a continuous wave output is used, the tracing is usually made around the edges of the spectral envelope (maximal velocity). These methods may produce slightly different results. Whichever method is used to obtain mean velocity, at least three to five complete cardiac cycles should be measured to reduce the potential error induced by beat-to-beat variation.[103,104] When performing serial studies in the same patient, similar methods should be used from one examination to the next.

Aortic Flow

The aortic valve is the location chosen most frequently for measurement of cardiac output. There are several ways to measure aortic area (Fig. 47–12), including measurement at the insertion of the aortic valve leaflets or in the aorta above the sinuses of Valsalva from the 2DE.[100] It is also possible to use the aortic valve leaflet separation diameter as demonstrated on an M-mode echo as an estimate of aortic diameter.[105,106] The first method—namely, measurement at the insertion of the aortic leaflets—is the most reproducible method,[107–109] although it tends to underestimate true flow area slightly.[110,111] Each of these methods assumes a circular aortic shape and each is subject to large discrepancies unless extreme care is taken in the measurement process.[99,108]

Doppler recording of velocity can be performed from the suprasternal notch or the apex. Because the highest velocities occur at the aortic valve, continuous wave Doppler can be used with the assumption that the maximal velocities occur at the annulus. If pulsed Doppler is used, the sample volume is placed as close as possible to the aortic leaflets. It is desirable to have valve clicks present on the Doppler tracing for confirmation of sample volume placement. Mean velocity is obtained by measuring the area under the Doppler tracing (Fig. 47–13) and cardiac output is determined using the following formula:

$$\text{Aortic flow} = \text{mean velocity} \cdot \left(\frac{D}{2}\right)^2 \cdot \pi$$

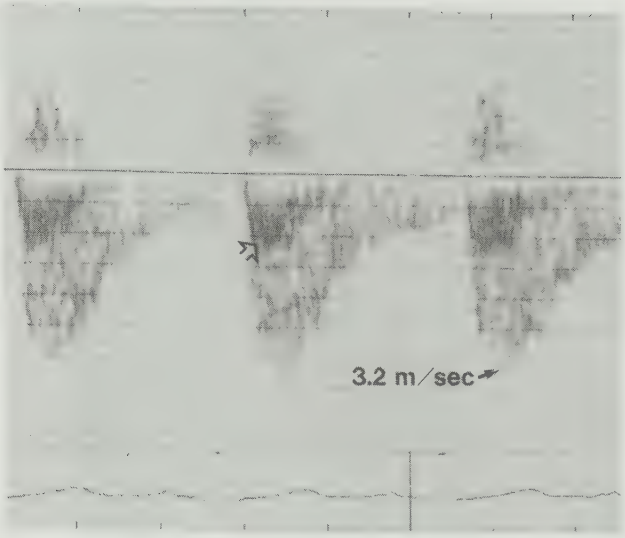

Fig. 47–11. Coarctation of the aorta. Continuous wave Doppler from the suprasternal notch directed toward the descending aorta. This tracing demonstrates Doppler signal from two populations of cells, one has a higher velocity (3.2 m/sec) with a persistence of flow into and through diastole. This pattern suggests obstruction at the site of coarctation. A second population of velocities (open arrow) can be demonstrated within the Doppler tracing.

where D is the aortic diameter. Alternatively, if the time velocity integral is used, the formula becomes:

$$\text{Aortic flow} = \text{TVI} \cdot \left(\frac{D}{2}\right)^2 \cdot \pi \cdot \text{HR}$$

Pulmonary Flow

The principles of Doppler flow measurement at the pulmonary valve are identical to those used for the aortic valve. Pulmonary artery diameter is measured from a 2DE. Unfortunately, the pulmonary artery annulus is frequently displayed in such a way that measurement is difficult without errors caused by poor lateral resolution. Pulmonary flow is best sampled using pulsed Doppler from the parasternal or subcostal positions, although a variety of locations should be used to identify the highest recordable pulmonary velocities.[112] The sample volume is moved to the pulmonary annulus as identified by valve clicks on the Doppler tracing. Optimal azimuthal angulation is obtained by listening to the Doppler audio output and manipulating the transducer to maximize the systolic velocities.

Mitral Flow

Measurement of flow across the mitral or tricuspid valve presents more potential for error. This is due to several factors including the fact that the mitral valve annulus is an elliptical structure that does not occupy a single Euclidean plane. In addition, the area of flow through the tips of the mitral leaflets changes throughout diastole as the leaflets first move apart, then re-appose and move apart again. Two methods are used for calculating mitral flow using Doppler echocardiography. The first measures flow at the mitral annulus. Doppler sampling is performed with a pulsed sample volume placed at the annulus using 2-D guidance. Mitral area is calculated either from a diameter obtained from the apical view (the orifice is assumed to be circular) or by tracing the area of the mitral annulus on the two-dimensional short axis image. Although both methods have been shown to correlate with other methods of measuring flow, there is considerable inaccuracy produced by the difficulties in measurement of the true mitral annulus area.[107,113]

An alternative method for estimation of mitral flow entails placement of a pulsed Doppler sample volume in the funnel of the mitral valve where the velocities are highest. The area at this point is calculated by measuring the leaflet separation area on an M-mode echocardiogram and normalizing for maximal mitral valve area. This method has also been shown to correlate with other methods,[102,114,115] but it is tedious and relies on several assumptions regarding the size and shape of the mitral orifice.

Tricuspid Flow

The most reasonable way to measure flow across the tricuspid valve is to sample at the annulus from the apex using pulsed Doppler. The tricuspid area is calculated by using a tricuspid diameter obtained from two-dimensional echocardiogram and assuming a circular shape.[116,117]

CLINICAL VALIDATION OF DOPPLER MEASUREMENT OF CARDIAC FLOW

There are a large number of studies validating the use of Doppler estimation of stroke volume in cardiac output in animals and adult patients.[118] There are fewer studies validating the use of this technique in infants and children. Estimates in the normal fetus,[119–121] preterm, and term newborn infants,[122,123] have been published. However, those studies did not include simultaneous invasive estimates of cardiac output, and the methodology for area measurement is different in each of the studies. Therefore, no reliable standards exist for Doppler cardiac output measurement in the fetus or infant. In fact, due to the small size of the valve orifices, the percent potential error due to a measurement inconsistency is considerably greater in the fetus or newborn than in the older child or adult.[119]

Studies have been performed in older children comparing simultaneous thermodilution or Fick estimates of cardiac output to Doppler measurements of output.[105,109,124–126] This research employs a variety of methods of both Doppler interrogation and aortic area measurement. Several studies have addressed the effect of different sites and methods of area measurement,[105,109,111] but there is no universal agreement on the ideal method for Doppler estimation of aortic flow.

Serial measurements of cardiac output in the same patient would alleviate the potential errors induced by aortic valve measurement if one assumes that the aortic diameter remains relatively constant. The value of serial measurements of aortic flow has been demonstrated during exercise[127] and during administration of pharmacologic agents.[109] In serial studies, one can expect changes of more than 10% in actual cardiac output to be accurately reflected in the Doppler measurements.[109,128,129]

Measurement of Shunt Flows

There has been a considerable interest in the development of noninvasive methods for measuring the volume of left-to-right

Fig. 47–12. Measurement of aortic area. A two-dimensional echocardiogram in the parasternal long axis view is shown. Three possible sites for measurement of the arotic cross-sectional area are demonstrated: 1) at the level of the aortic valve (AV), 2) at the aortic root at the level of the sinus of Valsalva (AR), and 3) in the ascending aorta above the sinus of Valsalva (AA). LA = left atrium, LV = left ventricle.

shunt in pediatric patients with congenital cardiac defects. In fact, in the pediatric population this may be more useful than the measurement of absolute cardiac output or stroke volume. The estimation of left-to-right shunt entails volumetric measurement at two intracardiac sites. For example, the ratio of pulmonary to systemic flow in patients with atrial septal defects can be estimated by comparing the flow measured at the pulmonary valve compared to that measured at the aortic valve. Alternatively, the tricuspid valve flow could be used for pulmonary flow estimation; likewise, the mitral valve flows could be used as an estimate of systemic flow volume. For the patient with patent ductus arteriosus, systemic flow is measured at the tricuspid or pulmonary valve and pulmonary flow is obtained at the aortic valve. The magnitude of the ductal shunt is calculated by subtracting the flow measured at the aortic valve from that measured at the pulmonary valve.

Doppler estimates of pulmonary to systemic flow ratios correlate roughly with other methods of shunt measurement.[103,130–132] However, such estimates are subject to wide variability primarily due to difficulties in accurate measurement of area. They can be used by the clinician as a semiquantitative estimate of magnitude of left-to-right shunt.

A similar approach has been used to measure regurgitant fractions or regurgitant volumes in patients with aortic or mitral regurgitation.[68,69,113–136] These calculations also require measurement of flow at at least two intracardiac sites and then the calculation of regurgitant volume by subtracting flow at one site from flow at another site. For example, aortic regurgitant volume is the difference between forward flow at the aortic valve and forward flow at the mitral valve. As with other Doppler flow estimates, these calculations require close attention to technical detail. Also, any inherent inaccuracies in the method are exaggerated by the fact that two flow estimates are being performed.

Estimation of Pressure Gradients

The theoretical basis for the use of Doppler velocities in the estimation of pressure gradients is discussed in Chapter 34. Several simplifications are made to the Bernoulli equation, and it is used clinically[137]:

$$\text{Pressure gradient} = 4(V_{max})^2$$

This equation can be applied to any pressure drop across a discrete obstruction and is useful in a variety of clinical situations. However, long segment obstructions' proximal velocities can be significant, causing an underestimation of the actual pressure gradient,[138] or relaminarization of flow can occur with loss of distal velocity and result in an overestimation of the pressure gradient using Doppler.[130] Pressure gradients across extremely small orifices can also be underestimated due to an inadequate jet formation. Finally, the shape of the orifice also has an effect on the jet that is produced and may affect the accuracy of the pressure gradient estimation.[138]

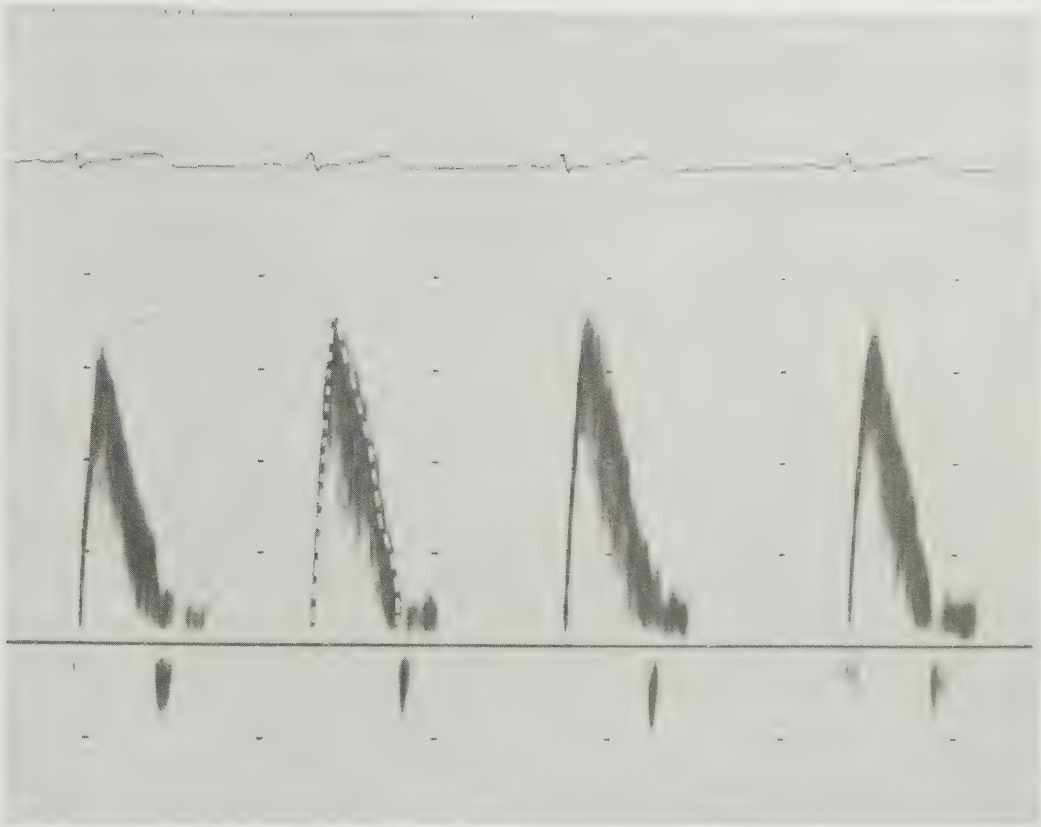

Fig. 47–13. Measurement of mean aortic velocity. A typical Doppler tracing from the ascending aorta is shown. There is a relatively narrow range of Doppler velocities that produces a discrete envelope. There is a slight increase in the range of velocities during deceleration. The method for measuring mean velocity is demonstrated. Modal Doppler velocities are traced (dotted white line) using a digitizer. Cardiac output is the product of cross-sectional area, mean velocity, and heart rate.

Clinical Use of Doppler Estimation of Pressure Gradients

Doppler echocardiography has been used to estimate the pressure gradient produced by stenosis in a variety of lesions. Good correlations between catheter measured gradients and Doppler estimated gradients have been shown for pulmonary stenosis,[36,140–149] aortic stenosis,[144,146,150–159] and mitral valve stenosis.[152,160–165] In addition, Doppler estimates correlate well with the gradients measured across subaortic obstructions,[80,81,151,166] ventricular septal defects,[167–170] pulmonary artery bands,[144,145,171,172] prosthetic valves,[173–175] surgically created shunts,[176] patent ductus arteriosus,[177,178] and coarctation of the aorta.[179,180] Doppler velocities also have been shown to correlate with severity of pulmonary venous obstruction[55] and obstruction due to a restrictive atrial septal defect.[55,181] The peak velocity of the tricuspid regurgitation jet has been used to estimate right ventricular pressure in a variety of situations.[182–186]

Estimation of pressure gradients using Doppler peak velocity allows the clinician to estimate the severity of stenotic lesions noninvasively. In addition, pressure gradient estimations and peak velocity can be used to estimate intracardiac pressure in a variety of situations. In the absence of aortic valve disease, the left ventricular systolic pressure is estimated by measuring brachial artery pressure with a sphygmomanometer. If aortic stenosis is present, peak left ventricular systolic pressure is estimated by calculating the peak or mean pressure gradients from the Doppler output of the aortic stenosis jet. When peak jet velocity is used, the peak instantaneous gradient is obtained. Peak instantaneous gradient is not identical to catheter measured peak-to-peak gradient in aortic stenosis (Fig. 47–14).[146] Peak instantaneous gradient is greater than the peak-to-peak measurement, which varies from between 70 to 84% of the maximal gradient.[154,158,187,188] On the other hand, in pulmonary stenosis, peak instantaneous gradient occurs in mid-systole and corresponds closely with peak-to-peak gradient (Fig. 47–15).[146,149,184]

Right ventricular systolic pressure can be estimated if tricuspid regurgitation or a ventricular septal defect is present. The peak velocity of the tricuspid regurgitation jet is converted to pressure gradient using the modified Bernoulli equation. This value is then inserted into a regression equation or more simply added to a clinical estimate of right atrial pressure. For example, if a tricuspid regurgitation jet of 3.5 m/sec peak velocity is obtained, this yields an estimated pressure gradient between right ventricle and right atrium in systole of 49 mm Hg. If the clinical estimate of right atrial pressure is 6 mm Hg, then the estimated right ventricular systolic pressure is 55 mm Hg. In the absence of right ventricular outflow tract obstruction, this would allow estimation of pulmonary artery systolic pressure of 55 mm Hg also. If, on the other hand, there is obstruction to right ventricular outflow, Doppler estimation of the gradient across the stenotic area allows estimation

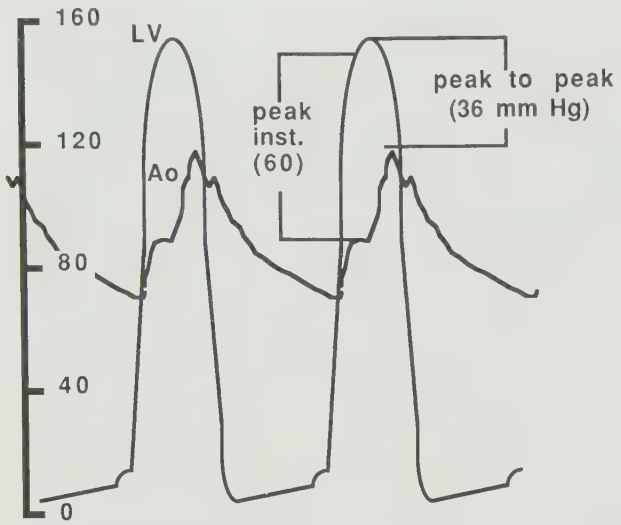

Fig. 47–14. Pressure gradients in aortic stenosis. A diagrammatic representation of aortic and left ventricular pressure tracings demonstrate the difference between peak instantaneous and peak-to-peak pressure gradients. Peak instantaneous gradient occurs early in systole. Peak-to-peak pressure gradient does not reflect simultaneous pressure readings. In aortic stenosis, peak-to-peak pressure gradient is generally 60 to 75% of peak instantaneous gradient.

of pulmonary arteries' systolic pressure. For example, if in the previous case a peak velocity across a stenotic pulmonary valve of 3 m/sec is obtained, pulmonary artery systolic pressure is estimated to be 55 mm Hg less the estimated gradient of 36 mm Hg, which equals 19 mm Hg.

The presence of a ventricular septal defect also provides an opportunity to estimate right ventricular systolic pressure. First, left ventricular systolic pressure is estimated or measured; then the peak velocity of the jet across the ventricular septal defect is obtained. Because of differences in the contraction sequence of the two ventricles, peak instantaneous gradients of 15 to 25 mm Hg may exist, even though peak systolic pressures are equal in the two ventricles. Therefore, ventricular septal defect jets less than 2.5 m/sec do not necessarily correlate with a right ventricular

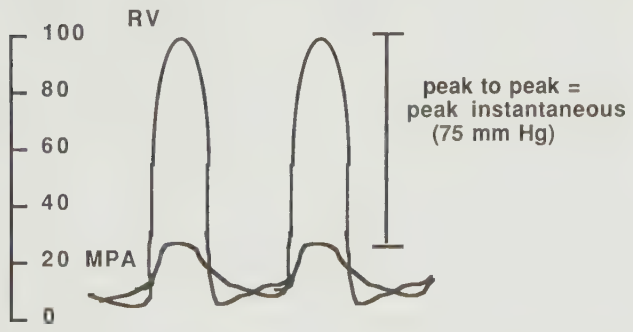

Fig. 47–15. Pressure gradients in pulmonary stenosis diagrammatic representation of pulmonary artery and right ventricular pressure tracings demonstrate that peak instantaneous and peak-to-peak pressure gradients occur in midsystole simultaneously. Therefore peak instantaneous pressure gradient is nearly identical to the peak-to-peak measurement.

systolic pressure that is less than that of the left ventricle. However, higher peak velocities allow reasonably accurate estimation of interventricular pressure differences and subsequent calculation of right ventricular systolic pressure.[169] Estimates of right ventricular pressure are particularly accurate when two independent methods are used in its estimation, thereby providing confirmatory evidence.

Estimation of systolic and mean pulmonary artery pressures is possible using peak and mean gradients from Doppler tracings of flow across both patent ductus arteriosus[177,178] and surgically created shunts.[176] As with all Doppler velocity estimates, this requires careful attention to technique and alignment of the Doppler beam as close to the axis of flow as possible. However, even if precise pulmonary artery pressures cannot be estimated, the technique can be useful clinically. For example, if an infant with transposition of the great arteries has a patent ductus arteriosus, the presence of a 3.5 m/sec systolic jet across the patent ductus insures that pulmonary artery systolic pressure is at most 50 mm Hg less than aortic pressure. This may reassure the clinician that significant pulmonary hypertension is absent and obviate the need for cardiac catheterization.

Other methods are available that use Doppler information to calculate pulmonary artery pressures. These include: 1) estimation of the mean and diastolic pulmonary artery pressure from pulmonary regurgitation;[189] 2) estimation of pulmonary artery pressure using Doppler derived systolic time intervals;[190–192] and 3) use of the ratio of pulmonary artery acceleration time to ejection time.[191,193–195] Although the statistical correlation of these methods with catheter measured pressures has been good, the wide variability and scatter makes individual estimates of pressure somewhat unreliable.

Theoretically, left ventricular diastolic pressure can be estimated using the peak velocity of the aortic regurgitation jet.[196] This end-diastolic gradient is subtracted from the aortic diastolic pressure to yield left atrial pressure. Similarly, in the presence of mitral regurgitation the peak velocity of the regurgitant jet is used to estimate a systolic pressure gradient between left ventricle and left atrium.[196] The difference between the cuff systolic blood pressure and the pressure gradient theoretically yields the left atrial systolic pressure. Unfortunately, the magnitude of left ventricular end-diastolic or left atrial pressure is frequently small. Therefore, slight errors in either cuff measurement of blood pressure or Doppler measurement of peak velocity will result in sizeable errors in estimation.

The following guidelines should be used in any quantitative estimate of peak velocity. First, perform a careful two-dimensional and pulsed Doppler study to determine which structural abnormalities and flow disturbances are present. This is particularly important when using continuous wave Doppler due to the inherent range ambiguity of the technique. Second, when possible, identify the jet of interest using pulsed Doppler or color Doppler first and then switch the Doppler unit to high-pulse repetition frequency Doppler or continuous wave Doppler for an initial estimate of the jet velocity. Third, use the audio signal to obtain the highest possible Doppler velocity. The transducer is moved so that the angle between the jet and the Doppler beam is as close to zero as possible. In general, correction for an assumed angle of incidence is not advisable. Fourth, interrogate the jet from as many echocardiographic windows as possible. For example, the jet of pulmonary

stenosis can be interrogated from the left parastenal, subcostal, apical, and suprasternal transducer positions. The jet caused by aortic stenosis is accessible from the apex, the high right parasternal location, and the suprasternal notch. Using a variety of echocardiographic windows increases the likelihood that the examination will yield the highest possible velocities.[36,112,156] Fifth, use different transducers for the examination of the same jet. Each transducer has an unique "footprint"; some may be better than others in a particular situation. Sixth, whenever possible, obtain flow information at the time of measuring a gradient. This increases the usefulness of the gradient estimation and allows meaningful serial comparisons. Finally, remember that Doppler peak velocity estimates the peak instantaneous gradient. For some lesions, such as pulmonary valve stenosis, peak instantaneous gradient occurs in midsystole and corresponds very closely with catheter-measured peak-to-peak gradient and mean gradient.[146,187] However, for aortic stenosis, peak instantaneous gradient (and peak velocity) occurs in early systole and exceeds both peak-to-peak and mean gradient.[146,154,188,197] However, Doppler estimated mean gradient correlates extremely well with catheter measured mean gradient.[154,188]

Stenotic Valve Areas

The gradient across a stenotic valve is not the sole indicator of the severity of obstruction. The presence and magnitude of a pressure gradient depends on the flow across the valve. For example, a newborn infant with critical aortic stenosis and low cardiac output may generate a small transaortic pressure gradient that will be reflected by a low peak velocity measured by Doppler. Alternatively, an older child with only moderate aortic stenosis may generate an extremely high peak instantaneous gradient during peak exercise. Another example of the limitation of peak velocity alone as an estimate of severity of obstruction occurs with mitral stenosis. Even with severe mitral obstruction, the pressure generated in the atrium is relatively low, and peak velocity does not vary directly with severity of obstruction. Therefore, Doppler velocity information should be used in conjunction with measurement of the amount of flow across the obstruction. This can be accomplished in one of two ways. Flow can be measured at a site different from that where the obstruction is present. For example, in the case of aortic stenosis, flow could be measured across the mitral valve,[198] or the pulmonary valve if there is no intracardiac shunt. An alternative approach is to use the continuity equation, which is based on the fact that flow volume is the same immediately proximal to the obstruction as it is in the obstructive jet itself (Fig. 49–16). Therefore, since flow is the product of mean velocity and cross-sectional area:

$$\text{Flow} = \text{area(proximal)} \times \text{mean velocity(proximal)}$$

$$= \text{area of obstruction} \times \text{mean velocity (jet)}$$

Solving for the area of obstruction:

$$\text{Area of obstruction} = \frac{\text{area(proximal)} \times \text{mean velocity(proximal)}}{\text{mean velocity (jet)}}$$

For aortic stenosis, the proximal area is measured using a two-dimensional echocardiogram measuring just proximal to the aortic valve. Proximal mean velocity is obtained using a pulsed Doppler sample volume placed in the left ventricular outflow tract. Care must be taken not to advance the sample volume too close to the aortic valve or the area of pre-jet acceleration will be entered. Mean jet velocity is obtained by using continuous wave Doppler and obtaining the maximal velocities in the jet itself. The mean velocity is obtained by obtaining the area under the jet velocity curve. Multiple reports have validated the use of the continuity equation in adults with aortic valve disease.[188,199–205]

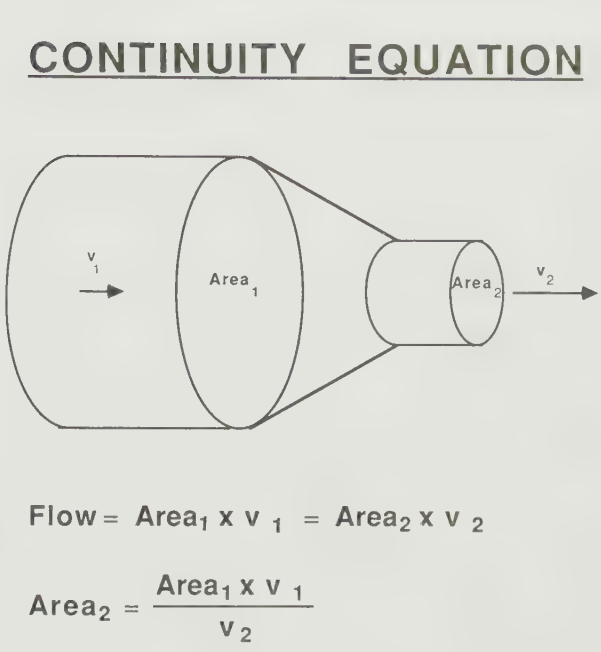

Fig. 47–16. The continuity equation for estimation of valve area.

Mitral Valve Area

Valve area in mitral stenosis can be calculated from peak or mean mitral velocity jets using a variety of formulas. However, the most successful method that is relatively independent of transvalvular flow uses the pressure half-time concept[152,162–165,206–208]:

$$\text{Mitral valve area (cm}^2\text{)} = \frac{220}{\text{pressure half-time (msec)}}$$

For use with Doppler measurements, the mitral inflow jet is obtained, and velocity measurements are converted to pressure estimates for pressure half-time measurement. This is done by dividing the peak velocity by 1.4. The point at which velocity reaches that magnitude is marked and the time from peak velocity to that point is measured. This time corresponds to the pressure half-time.

Diastolic Function

Ventricular inflow produces a plot of blood velocity versus time. These inflow velocities reflect the balance between pressure and volume during diastole and may indicate ventricular compliance. The normal ventricular inflow pattern is characterized by an early diastolic filling phase and a late filling phase following atrial contraction. Ventricular diastolic function is responsible to some extent for the relative peak velocities of these two phases as well as

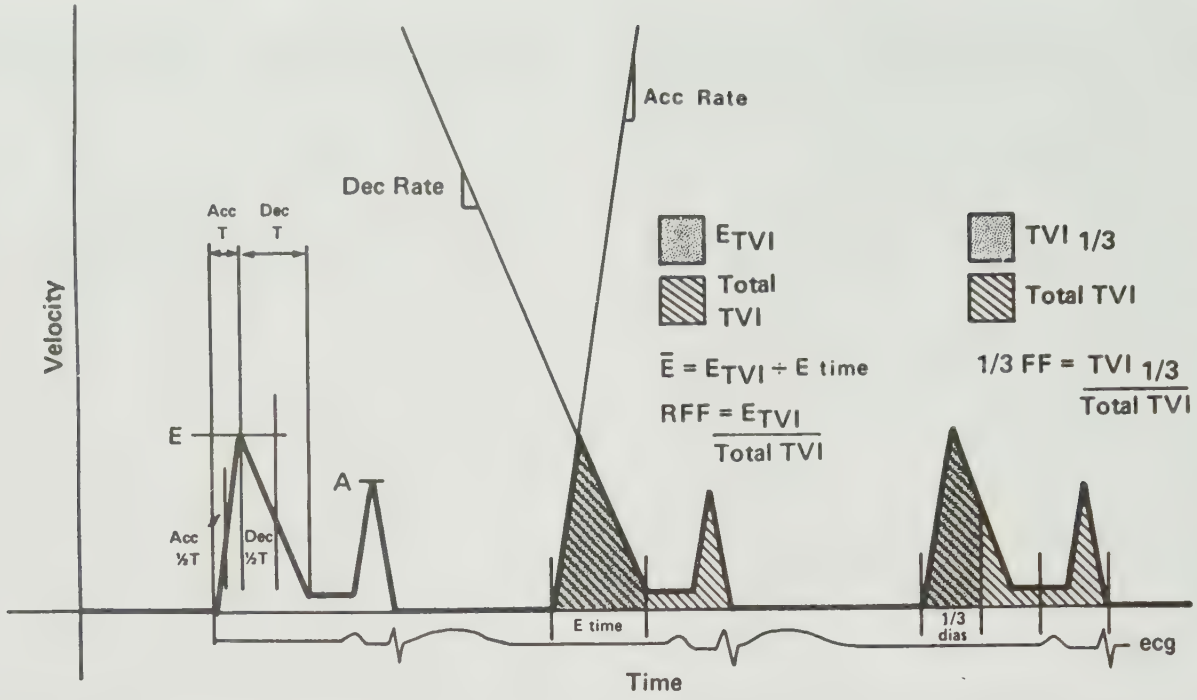

Fig. 47–17. Previous published Doppler parameters of diastolic function. ACC = acceleration; DEC = deceleration; FF = filling fraction; RFF = rapid filling fraction; T = time; TVI = time velocity integral. (Reproduced with permission from Snider, A.R.: Prediction of intracardiac pressures and assessment of ventricular function with Doppler echocardiography. Echocardiography, *3*:36, 1986).

the proportion of filling that occurs during each phase and the rate at which ventricular filling occurs.

Some studies have demonstrated good correlation between Doppler estimates of peak filling rates and similar determinations made using angiographic[209] or radionuclide methods.[210,211] Other studies have shown differences between different methods.[212] In addition to filling rates, a variety of Doppler indices of diastolic function have been used.[213,214] They include a simple ratio of peak early diastolic velocity (E) to peak late diastolic velocity (A), early diastolic acceleration and deceleration times, half-times, and filling rates. In addition, using the integral under the Doppler curve as an estimate for filling volume, a number of filling fractions have been measured for use as indicators of ventricular compliance.

As compliance decreases and the ventricle becomes stiffer, early diastolic filling velocities fall. As stroke volume falls, left atrial pressure rises, which in turn leads to increasing filling velocities; but filling occurs over a longer period of time. Therefore, reduced ventricular compliance is manifest in the ventricular inflow Doppler tracing as a reduction in peak early diastolic filling velocity and the prolongation of the early filling phase. Because of the late diastolic redistribution of inflow that occurs as a compensatory mechanism, early filling fraction is reduced and A:E ration is increased (Fig. 47–17).[213]

Left ventricular diastolic filling has been shown to change with age. In fact, the use of Doppler echocardiography has made possible examination of ventricular inflow patterns in the fetus. The normal fetal pattern includes reversed E:A ratio with higher late diastolic rather than early diastolic peak filling velocities. This is true for both the mitral and tricuspid valves.[215] As the fetus nears term, early filling velocities increase, lowering the A:E ratio.[216] After birth, the A:E ratio normalizes, and in adults peak filling rates tend to decrease with advancing age.[217]

Studies in adult patients have demonstrated Doppler inflow abnormalities in dilated cardiomyopathy,[218] restrictive ventricular physiology,[10] hypertrophic cardiomyopathy,[219,220] coronary artery disease,[221,222] primary pulmonary hypertension,[223] and systemic hypertension.[224]

Thus far, diastolic ventricular function has been characterized in normal children as well as children with systemic hypertension and children with hypertrophic cardiomyopathy. Whether these techniques will be applicable to children with congenital heart disease awaits further study.

CHAPTER 48

Fetal Echocardiography

W Robert Morrow
James C Huhta

The ability to observe the human fetus in utero with transabdominal ultrasonography has revolutionized obstetric diagnosis and treatment of fetal disease. Likewise, the use of echocardiography in the human fetus has paralleled the development of echocardiographic technology and has permitted early diagnosis of structural and functional abnormalities of fetal circulation. Early application of M-mode cardiac ultrasound to cardiac imaging in the human fetus was first reported by Garrett and Robinson.[1] Egeblad and associates[2] recognized the atrioventricular septum in the fetus using M-mode echocardiography, and M-mode echocardiographic parameters of ventricular size and function have since been developed.[3] The use of two-dimensional echocardiography in the diagnosis of structural congenital heart disease was pioneered by Allan and associates[4] and Kleinman and associates.[5] The accurate diagnosis and effective treatment of fetal arrhythmias are now possible as a result of M-mode and pulsed Doppler echocardiography. Thus the full range of fetal cardiac disease can be investigated noninvasively, allowing appropriate and timely treatment of the affected fetus.

FETAL CIRCULATION

Accurate diagnosis of heart disease in the fetus requires an appreciation for the basic differences between the circulation of the fetus and the circulation of the neonate adapted to extrauterine life. The circulation of the fetus is described in Chapter 15 of this text. A brief description of the major features of fetal circulation follows.

The placenta is the organ of gas exchange, nutrient supply, and waste elimination in the fetus and therefore must receive a major proportion of fetal cardiac output. In addition, the fetal lungs and bowel are active only in a metabolic sense and do not contribute directly to gas exchange and nutrient supply. Three cardiovascular shunts exist in the fetus to accomplish the distribution of oxygen and nutrients to the fetus and carbon dioxide and other products of metabolism to the placenta. These are the ductus arteriosus, ductus venosus, and foramen ovale cordis. Because of the presence of these cardiovascular shunts, the fetal circulation functions in parallel rather than in series as in the adult. Fetal cardiac output, therefore, may be described only in terms of combined ventricular output.

The venous return to the fetal heart by the inferior vena cava is directed primarily to the foramen ovale and left atrium by the eustachian valve, although a small percentage of inferior vena caval return is directed to the tricuspid valve.[6] Inferior vena caval return is primarily composed of umbilical venous flow directed to the inferior vena cava by the ductus venosus with the addition of portal and hepatic venous flow. Therefore the oxygen-rich umbilical venous return ultimately enters the left ventricle and is distributed to the fetal head and upper body. The output of the left ventricle represents approximately 30% of combined ventricular output in the fetal lamb[7] and has an oxygen saturation of approximately 65%. Total umbilical venous flow therefore represents placental blood flow returning to the fetus. The superior vena caval return, representing venous flow from the fetal head and upper body, is directed primarily through the tricuspid valve to the right ventricle. The superior vena caval return and a portion of inferior vena caval return are ejected from the right ventricle, where the majority, approximately 60% of combined ventricular output,[8]

enters the ductus arteriosus and supplies the descending aorta. Approximately 10% of the ascending aortic flow in the fetal lamb enters the descending aorta by way of the aortic isthmus. Umbilical arterial flow in the paired umbilical arteries arising from the descending aorta represents approximately 40 to 50%[8] of combined ventricular output and is the arterial supply to the placenta on the fetal side.

The proportion of blood flow to fetal organs varies with gestational age, metabolic activity of the organ, organ growth, and species.[8] The proportion of blood flow to the fetal head and lungs increases with increasing gestational age, whereas the proportion of blood flow to the fetal heart remains approximately the same. In the human fetus, the proportion of combined ventricular output ejected by the left ventricle is greater than that in the fetal lamb, probably as a result of the greater mass of cerebral tissue in the human fetus.[9–11] Nonetheless, in the human as in the lamb, the right ventricle supplies the greatest contribution to descending aortic flow and consequently to umbilical arterial flow. Therefore heart failure in the fetus is often initially accompanied by right ventricular enlargement and ultimately by signs of right ventricular failure such as ascites, edema, and pleural and pericardial effusions.[12,13]

INDICATIONS FOR FETAL ECHOCARDIOGRAPHY

Among the many indications for fetal echocardiography,[14–17] a number of maternal factors may predispose the fetus to structural or functional abnormalities of the heart. Congenital heart disease in the mother, father, or siblings increases the risk of congenital heart disease in the fetus. Maternal exposure to known cardiac teratogens such as the rubella virus or lithium or to other potentially teratogenic environmental agents necessitates careful examination of the fetal heart. Maternal disease may produce abnormalities of cardiac structure, function, or heart rate in the fetus. Reduced cardiac function and septal hypertrophy may be recognized in infants of poorly controlled diabetic mothers. Congenital AV block is often associated with maternal autoimmune disease such as systemic lupus erythematosus. Reduced placental blood flow and elevated placental resistance may be recognized in toxemic pregnancies associated with intrauterine growth retardation.

Among the fetal indications for cardiac ultrasound, the most common cause for referral is the recognition of fetal abnormalities detected on routine obstetric ultrasonic examination. Abnormal fetal cardiac structure may be demonstrated in the course of obstetric examination of the fetal thorax. Fetal polyhydramnios may be associated with abnormalities of cardiac structure and function in addition to other congenital defects. The development of nonimmune fetal hydrops should lead to fetal echocardiographic examination to exclude structural heart disease or fetal arrhythmia. Cardiac failure in the fetus is manifest on routine obstetric ultrasound as cardiac enlargement in association with nonimmune hydrops.[12,13] Serial assessment of cardiac function may be useful in fetuses with hemolytic disease and associated hydrops. Abnormalities of fetal heart rate and rhythm are being recognized with increasing frequency because of widespread use of antepartum fetal heart rate monitoring; these abnormalities often lead to fetal echocardiographic examination. Accurate assessment of fetal arrhythmias then allows effective treatment to be instituted. The detection by amniocentesis of chromosomal abnormalities that are known to predispose to cardiac disease, such as trisomy 21, should lead to referral for fetal echocardiography.

FETAL CARDIAC ULTRASOUND METHODOLOGY

In the following section we will explore the application of echocardiography to examination of the fetal cardiovascular system. The methodological approach to the fetal echocardiographic examination will be described, emphasizing the application of fetal echocardiography to the diagnosis of structural heart disease, diagnosis of arrhythmia, assessment of fetal heart function, and assessment of placental blood flow and resistance.

Instrumentation

There is no system that is ideally suited to every application of echocardiography in the fetus. Conventional linear array obstetric scanning instruments offer the advantage of improved depth of penetration, improved image resolution, and a rectangular image, allowing full visualization of the fetus. However, the relatively large linear-array scanheads are cumbersome and do not easily rotate around an axis with the fetal heart at the center. In addition, duplex Doppler imaging has only recently become available on linear array systems and employs an independent offset Doppler crystal. The availability of combined two-dimensional and M-mode imaging, essential for obtaining accurate chamber dimensions and for the accurate diagnosis of fetal arrhythmias by M-mode echocardiography, is standard in mechanical and phased-array cardiac imaging systems.

Mechanical and phased-array sector scanning systems offer good image resolution and in-line M-mode and duplex Doppler. There are some disadvantages to mechanical and phased-array sector-scanning instruments. Unfortunately, to achieve adequate penetration, a relatively low carrier frequency in the range of 3 to 5 mHz must be used. In examining the fetal heart, the use of transducer frequencies in this range results in significantly reduced image resolution. Dynamically focused anular-array imaging systems offer improved image resolution. In any sector scanner, far-field images are inferior because of reduced line density with increasing distance from the transducer.

Pulsed and continuous-wave Doppler may be performed with linear-array, phased-array, or mechanical systems in carrier frequency ranges from 2 to 5 mHz. Lower carrier frequencies allow greater depth of penetration for Doppler examination. When continuous-wave Doppler interrogation of the fetus is absolutely necessary, linear- and phased-array systems offer the advantage of two-dimensional guidance of the continuous-wave beam. In summary, both sector scanning and linear scanning offer advantages to the fetal echocardiographer and should be used in a complementary fashion to achieve the best possible diagnostic accuracy.

INITIAL OBSTETRIC ULTRASOUND EXAMINATION

In conjunction with fetal cardiac imaging, a complete obstetric ultrasound examination of the fetus should be performed by a qualified perinatologist. An accurate assessment of fetal gestational age using fetal biparietal diameter, abdominal circumference, or femur length should accompany fetal cardiac examination. An assessment of appropria e fetal growth is useful in identifying

either growth-retarded fetuses or fetuses that are large for gestational age. As was noted above, fetal edema, ascites, and pleural effusion may be noted by the obstetric examiner in patients with fetal hydrops secondary to congestive heart failure. An assessment of the degree of hydrops is important in evaluating therapy for congestive heart failure secondary to structural heart disease or fetal arrhythmia. It is also important to note the presence or absence of congenital defects affecting organ systems that may be associated with congenital heart disease. In addition, routine obstetric scanning of the fetus before fetal echocardiography should include an assessment of fetal cardiac structure, emphasizing recognition of a normal four-chambered heart.

CARDIAC IMAGING

After a careful obstetric examination has been performed and an accurate assessment of fetal gestational age has been obtained, the examination is directed to cardiac imaging. An adequate cardiac ultrasound to exclude serious congenital heart disease can be performed in the great majority of patients at greater than 18 weeks gestation. However, the examination may be limited by fetal mobility, particularly early in gestation, and by fetal position. As the fetus matures, ossification of the ribs and vertebral bodies adds to the difficulty of obtaining adequate images. The occiput anterior position with an anterior placenta is most troublesome because the fetal spine and the placenta lie between the echocardiographic transducer and the fetal heart. Other factors that may impair imaging include maternal obesity, advanced fetal edema, and polyhydramnios.

A traditional "view"-oriented approach to imaging of the fetal heart is difficult because of lack of control of fetal position and the resulting unconventional orientation of cardiac images. A segmental approach that emphasizes visualization of venous, atrial, ventricular, and great vessel connections is preferable to a "view"-oriented approach. Nonetheless, an attempt is made to obtain images in at least three conventional imaging planes: the short-axis, four-chamber, and long-axis planes. Images that are comparable to the suprasternal notch views obtained postnatally can also be obtained in many fetuses.

The examination begins by establishing fetal position in the maternal abdomen. In cross section of the maternal abdomen, the mother's left is displayed on the right-hand side of the video screen. In the maternal sagittal plane, the mother's head is to the right of the screen, and the symphysis pubis is to the left. In this way, maternal landmarks can be used to provide orientation of fetal position. After establishing orientation of the fetus wth respect to the mother, the fetus is scanned to determine the position of the fetal head and spine. This establishes the anterior/posterior and left/right orientation of the fetus. For instance, when the fetus is vertex with occiput anterior, the fetal spine will be anterior and the left of the fetus in cross section will be to the right of the video screen. If the fetus is vertex with occiput posterior, the left of the fetus in cross section will be to the left-hand side of the video screen. With breech presentation, these relationships are reversed. The fetus is likely to change position within the maternal abdomen, and fetal position must then be reestablished with respect to the maternal abdomen. The examiner should avoid the temptation to reverse video image orientation when fetal position changes or to obtain conventional cardiac image orientation. Doing so could lead to great confusion of right and left in the fetus, which could lead to errors in the diagnosis of cardiac or visceral situs and ventriculoarterial connection.

After establishing fetal position, the examination is directed to the fetal thorax and abdomen. Scanning from cephalad to caudad in the transverse plane establishes cardiac position in the chest and position of the descending aorta and inferior vena cava. Because the lungs are filled with fluid and the liver is large, the usual orientation of the heart is to the left and horizontal with the apex clearly directed to the left. Thus scanning in a sagittal plane parallel to the fetal spine produces short-axis images. A diagnosis of dextrocardia is made when the fetal heart is in the right chest, usually with the cardiac apex directed to the right. However, when dextrocardia is produced by displacement of the heart from the left hemithorax, as in left diaphragmatic hernia, the apex may be in the midline or directed to the left, and the herniated abdominal contents will be visible.

In assessing atrial and visceral situs, the position of the inferior vena cava and the descending aorta relative to the fetal spine are critical.[18] In atrial situs solitus, the inferior vena cava courses to the right and anterior to the fetal spine and descending aorta. The descending aorta is to the left and anterior to the fetal vertebral bodies, and the inferior vena cava is anterior to the descending aorta. The inferior vena cava and superior vena cava enter the right atrium, whereas the left atrium has no systemic venous connection. In situs inversus, this relationship is reversed; the inferior vena cava is on the left and anterior to the fetal spine and the descending aorta is on the right. In right atrial isomerism, the descending aorta and inferior vena cava are usually together on either side of the fetal spine with the inferior vena cava anterior to the descending aorta. In left atrial isomerism, the aorta is usually midline with absence of the suprarenal inferior vena cava and with azygous continuation (Fig. 48–1). The azygous vein is almost always posterior to the descending aorta but could be to either side of the fetal spine. In addition, with left atrial isomerism, there is total anomalous hepatic venous connection with the hepatic veins connecting directly to the atria. Atrial situs may also be determined by demonstrating characteristic morphology of the atrial appendages (Fig. 48–2). Visceral situs may be demonstrated by the position of the fluid-filled stomach on either the left or the right. However, the left lobe of the liver is larger in utero than in postnatal life; therefore the presence of a large left lobe of the liver does not imply situs ambiguous or inversus.

After assessing the pattern of venous connection to the heart, an assessment of atrial morphology in the normal fetus often reveals a large eustachian valve in the right atrium directing inferior vena caval return to the foramen ovale. The septum primum will be directed toward the left atrium in utero (Fig. 48–3). The existence of a secundum atrial septal defect therefore cannot be excluded in utero. However, common atrium and the characteristic morphology of the atrial component of complete or incomplete atrioventricular canal defects are usually clearly identified (Fig. 48–4). These abnormalities are best appreciated in the four-chamber plane. The morphology of the atrioventricular valves is also assessed in the four-chamber plane, as is the atrioventricular connection (Fig. 48–5). Normal valve motion can be demonstrated by both two-dimensional and M-mode echocardiography. The relative size of the tricuspid and mitral valves should be noted; they are approximately the same size in a normal fetus.

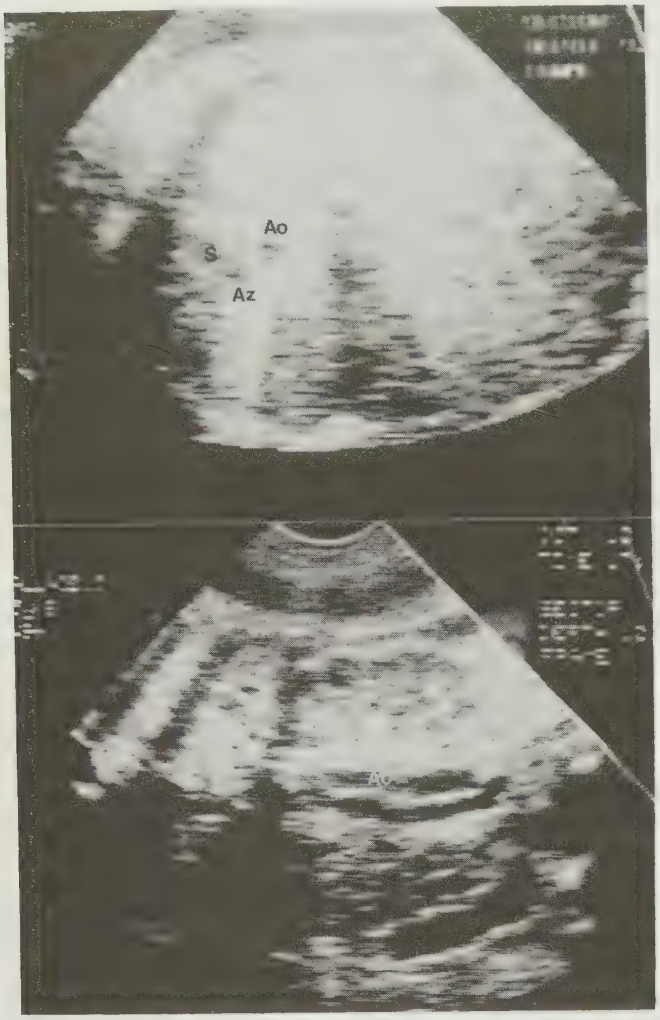

Fig. 48–1. Transverse (upper panel) and sagittal (lower panel) two-dimensional echocardiograms of the fetal abdomen demonstrating absence of the suprarenal inferior vena cava with azygous continuation. The azygous vein (Az) is posterior to the aorta (Ao). These findings are compatible with left atrial isomerism. In atrial situs solitus, the aorta is anterior to the fetal spine, and the inferior vena cava is to the right and anterior to the aorta. S = fetal spine.

Establishing atrioventricular connection requires demonstration of the characteristic morphologic features of the left and right ventricles. The tricuspid valve is located nearer the cardiac apex than the mitral valve. The inferior position of the tricuspid valve is actually a characteristic of normal right ventricular morphology, although extreme apical displacement of the tricuspid valve with gross right atrial enlargement is seen in the fetus with Ebstein's anomaly. Other morphologic characteristics of the normal right ventricle that should be noted include lack of atrioventricular–semilunar valve continuity, the presence of muscular conus, the existence of an infundibular or "outflow" portion of the ventricle, the presence of a moderator band, and poorly defined papillary muscles. In contrast, characteristic morphologic features of the left ventricle that are easily demonstrated with fetal echocardiography include atrioventricular–semilunar valve fibrous continuity, well-defined papillary muscles, and absence of a muscular conus. In fetal echocardiography, the most easily identified of these feaures is atrioventricular–semilunar valve continuity, which is seen to best advantage in the long-axis plane (Fig. 48–6).

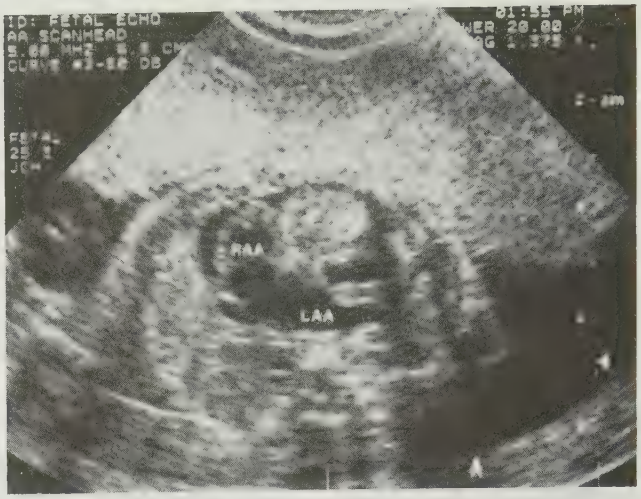

Fig. 48–2. Transverse plane of the fetal chest demonstrating characteristic right atrial appendage (RAA) and left atrial appendage (LAA) morphology in a fetus with atrial situs solitus. The left atrium lies immediately anterior to the fetal spine.

In addition to examination of the atrioventricular valves, the relative size of the ventricles can be assessed in the four-chamber plane. The left and right ventricle should appear to be approximately equal in size (Fig. 48–3). However, although right and left ventricular dimensions may be comparable,[19–22] analysis of ventricular geometry reveals a pattern of right ventricular dominance, which produces an elliptical left ventricular short axis in the fetus compared to the circular shape seen in infants and children.[23] Right ventricular enlargement is seen in some forms of pulmonary atresia with right ventricular dilation,[24] right ventricular

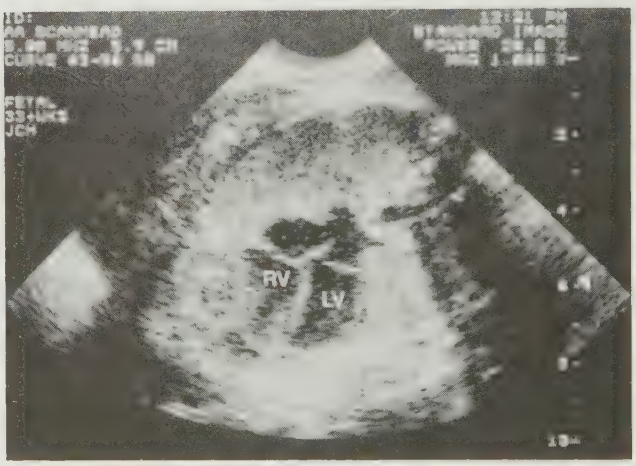

Fig. 48–3. Four-chamber view of a normal fetal heart seen in a transverse scan of the fetal chest. The apex is directed to the left, and the right ventricle (RV) and left ventricle (LV) are of approximately equal size. The septum primum is directed from the right atrium to the left atrium. The left atrium is immediately anterior to the aorta and fetal spine.

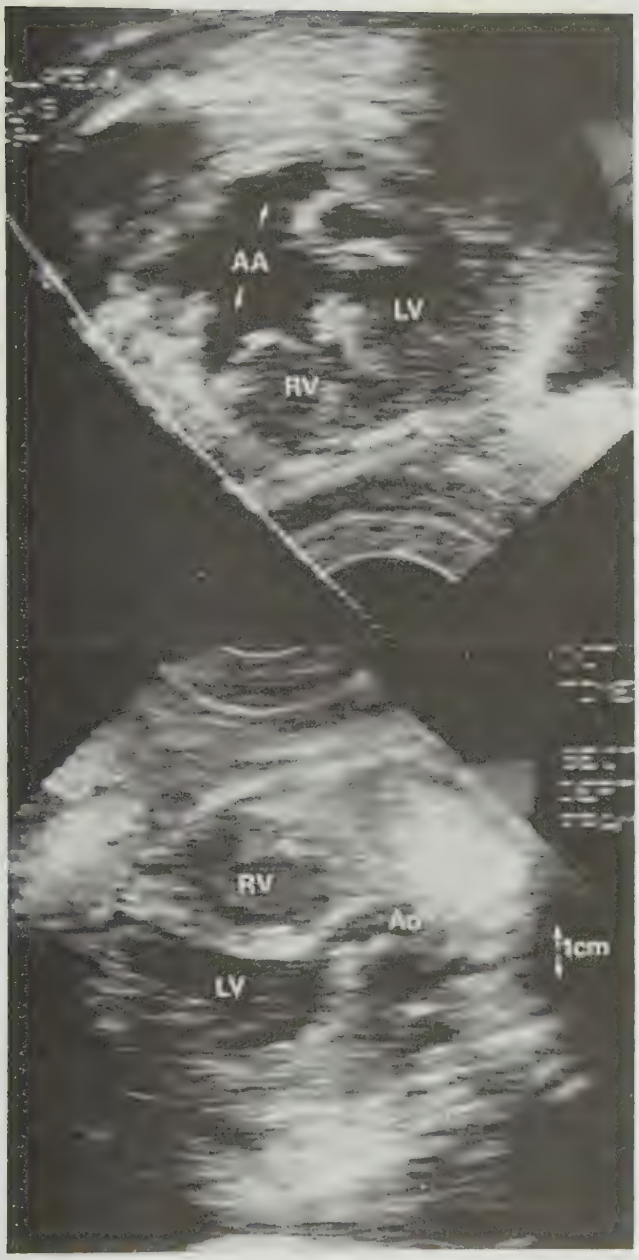

Fig. 48–4. The equivalent of a subcostal scan (upper panel) demonstrating a common atrium and common atrioventricular valve. The atrial appendage (AA) morphology suggests left atrial isomerism. In the long-axis scan (lower panel), the "gooseneck" deformity of the left ventricular outflow tract in atrioventricular canal defects is seen. In this fetus, there is narrowing of the left ventricular (LV) outflow tract and a small aortic root (Ao). RV = right ventricle.

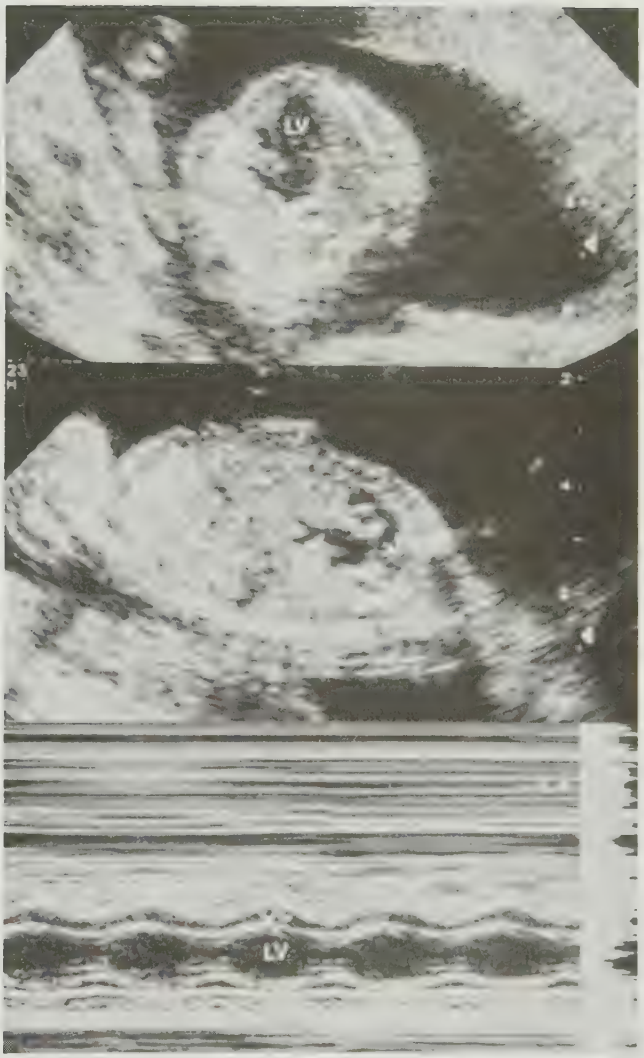

Fig. 48–5. Univentricular atrioventricular connection is demonstrated in the upper panel. A single atrioventricular valve connects to the left ventricle (LV) with a small, anterior, right ventricular outlet chamber (RVOC). Ventriculoarterial connection is concordant as demonstrated in the modified short-axis scan (middle panel). M-mode echocardiography (lower panel) also demonstrates a single ventricle with a small outlet chamber (OC). Ao = aorta; IVC = inferior vena cava; PA = pulmonary artery.

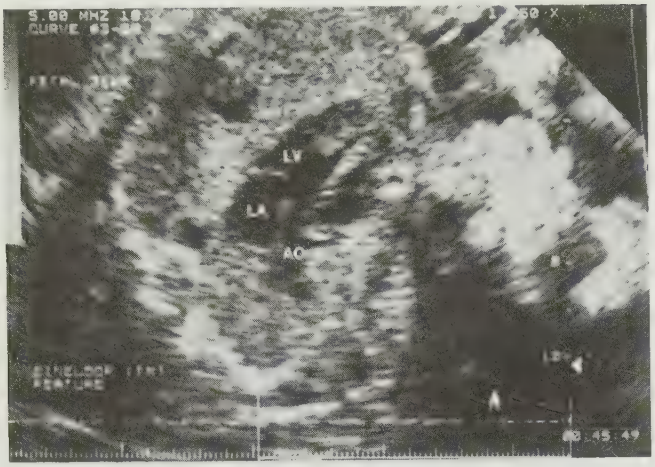

Fig. 48–6. Left ventricular (LV) morphology is established in the apical long-axis scan of a normal fetus. The mitral valve is in fibrous continuity with the aortic valve (AO) between the left atrium (LA) and left ventricle (LV). Demonstration of atrioventricular valve–semilunar valve fibrous continuity is the most useful morphologic characteristic for identifying the left ventricle in fetal echocardiography.

dominant atrioventricular canal, hypoplastic left heart syndrome,[25] coarctation of the aorta,[26] and nonimmune hydrops fetalis secondary to congestive heart failure[12] (Fig. 48–7). Enlargement of the left ventricle, usually in association with right ventricular enlargement, may be seen in critical aortic stenosis, endocardial fibroelastosis, cardiomyopathy, or congestive heart failure of undetermined cause[14] (Fig. 48–8).

The inlet ventricular septum is also best assessed in the four-chamber plane and easily demonstrates the inlet muscular ventricular septal defect and typical abnormal valve morphology of complete atrioventricular canal[12,14] (Fig. 48–9). In addition, septal hypertrophy and reduced cardiac function are demonstrable in fetuses of poorly controlled diabetics,[17] as well as those with a thick septum for other reasons (see Fig. 48–10). Naturally, absence of the ventricular septum or atresia of one or the other atrioventricular valve is characteristic of single ventricle with mitral or tricuspid atresia, single ventricle with common atrioventricular valve, and double-inlet left ventricle (Fig. 48–5). These congenital defects are usually readily apparent when adequate four-chamber imaging is obtained. Ventricular septal defects (Fig. 48–9 and Fig. 48–11) have been diagnosed in utero, although a false positive or false negative diagnosis of small ventricular septal defects is likely. Silverman and Golbus have observed closure of a ventricular septal defect during the course of gestation.[14]

After establishing atrioventricular connection and examining ventricular morphology and the ventricular septum, ventriculoarterial connection is established. This is accomplished by using a combination of long- and short-axis planes. Demonstration of a normal right ventricular outflow tract connecting to the pulmonary artery and ductus arteriosus is important to establish normal ventriculoarterial connection (Fig. 48–12). However, the pulmonary artery and ductus arteriosus may be easily mistaken for the ascending aorta and aortic arch because of the normal continuity of the ductus to the descending aorta. Careful demonstration of the aortic arch with brachiocephalic branches, which are usually readily identified, differentiates the aortic arch from the pulmonary artery and ductus arteriosus. In addition, the aortic arch courses more cephalad and is smaller than the ductus. In particular, the continuity of the aortic arch with the descending aorta, the aortic isthmus, is very small in the human fetus, in contrast to the ductus arteriosus, which is virtually equal in size to the descending aorta. Establishing connection of the aorta to the left ventricle with mitral/aortic continuity completes the picture of normal ventriculoarterial connection.

The normal appearance and function of the semilunar valves can be demonstrated by both two-dimensional and M-mode echocardiography. Demonstration of normal pulmonary valve size and function is useful in excluding pulmonary atresia. In patients with pulmonary atresia, in addition to abnormal pulmonary valve anatomy and motion, there is also hypoplasia of the main pulmonary artery and ductus arteriosus (Fig. 48–13) with relative enlargement of the ascending aorta. These patients also exhibit abnormalities of right ventricular size and function.[24] In tetralogy of Fallot, varying degrees of right ventricular outflow tract and pulmonary

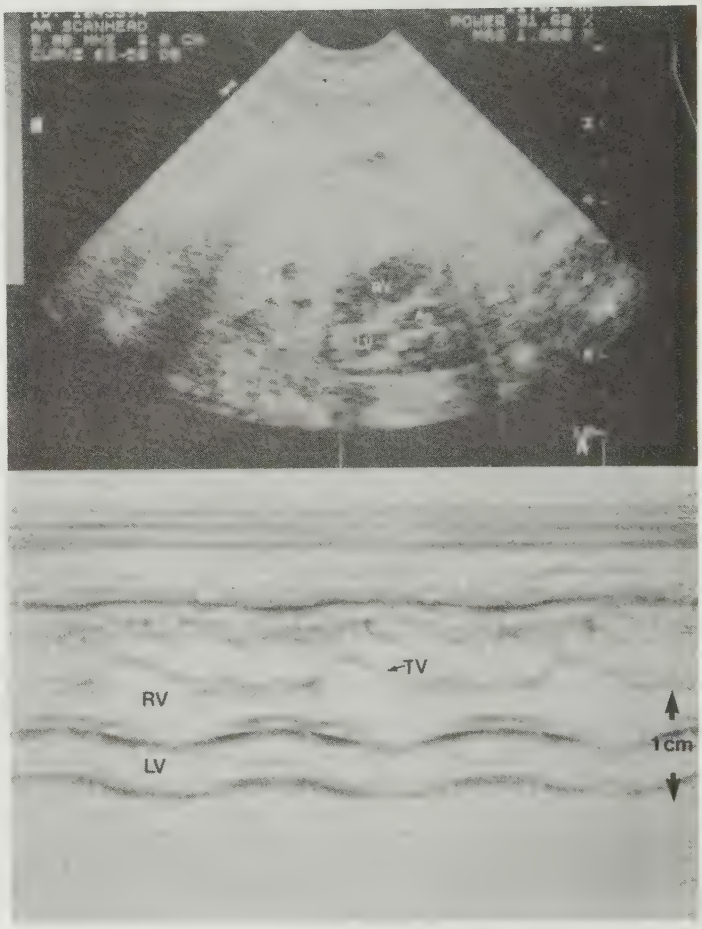

Fig. 48–7. Right ventricular (RV) enlargement and endocardial fibroelastosis of the left ventricle (LV) are demonstrated in both the two-dimensional (upper panel) and M-mode (lower panel) echocardiogram. Significant hypoplasia of the left ventricle and echodensity of the left ventricular endocardium are characteristic of critical aortic stenosis in affected fetuses. Mild poststenotic dilation of the aorta (Ao) can also be seen in the two-dimensional images (upper panel). TV = tricuspid valve.

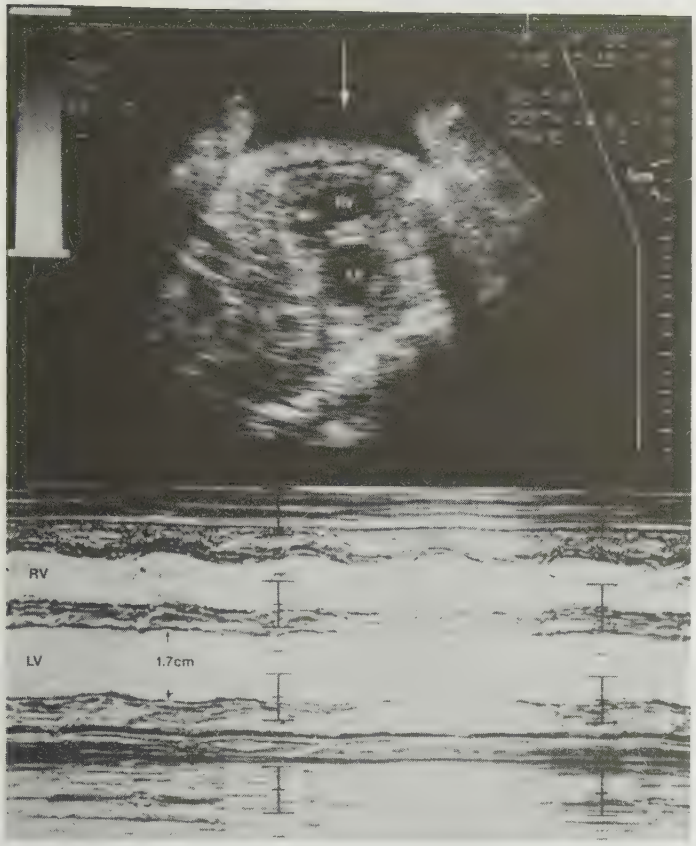

Fig. 48–8. Two-dimensional (upper panel) and M-mode (lower panel) echocardiogram in a 32-week fetus with cardiomyopathy. A small pericardial effusion is visible in the two-dimensional image. The left ventricle (LV) is enlarged, and the left ventricular posterior wall motion is abnormal. Although the right ventricle (RV) is mildly enlarged on the two-dimensional echocardiogram, the left ventricle is more severely affected by M-mode, a finding that implies ventricular myocardial disease.

hypoplasia are observed in addition to a large ventricular septal defect with a large overriding aorta.[12] Conversely, in aortic atresia, extreme hypoplasia of the ascending aorta and aortic arch is observed in addition to gross right ventricular enlargement[15] with enlargement of the main pulmonary artery and ductus. Lesions that produce aortic arch obstruction, such as coarctation of the aorta or interrupted aortic arch, should be suspected in any fetus with right ventricular enlargement but without evidence of proximal aortic obstruction.[26] Actual demonstration of aortic coarctation or interruption is difficult because of the small size of the aortic isthmus in the normal fetus; therefore aortic coarctation is one of the most difficult diagnoses to make on fetal ultrasound. However, on fetal examination, the appearance of the characteristic hypoplasia of the transverse arch and enlargement of the pulmonary artery observed in neonates with isolated coarctation should alert the fetal ultrasonographer to the possible existence of an aortic coarctation. Critical aortic stenosis (Fig. 48–14) can be recognized by the presence of a small aortic anulus; poststenotic dilation of the ascending aorta; abnormal aortic valve morphology, left ventricular dilation, hypertrophy, or hypoplasia; and endocardial fibroelastosis.[27,28]

The spectrum of cardiac anomalies that may be detected in utero is considerably different from the spectrum of defects that are observed in postnatal life.[14,24,29] The indications for referral to a specialist for fetal cardiac ultrasound will lead to a greater proportion of fetuses affected by severe congenital anomalies that produce fetal congestive heart failure and hydrops, fetal arrhythmia, or abnormal ventricular or atrioventricular valve morphology detected on routine obstetric ultrasound. Because of the route of the fetal circulation, some of the more common defects of postnatal life cannot be detected in utero, such as secundum atrial septal defects and patent ductus arteriosus. Other common postnatal defects are diagnosed with difficulty in utero, such as small ventricular septal defects and coarctation of the aorta, or are recognized only in their most severe forms, such as pulmonary or aortic stenosis. The addition of pulsed Doppler, in either the conventional or color flow format, to the two-dimensional echocardiographic examination may improve accuracy of diagnosis in milder degrees of semilunar valve stenosis or in patients with complex lesions.

Fig. 48–9. Transverse scan of the fetal chest demonstrating dextrocardia in a fetus with complete atrioventricular canal. The ventricular apex is directed to the right (upper panel). A common atrium, common atrioventricular valve orifice (CAVO), and inlet ventricular septal defect (arrow, lower panel) are demonstrated. The descending aorta (DAo) is to the left of the fetal spine. Mild ascites and a small pericardial effusion are also visible. RV = right ventricle; LV = left ventricle.

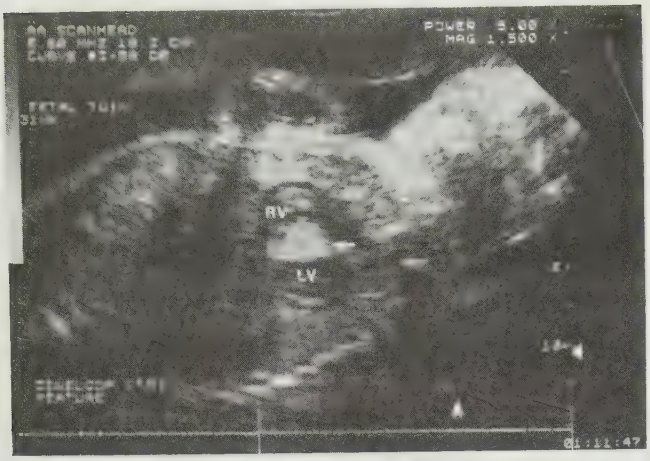

Fig. 48–10. Two-dimensional echocardiogram in the short-axis plane demonstrating significant thickening and echodensity (arrow) of the interventricular septum (IVS) in a 31-week fetus of a nondiabetic twin pregnancy. The right ventricle (RV) and left ventricle (LV) are of approximately equal size without hypertrophy of the ventricular free wall. The septal mass extends into the atrial septum and probably represents a septal rhabdomyoma.

As a rule, in the majority of cases, those defects that have the greatest effect on fetal and perinatal morbidity and mortality may be recognized in utero in most affected patients, allowing rational prenatal and postnatal intervention.

EVALUATION OF FETAL HEART RATE AND RHYTHM

As was noted above, with increased use of antepartum fetal heart rate monitoring, an increasing number of patients are being referred for evaluation of abnormalities of fetal heart rate and rhythm. It appears that abnormalities of heart rate and rhythm occur in only a small number of normal pregnancies. Southall and associates[30] have noted transient bradycardia in 1.1 to 1.3% of normal pregnancies and transient tachycardia in less than 1%. Premature contractions occur with only a slightly higher prevalence in fetuses than in neonates, being present in 1.7% of normal fetuses. Although abnormalities of heart rate and rhythm are uncommon and usually transient in normal pregnancies, patients undergoing antenatal heart rate monitoring as a means of assessing fetal well-being may be noted to have bradycardia, tachycardia, or an irregular rhythm. Unfortunately, fetal electrocardiograms are difficult to interpret because of the absence of fetal P waves, extraneous electrical noise, and the inability to recognize changes in QRS morphology. Nonetheless, accurate diagnosis and treatment of fetal arrhythmia are important to avoid unnecessary cesarian section or fetal death. Fetal echocardiography has been proven to be useful in the accurate diagnosis of fetal arrhythmia in the majority of cases. With this method, the electrical activation sequence of the atria and ventricles is inferred from the mechanical events detected by echocardiography.

Although a normal activation sequence may be recognized by two-dimensional echocardiography alone, accurate rhythm diagnosis requires the use of either two-dimensionally directed M-mode echocardiography[31–36] or duplex pulsed Doppler echocardiography.[35,36] A careful two-dimensional echocardiographic examination of the fetus is important to establish the presence or absence of congenital heart disease or cardiac failure. The latter is manifested by cardiac enlargement and fetal hydrops. The nature of the rhythm disturbance can then be established by either M-mode or Doppler echocardiography.

M-Mode Echocardiography

In using M-mode echocardiography, the line of M-mode interrogation is directed by two-dimensional imaging through both atrial and ventricular structures, such as atrial and ventricular wall, through the aortic root and left atrium, or through an atrioventricular valve. In this way, atrial contraction is established by atrial wall motion or an A wave of the atrioventricular valve.[31–36] Ventricular contraction is recognized by ventricular wall motion, closure of the atrioventricular valve, or opening of arterial valves. An irregular rhythm is the most common reason for referral for diagnosis of fetal arrhythmia. The irregular rhythm is almost always the result of premature contractions followed by a pause. Premature contractions preceded by atrial wall motion or an early A wave are premature atrial contractions (Fig. 48–15). Ventricular premature contractions are characterized by early ventricular wall

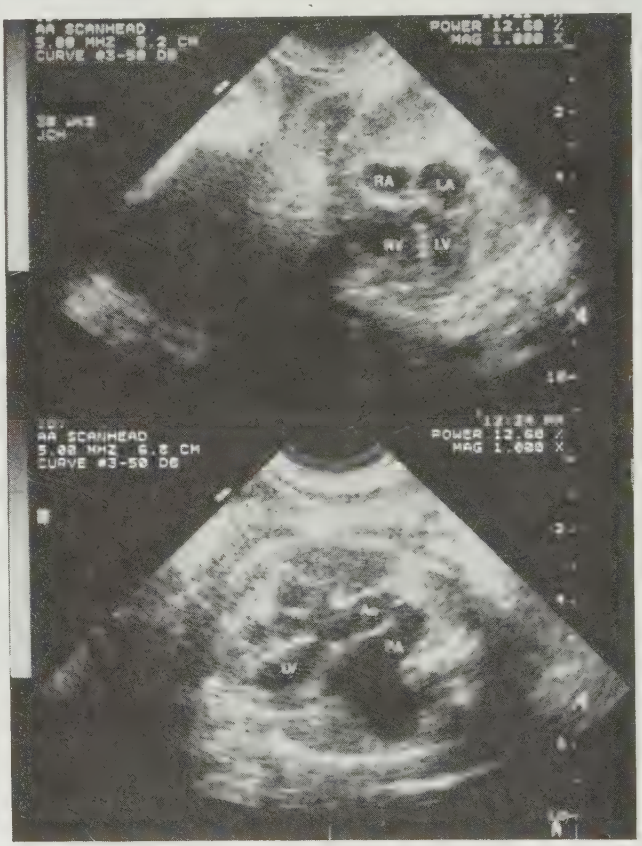

Fig. 48–11. Aortic override of a ventricular septal defect in a fetus with absent pulmonary valve syndrome. In the upper panel, the ventricular septal defect is easily seen in a four-chamber scan of the fetal heart. In a modified long-axis scan (lower panel), the aorta overrides the ventricular septal defect with marked enlargement of the pulmonary artery. RV = right ventricle; LV = left ventricle; Ao = aorta; PA = pulmonary artery; RA = right atrium; LA = left atrium.

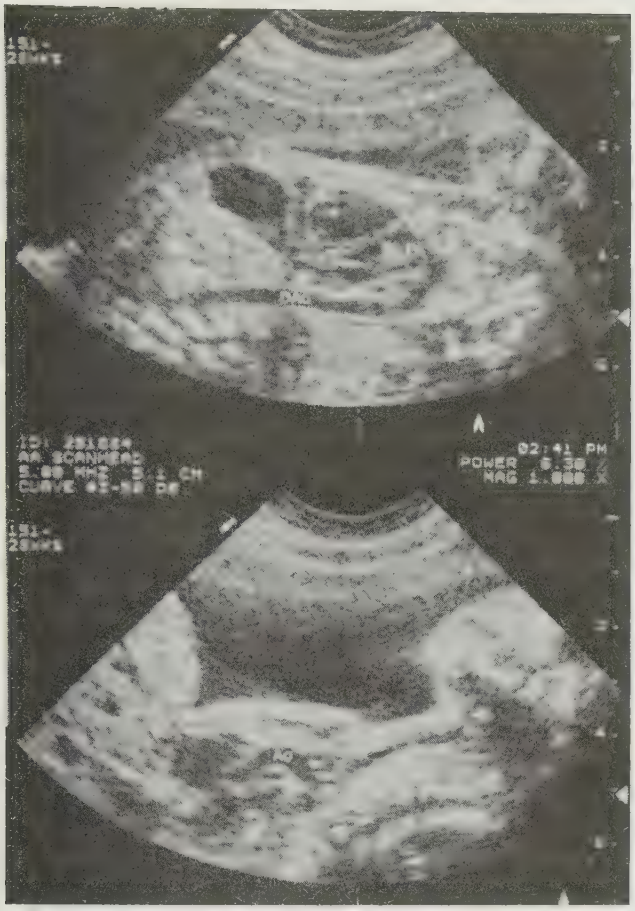

Fig. 48–12. Normal ventriculoarterial connection is established by demonstrating connection of the pulmonary artery (PA) to the right ventricle (upper panel) and of the aorta (Ao) to the left ventricle (lower panel). The pulmonary artery is identified by branching of the right and left pulmonary arteries and ductus arteriosus. The aorta is identified by branching of the brachiocephalic vessels. DAo = descending aorta.

motion or atrioventricular valve closure without evidence of a preceding atrial contraction. Rarely, mixed premature atrial and ventricular contractions occur in the same patient.[31,33]

Fetal bradycardia, defined for purposes of arrhythmia diagnosis as a sustained heart rate below 100 beats per minute, is usually sinus bradycardia with evidence of atrial contraction preceding each ventricular contraction. The discussion that follows is limited to fetal bradycardia not associated with labor and does not include discussion of characteristic patterns of sinus bradycardia associated with fetal distress during parturition. Sinus bradycardia noted during echocardiographic examination is most often transient and may be the result of transducer pressure on the maternal abdomen.[35] Another cause of fetal bradycardia that may be mistaken for complete AV block is blocked premature atrial contractions or blocked atrial bigeminy. Blocked premature atrial contractions are represented by early atrial wall motion or A wave without subsequent ventricular contraction followed by a pause in atrial contraction. In contrast to complete AV block, blocked premature atrial bigeminy is characterized by an irregular atrial rate and an atrial contraction preceding every other ventricular contraction. In complete AV block, atrial contraction occurs without relation to ventricular contraction and with ventricular bradycardia. In complete AV block, M-mode echocardiography reveals A waves "marching through" regular atrioventricular valve closure or atrial wall motion without relation to ventricular wall motion. Ventricular rates in complete AV block usually range from 60 to 80 beats per minute. Second-degree AV block with fixed or variable ratios of atrioventricular conduction may also be recognized by M-mode echocardiography (Fig. 48–16). It is important to establish the mechanism of fetal bradycardia before instituting therapy. Unnecessary cesarean section has resulted from assuming that fetal bradycardia was secondary to fetal distress and failing to recognize complete AV block or blocked premature atrial contractions.

Supraventricular tachycardia is characterized by atrial rates above 180 beats per minute with atrial contractions or A waves usually preceding each ventricular contraction (Fig. 48–15). This rhythm cannot be distinguished by echocardiography from ventricular tachycardia with 1:1 retrograde conduction to the atrium. However, many cases of supraventricular tachycardia diagnosed and treated in utero have recurred in the neonatal period, allowing confirmation of the in utero echocardiographic diagnosis. There

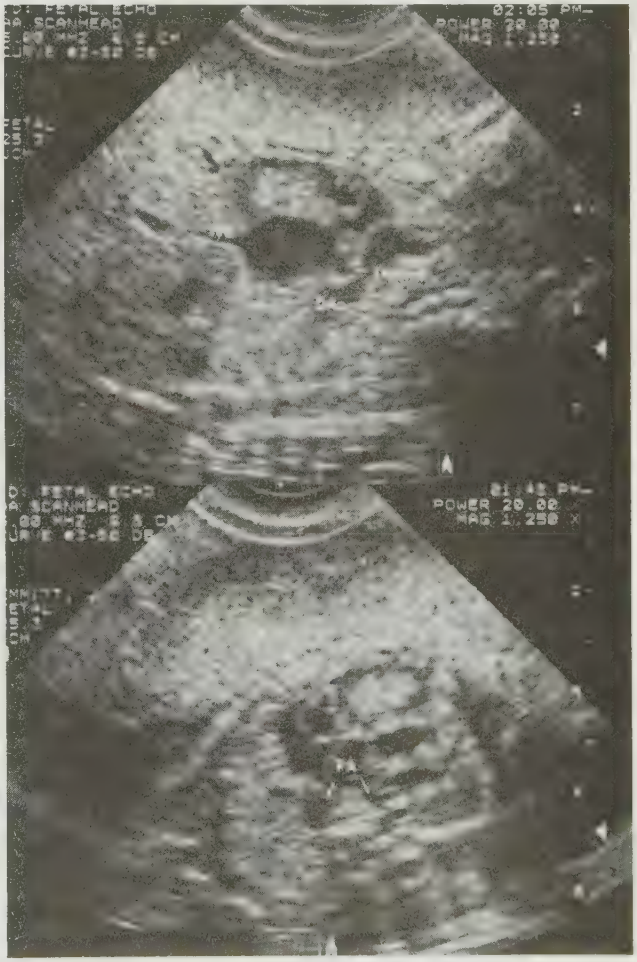

Fig. 48–13. A small serpiginous ductus arteriosus in a fetus with pulmonary atresia demonstrated in the upper panel. In the lower panel the small right and left pulmonary arteries are visible. PA = pulmonary artery; Ductus = ductus arteriosus; IVC = inferior vena cava.

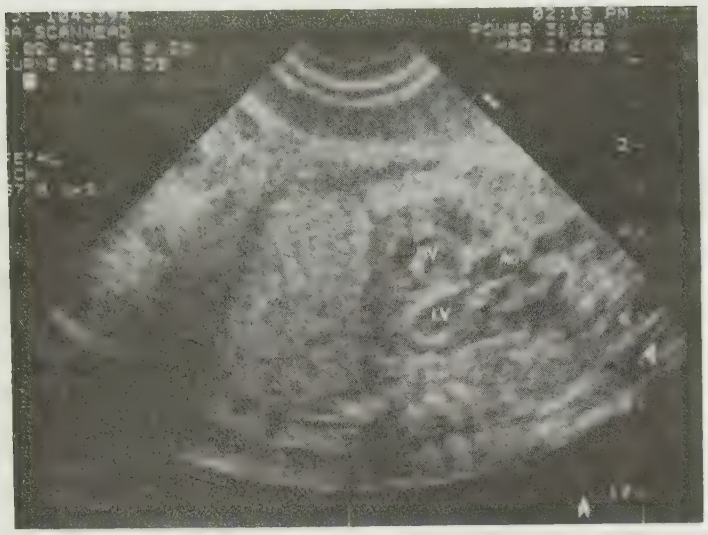

Fig. 48–14. Modified long-axis scan of a fetus with critical aortic stenosis. Echodensity of the left ventricular (LV) endocardium, poststenotic dilation of the aorta (Ao), and right ventricular (RV) enlargement are characteristic of this lesion in the fetus and neonate.

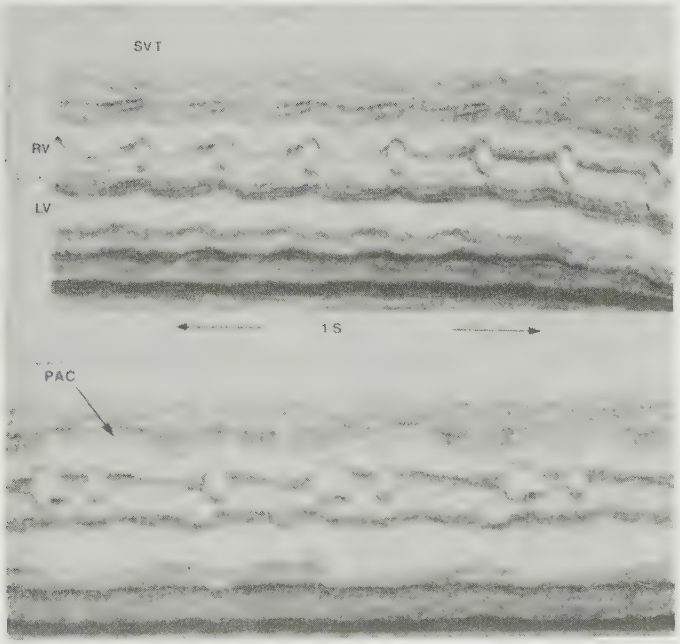

Fig. 48–15. M-mode echocardiograms in supraventricular tachycardia (upper panel) and sinus rhythm with premature atrial contractions (lower panel). In supraventricular tachycardia (SVT), separate tricuspid valve E and A waves are not visible because of the rapid atrial rate. In contrast, during sinus rhythm separate E and A waves are easily seen. The premature opening of the tricuspid valve (arrow) in the lower panel occurs as the result of a premature atrial contraction (PAC) occurring immediately following ventricular systole. This is followed by an atrial pause. RV = right ventricle; LV = left ventricle.

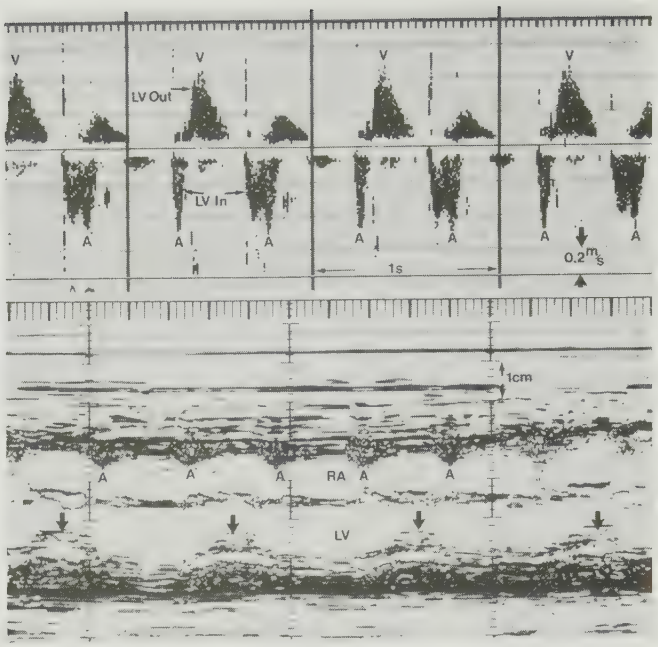

Fig. 48–16. Comparison of Doppler (upper panel) and M-mode (lower panel) echocardiograms in a fetus with 2:1 AV block. The Doppler recording from the left ventricular (LV) inlet demonstrates inflow (LV In) and outflow (LV Out) in opposite directions. A waves (A) produced by atrial systole occur at regular intervals with a 2:1 relationship to ventricular systole (V). In the M-mode echocardiogram, right atrial (RA) wall motion occurs with a 2:1 relationship to left ventricular wall (LV) motion (arrows). m/s = meters per second; s = second.

have been only a few cases of ventricular tachycardia that was incorrectly diagnosed as supraventricular tachycardia in utero. Atrial flutter is recognized by M-mode echocardiography by very high rates of atrial contraction, usually above 400 beats per minute. Variable ratios of AV block are observed with atrial flutter. Atrial contraction is followed by ventricular contraction in ratios of 2:1 to 4:1 in the majority of cases.

Doppler Echocardiography

Doppler echocardiography may be used to diagnose fetal arrhythmia with an accuracy equal to that of M-mode echocardiography.[36] The basic principle is to deduce the activation sequence from the sequence of flow detected by range-gated pulsed Doppler. Sampling of atrioventricular valve flow or foramen ovale flow allows description of the pattern of atrial contraction, whereas sampling of left ventricular outflow tract or arterial flow allows description of the pattern of ventricular contraction (Fig. 48–17). Doppler interrogation of the left ventricular inlet usually allows simultaneous description of atrioventricular valve and left ventricular outflow tract flow, thus allowing description of the activation sequence by sampling in one location. Sinus rhythm and sinus bradycardia are characterized by an atrial A wave preceding each systolic velocity profile (Fig. 48–18). Premature atrial contractions are characterized by early occurrence of the A wave, by accentuation of peak atrioventricular valve velocity, or by early accentuation of peak velocity through the foramen ovale. The early atrial flow is followed by ventricular flow of lower velocity than the preceding sinus beat. Prolonged passive ventricular filling and

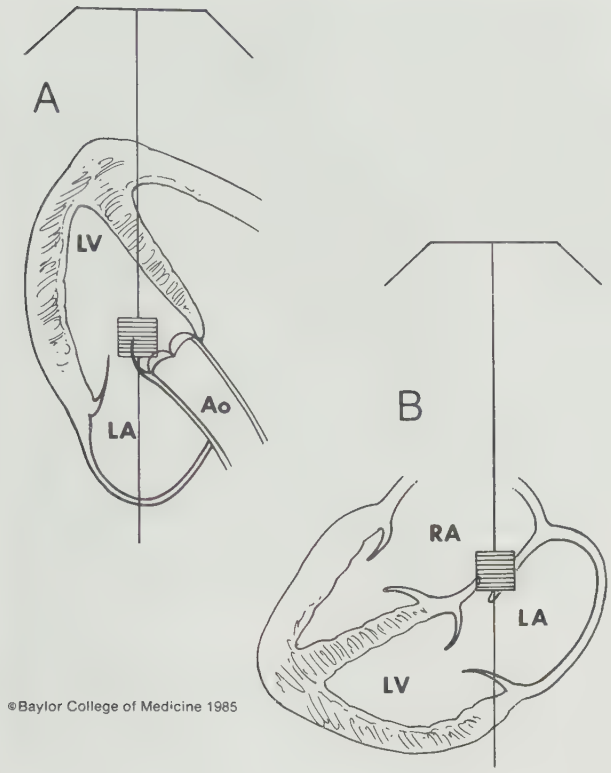

Fig. 48–17. Illustration of Doppler sample volume positions (a) in the left ventricular (LV) inlet to record left ventricular diastolic inflow and systolic outflow and (b) in the foramen ovale to record atrial systole. LA = left atrium; RA = right atrium; Ao = aorta. (From Strasburger, J.F., et al.: Doppler echocardiography in the diagnosis and management of persistent fetal arrhythmias. J. Am. Coll. Cardiol., 7:1386, 1986.)

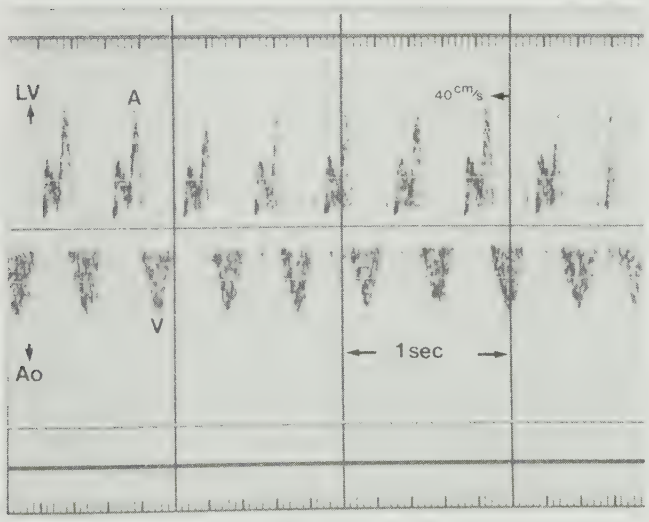

Fig. 48–18. Left ventricular (LV) inflow and outflow recorded in sinus rhythm from the left ventricular inlet. Atrial systole (A) follows passive filling and is greater in amplitude in the fetus. Ventricular systole (V) follows each atrial systole, documenting a normal activation sequence. Ao = aorta.

accentuation of ventricular flow velocities (postextrasystolic potentiation) occur following an atrial pause. Early atrial flow may not be followed by ventricular flow if AV block occurs (Fig. 48–19). With premature ventricular contractions, early venticular systole causes abbreviation of atrioventricular valve flow associated with early ventricular flow of lower velocity than the preceding normal beat (Fig. 48–20). There may be associated systolic atrioventricular valve insufficiency (Fig. 48–21). With premature ventricular contractions, a pause is observed with prolonged passive ventricular filling and accentuated ventricular velocities on the beat following the premature contraction.

Complete AV block is characterized by an atrial A wave that is dissociated from ventricular or arterial flow (Fig. 48–22). Diastolic atrioventricular valve insufficiency, produced by failure of atrioventricular valve closure following atrial systole, may be observed in some patients with complete AV block (Fig. 48–23). As with M-mode echocardiography, atrial bigeminy can be distinguished from complete AV block by the presence of early atrial flow without subsequent ventricular flow alternating with 1:1 atrial and ventricular flow. In supraventricular tachycardia and atrial flutter, rapid atrial contraction produces low-amplitude atrial A waves that merge with passive atrial filling followed by low-amplitude ventricular flow. Rapid atrial contraction may also be demonstrated by pulsed Doppler sampling in the foramen ovale (Fig. 48–24). Although atrial flutter with 1:1 conduction and supraventricular tachycardia may not be distinguished by Doppler echocardiography, atrial flutter usually occurs with atrial rates of 400 beats per minute or more and is usually associated with AV block (Fig. 48–25). Supraventricular tachycardia is more likely to occur at rates of 200 to 300 beats per minute with 1:1 atrioventricular conduction.

By using the echocardiographic methods described above, the spectrum and outcome of fetal arrhythmias have been described.[31–36] By far the most frequent arrhythmias observed in the fetus are isolated premature contractions. In most studies, the great majority of premature contractions are atrial in origin.[31–34,36] Although occasional patients with premature atrial contractions develop supraventricular tachycardia, the majority experience resolution of premature contractions either in utero or early in their neonatal course. Premature ventricular contractions, although uncommon, appear to have a similarly benign prognosis. Transient bradycardia to rates below 100 beats per minute is not uncommonly observed and may result from fetal movement[33] or transducer pressure.[35] As was noted above, sustained bradycardia, defined as a heart rate persistently below 100 beats per minute, may be due to sinus bradycardia and fetal distress, blocked atrial bigeminy, or complete AV block. Complete AV block is associated with maternal autoimmune disease in the majority of cases.[31,33] When associated congenital heart disease is present, complex anomalies are usually observed, most often involving right or left atrial isomerism with common atria, common atrioventricular valve, and abnormal systemic venous return.[31–33,36,37] Recognition of complete AV block in the fetus should lead to a thorough search for associated cardiac defects or maternal autoimmune disease. Likewise, patients with fetal AV block should be observed at frequent intervals for the development of signs of hydrops. The ultimate prognosis for fetuses with complete AV block and hydrops is poor. Successful transabdominal fetal ventricular pacing has been performed in a hydropic previable human fetus[37] and should be con-

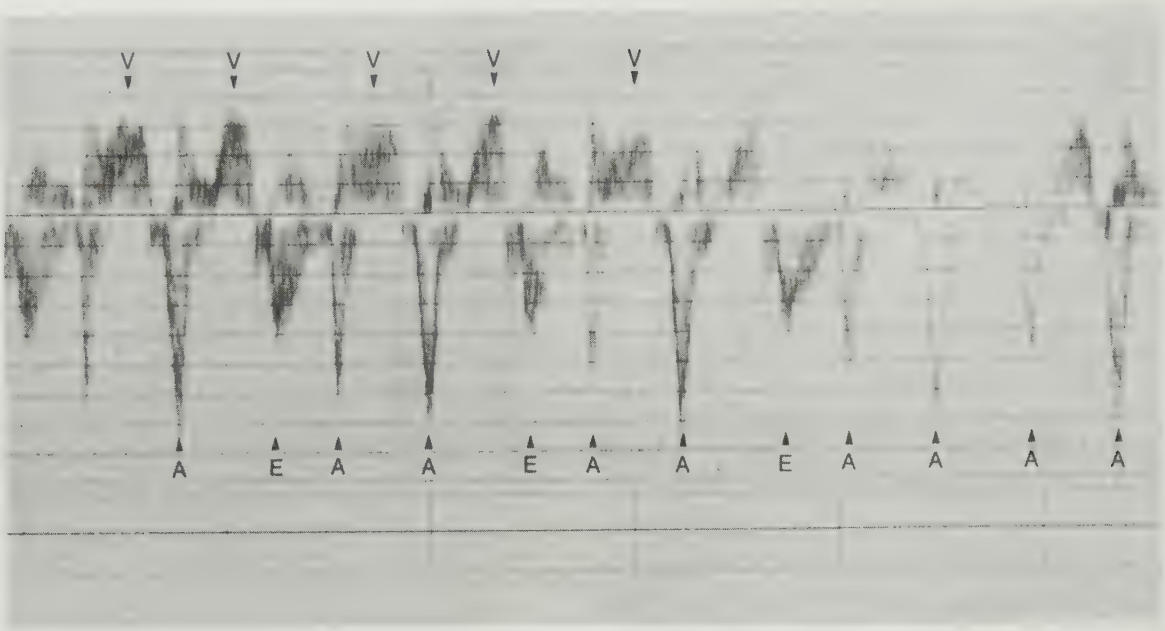

Fig. 48–19. Atrioventricular contraction sequence is recorded here by pulsed Doppler sampling in the left ventricular outflow tract. Atrial bigeminy is demonstrated by accentuation of the A wave (A) during diastole followed by a compensatory pause and prolonged passive filling (E). Each atrial contraction is followed by a ventricular systole (V). After a sequence of atrial bigeminy, a series of three premature atrial contractions occurs.

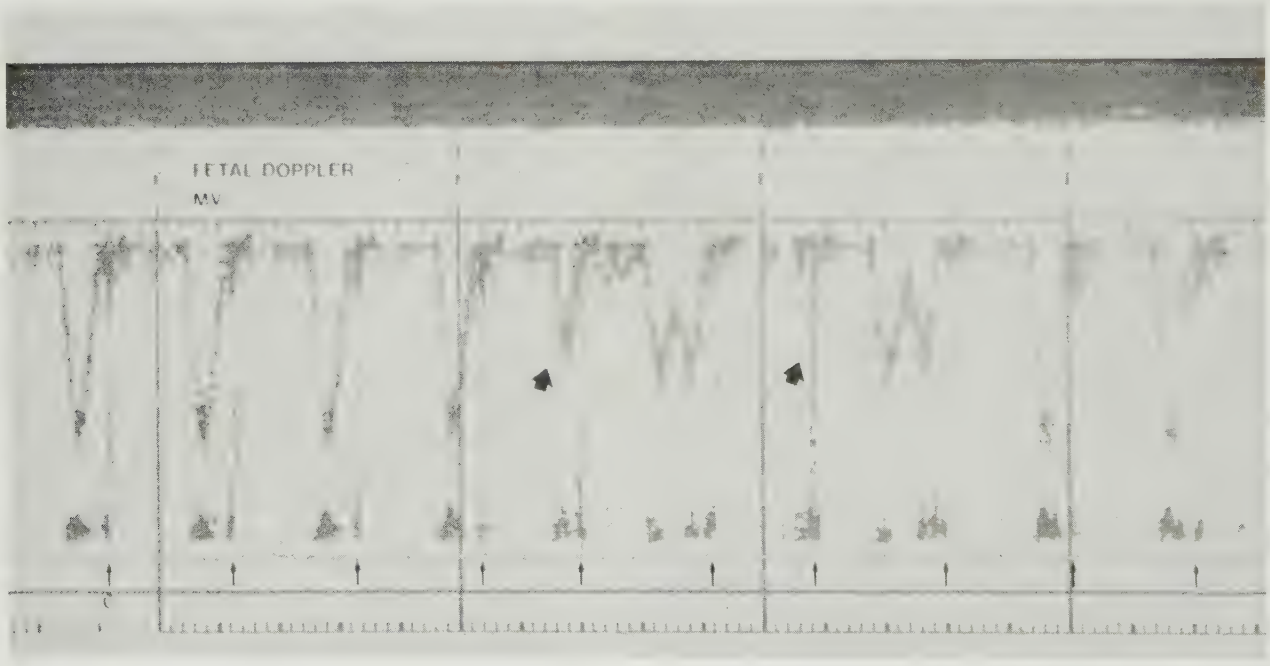

Fig. 48–20. Doppler sampling in premature contractions, probably junctional or ventricular. Early mitral valve (MV) closure (arrows) attenuates left ventricular filling with a compensatory pause. The latter occurs as a result of retrograde conduction of the premature junctional or ventricular contraction to the atrium. Because of the compensatory pause, separate E and A waves are visible during the diastolic period following the premature contraction.

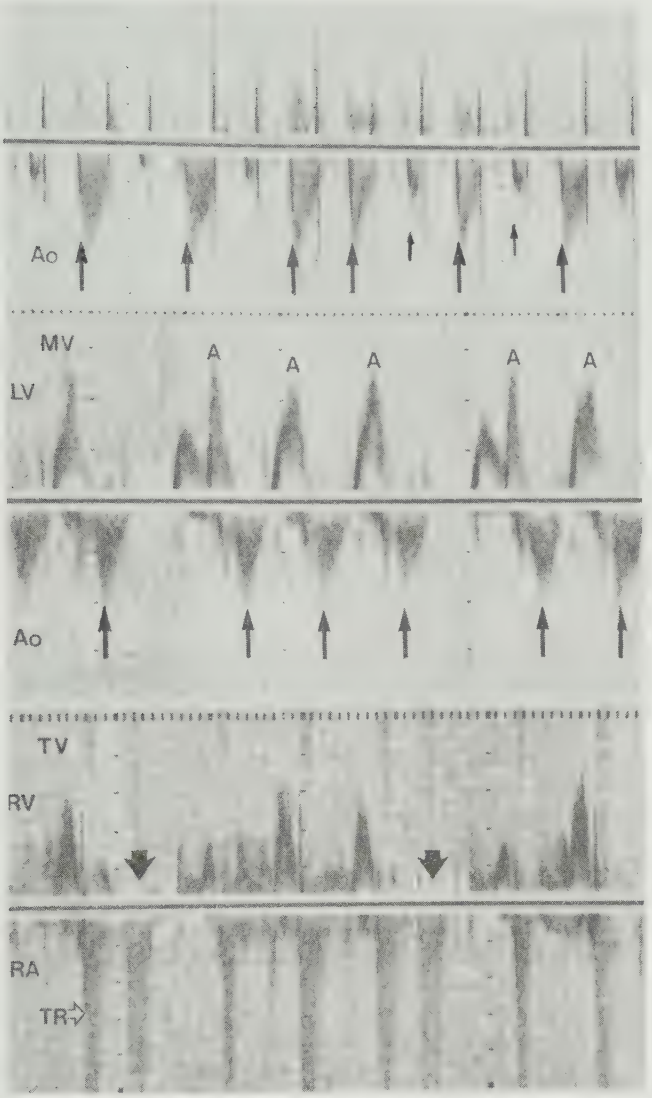

Fig. 48–21. A series of premature contractions are demonstrated by Doppler sampling of aortic (Ao) flow (upper panel), left ventricular inflow and outflow (middle panel), and tricuspid valve flow (lower panel). Frequent premature contractions result in varying amplitude of aortic velocities, which occur at irregular intervals (upper panel). The nature of the rhythm disturbance cannot be determined from aortic sampling. Doppler sampling in the left ventricular (LV) inlet (middle panel) reveals the complex nature of the arrhythmia. Mitral valve (MV) velocities are recorded on the first diastole and are followed by ventricular systole (arrow). Following ventricular systole, however, mitral valve opening does not occur. After a pause, mitral opening occurs with both passive filling and atrial systole. Following a series of three atrial and ventricular systoles, failure of mitral valve opening occurs again but without a corresponding ventricular systole. Doppler sampling in the tricuspid valve (TV) orifice (lower panel) reveals the true nature of the premature contractions. The presence of tricuspid regurgitation (TR) in the right atrium (RA) allows differentiation of systolic and diastolic events. Early occurrence of tricuspid regurgitation (dark arrows in the lower panel) immediately following ventricular systole is the result of very early premature junctional or ventricular contractions. This results in atrioventricular valve closure but produces only trivial systolic aortic flow (upper panel).

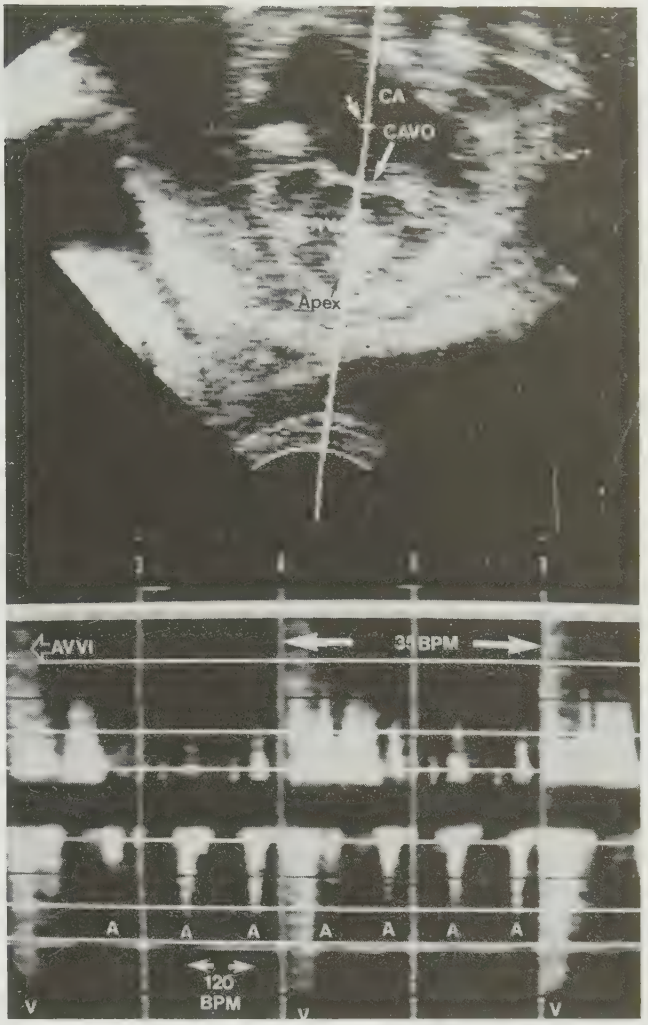

Fig. 48–22. Complete AV block is demonstrated by pulsed Doppler sampling in the common atrium (CA) of a 24-week fetus with complete atrioventricular canal and left atrial isomerism (upper panel). Regular atrial systole (A) occurs at a rate of 120 beats per minute (BPM). Ventricular systole (V) is recognized by high-velocity atrioventricular valve insufficiency (AVVI) at a rate of 35 beats per minute. Atrial systole and ventricular systole are dissociated. CAVO = common atrioventricular valve orifice; RV = right ventricle.

sidered in fetal patients with inadequate pulmonary maturity to sustain life. If pulmonary maturity is adequate, early delivery by cesarean section should be performed for the patient with complete AV block and progressive development of nonimmune hydrops fetalis.

Sustained tachycardia, defined as a heart rate persistently greater than 180 beats per minute, is usually caused by either supraventricular tachycardia or atrial flutter. Supraventricular tachycardia is the cause of sustained fetal tachycardia in 50 to 80% of cases,[31–36] atrial flutter accounting for the most of the remaining cases. Patients with fetal supraventricular tachycardia or atrial flutter should be hospitalized for medical treatment. With supraventricular tachycardia, the response to medical treatment is good even in some patients with fetal hydrops. However, early delivery following

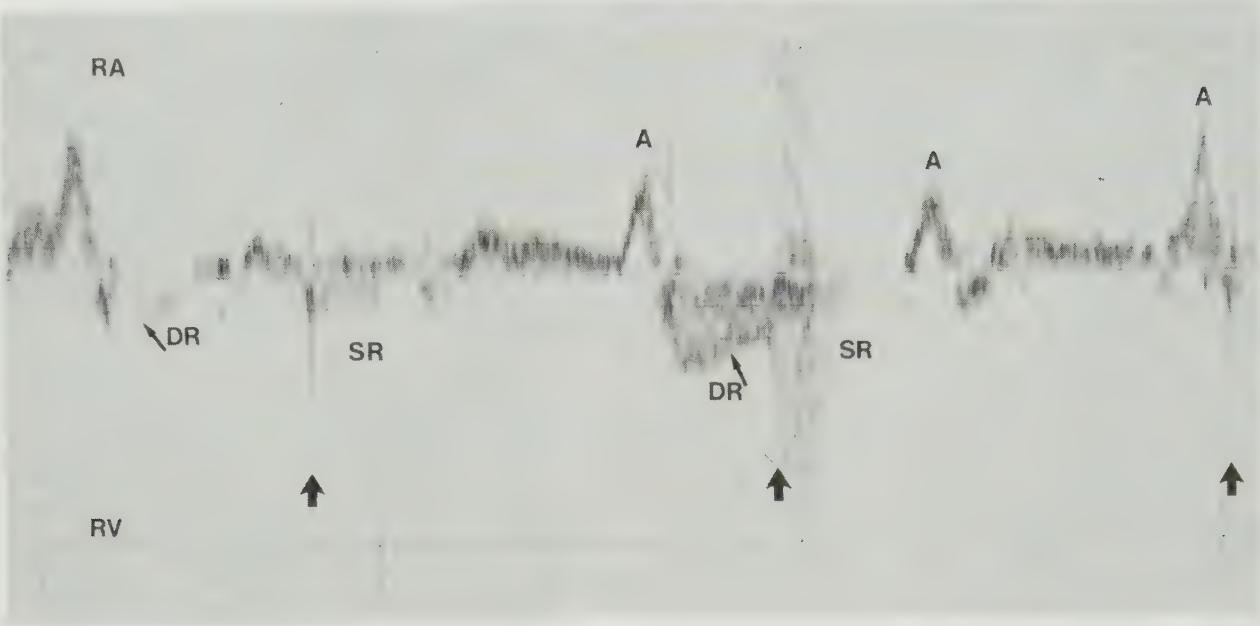

Fig. 48–23. Doppler recording of diastolic atrioventricular valve regurgitation (DR) occurring as a result of delayed closure of the tricuspid valve in a fetus with complete AV block. Systolic regurgitation (SR) marks the occurrence of ventricular systole (arrow), which is dissociated from atrial systole (A). RA = right atrium; RV = right ventricle.

assessment of pulmonary maturity should be considered for patients with sustained tachycardia when medical therapy fails and signs of hydrops become progressive.[34]

EVALUATION OF FETAL CIRCULATORY FUNCTION

Cardiac dysfunction in the fetus may result from a variety of causes, only some of which are primarily cardiac in origin. The first and major manifestation of cardiac failure noted by the obstetrician is often hydrops fetalis.[12] Nonimmune hydrops fetalis may be the initial manifestation of cardiac failure in a variety of clinical settings, including maternal anemia, pre-eclampsia, and polyhydramnios.[38] Cardiac enlargement is often noted in hydropic fetuses, regardless of the cause, and disproportionately affects the right ventricle. This is probably because the right ventricle provides the majority of fetal blood flow ultimately supplying the placenta. Congenital anomalies are frequently encountered in the fetus with nonimmune hydrops, only a minority of which are cardiac defects.[38,39] However, nonimmune hydrops appears to be much more likely to occur if the congenital anomalies that are present include malformation of the heart. Hydrops frequently intervenes when fetal arrhythmias are not successfully controlled in utero.[12,14,31,37] In addition to cardiac enlargement, other indices of reduced cardiac function may be present. After excluding fetal arrhythmia and cardiac defects, the echocardiographic assessment of heart size and function is an important part of the evaluation of the fetus with hydrops. Assessment of heart function using two-dimensional, M-mode, and Doppler echocardiography is described below.

Two-Dimensional and M-Mode Echocardiography

Disparities in cardiac chamber size often provide strong evidence of congenital heart disease or abnormal cardiac function in

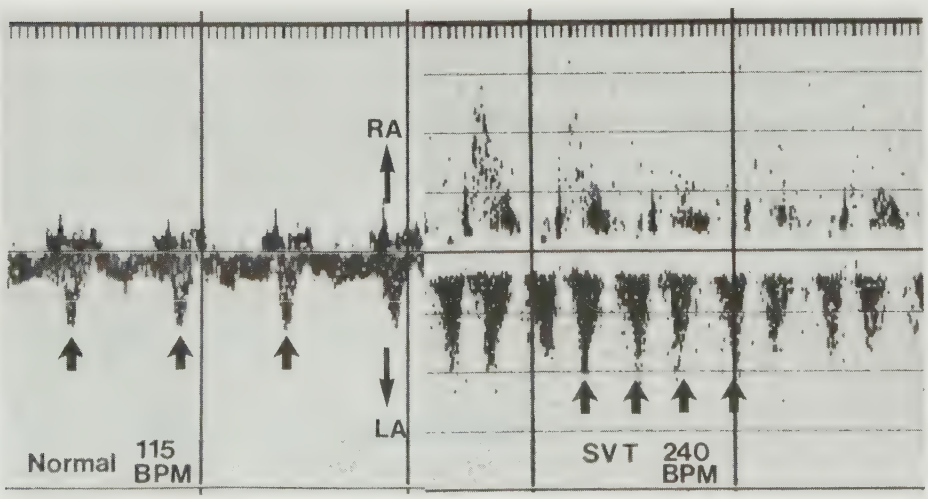

Fig. 48–24. Atrial systole recorded by pulsed Doppler sampling in the foramen ovale. On the left, in normal sinus rhythm, atrial systole (arrow) occurs at a rate of 115 beats per minute (BPM). On the right, atrial systole occurs at 240 beats per minute in a 28-week fetus with supraventricular tachycardia (SVT). RA = right ventricle; LA = left atrium.

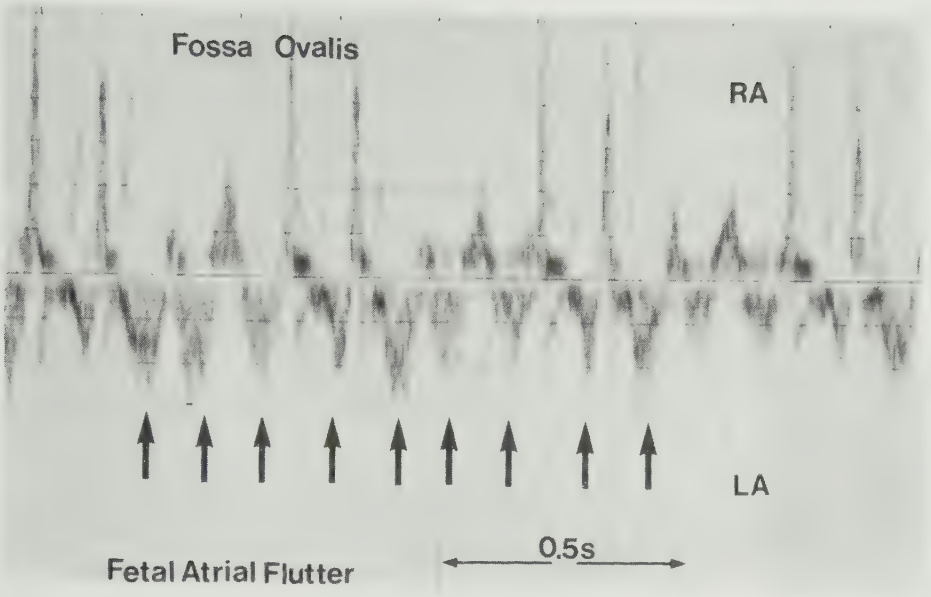

Fig. 48–25. Atrial flutter recorded by Doppler sampling in the fossa ovalis. Atrial systole (arrow) occurs at approximately 480 beats per minute. RA = right atrium; LA = left atrium. s = second.

the fetus. In comparison of right and left ventricular size, one ventricle may appear larger than the other (Figs. 48–7 and 48–8). However, without an appreciation of normal cardiac chamber size in the fetus, it would be difficult to determine whether one ventricle was enlarged, the other was unusually small, or both.

In two-dimensional echocardiographic scanning of the normal human fetus, at any gestational age, the right and left ventricles should be of approximately equal size in the four-chamber and short-axis scans (Fig. 48–26). A number of studies using both two-dimensional and M-mode echocardiography have established normal ventricular size in the human fetus.[19–23,40] However, a variety of methods have been employed in obtaining measurements of fetal ventricular size that have led to some variation in the results of investigators. In addition, since synchronization of the M-mode recording with the electrocardiogram is not possible with fetal echocardiography, standard methods of measurement of ventricular diastolic dimensions cannot be employed. The comparison of ventricular size and shortening fraction in the fetus to the same parameters in the neonate is not possible because of the presence of paradoxical or flat septal motion in the fetus and differences in ventricular geometry before and after birth. This is presumably the result of the relative volume loading of the right ventricle in utero.[20,23] Normal values in the fetus may be related to estimated fetal gestational age, estimated fetal weight, or fetal parameters of growth such as biparietal diameter, abdominal circumference, or femur length. Despite differences in methodology, the results of these studies provide useful parameters that may aid in the diagnosis of chamber enlargement or dysfunction.

Sahn and associates[22] have described the changes in ventricular and great vessel size with increasing gestational age in fetuses of greater than 20 weeks gestation using measurements obtained with two-dimensional echocardiography. Measurements of ventricular dimension were taken from four-chamber views at the level of the atrioventricular valves and immediately prior to atrioventricular valve closure. Great vessel dimensions were recorded from short-axis views. Values were related to estimated fetal weight. A curvilinear relationship was found between estimated fetal weight and ventricular diameter and between estimated fetal weight and great vessel diameter. The mean ratio of right ventricular diameter to left ventricular diameter was 1.2:1, and the ratio of pulmonary artery to aortic diameter was approximately 1.2:1. Wladimiroff and associates[20] studied fetuses of greater than 28 weeks gestation using two-dimensionally directed M-mode of both ventricular chambers in the four-chamber view. Parameters were related to estimated gestational age. End-diastole was defined as the point of maximum dimension of the ventricles, and end-systole as the minimum dimension. Left and right ventricular end-diastolic dimensions ranged from approximately 11 mm at 28 weeks to 18 mm at 40 weeks. End-systolic dimensions for both ventricles ranged from 8 mm at 28 weeks to 14 mm at term. Thus the ratio of right ventricular to left ventricular dimensions was consistently 1:1. Ventricular diameters increased linearly with increasing gestational age.[41] A longitudinal study by St. John Sutton and associates[21] was performed in 16 normal fetuses from 20 weeks to term. Two-dimensionally directed M-mode recordings were obtained at the level of the atrioventricular valves. Values were related to gestational age calculated from date of the last menstrual cycle and biparietal diameter. Right ventricular to left ventricular dimensions were comparable throughout gestation, increased linearly, and yielded a ratio of 0.96:1. Somewhat lower mean values for chamber dimensions were obtained in this study than in the study by Wladimiroff and associates, with an internal ventricular diameter at 20 weeks of 7 mm + 1 mm and at term of 15 mm + 2 mm. Left ventricular, right ventricular, and septal thickness were comparable and increased linearly throughout gestation. Maximum systolic wall thickness was 3 mm, and minimum thickness was 2 mm at 20 weeks gestation, increasing to 4.5 mm in systole and 3.5 mm in diastole at term. Similar results for chamber dimensions have been obtained by Devore and associates[19] and Allan and associates.[40] Devore and associates[19] found a linear relationship between ventricular diameters and biparietal diameter with a mean ratio of right ventricular diameter to left ventricular diameter of 1:1.

It is clear that the right and left ventricles are of approximately equal transverse diameter throughout gestation. However, this does not imply equal ventricular volume or equal stroke volume.

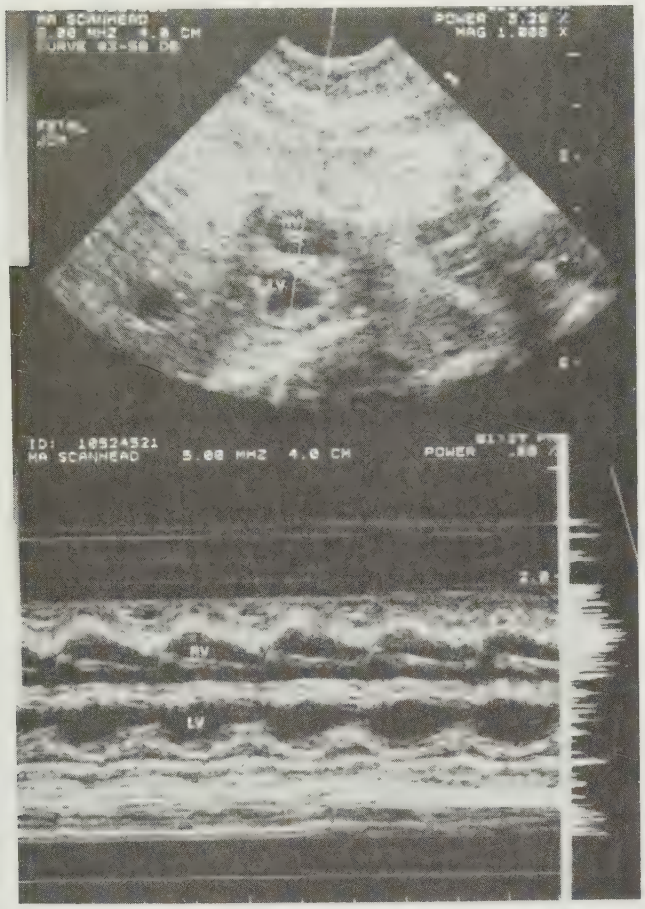

Fig. 48–26. Demonstration of two-dimensionally directed M-mode echocardiogram in a fetus with normal ventricular size and function. The M-line is directed through the right ventricle (RV) and left ventricle (LV) in the short axis at the level of the atrioventricular valves (upper panel). The M-mode echocardiogram (lower panel) demonstrates normal ventricular size and normal right ventricular and left ventricular free wall motion. Note that septal motion is relatively flat in the fetus.

Substantial differences in ventricular geometry may produce greater right ventricular end-diastolic and end-systolic volume and, consequently, greater right ventricular stroke volume. Anzacot[23] described changes in left and right ventricular geometry in the short axis from a left ventricular cross-sectional configuration of a flattened ellipse in the fetus, a circle in older infants, and transitional shapes in newborns. Left ventricular shape in the fetus and newborn was similar to left ventricular shape observed in postnatal patients with congenital heart disease that produces right ventricular pressure or volume overload. Thus although right and left ventricular transverse diameter in the four-chamber view may be equal, differences in three-dimensional ventricular geometry may reflect the dominance of the right ventricle in fetal circulation.

Echocardiographic parameters of ventricular function are load dependent and are therefore of limited use in the assessment of contractile state. The parameters that are employed in postnatal life are primarily ejection phase indices such as the pre-ejection/ejection period ratio, shortening fraction, mean velocity of shortening, and ejection fraction. Although an assessment of systolic time intervals in the human fetus is possible[17,42] by using transabdominal fetal electrocardiograms, these measurements are affected by changing afterload and are technically difficult to obtain. Kleinman and Donnerstein[17] have demonstrated an increasing pre-ejection/ejection period ratio with gestational age. Postextrasystolic potentiation in the human fetus has been demonstrated by using M-mode recordings and assessment of shortening fraction and peak systolic wall velocity. The presence of postextrasystolic potentiation is probably the result of increased preload and as such confirms the presence of a Starling response in the human fetus. Fractional shortening of the right and left ventricles appears to be similar at approximately 32%[19] (standard deviation = 4%) and decreases slightly from 20 weeks to term.[21,43] However, conclusions concerning the contractile state of the fetal myocardium cannot be reached in any given clinical setting because of inability to assess changes in fetal loading conditions. In addition, comparison of left ventricular shortening fraction in the fetus to shortening fraction in the neonate and infant is not possible because of changes in ventricular geometry with birth. Ultimately, right ventricular enlargement, pleural and pericardial effusions, and scalp edema are noted in the fetus with heart failure. However, these changes occur late in the course of fetal heart failure.

Pulsed and Continuous Wave Doppler

As was described above, pulsed Doppler examination of the fetal heart is useful in the diagnosis of fetal arrhythmia and may be used to estimate fetal blood flow, to detect valvular insufficiency, to demonstrate turbulent great vessel flow, and to detect constriction of the fetal ductus arteriosus. The pulsed Doppler examination of the human fetus has been described.[44–48] However, a number of factors add to the difficulty of performing Doppler examination of the fetus. Pulsed and continuous-wave Doppler examination exposes the fetus to higher-intensity ultrasound energy than does either two-dimensional or M-mode imaging. In addition, Doppler sampling often must be performed at a greater depth in the fetus despite the necessity of limiting ultrasound energy output. This may lead to a poor signal-to-noise ratio and to frequency aliasing. In addition, because of variations in fetal position, velocities cannot always be recorded from all four cardiac valves, and optimal angles for pulsed Doppler sampling often cannot be obtained. Angle correction of recorded velocities is necessary if volume flow is to be estimated. Measurements of fetal valve orifice or vessel diameters are frequently obtained at the limits of resolution of two-dimensional imaging and therefore can introduce significant error into the calculation of volume flow. Despite these limitations, pulsed Doppler examination is a useful adjunct to cardiac evaluation of the fetus. Although adverse effects of Doppler examination of the human fetus have not been demonstrated, addition of Doppler to cardiac imaging should not be considered routine. Indications for pulsed Doppler examination include:

1. demonstration of abnormal flow in patients with suspected congenital heart disease,
2. diagnosis of fetal arrhythmia,
3. assessment of cardiac function in the fetus at risk for congestive heart failure.[45]

In addition to using minimum energy output, the pulsed Doppler examination should be performed with the smallest possible sample volume size. In the four-chamber view, Doppler sampling

should be performed at the atrioventricular valve orifice to obtain maximal diastolic atrioventricular valve flow and, in addition, proximal to the valve to detect atrioventricular valve insufficiency. Atrioventricular valve insufficiency is often recognized in the fetus with nonimmune hydrops and heart failure (Fig. 48–27).[49] Atrioventricular valve insufficiency may also be noted in association with congenital heart disease such as Ebstein's anomaly (Fig. 48–28) or atrioventricular canal defects.

Flow velocity can be recorded from the tricuspid or mitral valve in approximately 50 to 60% of fetuses.[47] In contrast to infants and adults, fetal atrioventricular velocity profiles demonstrate dominant A wave (Fig. 48–18). The ratio of the E wave to the A wave increases during gestation.[47] It has been postulated that the A wave dominance in the fetus reflects reduced ventricular compliance and suggests a dependence on atrial systole to ensure adequate ventricular filling.[44–47] When adequate velocity profiles are obtained from both atrioventricular valves, calculated tricuspid flow exceeds mitral flow by approximately 30%.[44]

Doppler sampling in the foramen ovale reveals flow from right to left, which is accentuated with atrial systole. Interrogation of the left ventricular inlet reveals characteristic mitral inflow and left ventricular outflow, which is useful in demonstrating atrioventricular activation sequence (Fig. 48–18). Ascending aortic flow velocities may be obtained from views simulating the apical long-axis view or the suprasternal notch view. Angles obtained from the suprasternal notch view are often suboptimal and exceed 20°. Flow velocities distal to the pulmonary valve may be recorded in modified short-axis views (Fig. 48–29). Doppler interrogation of the ascending aorta and pulmonary artery is useful in detecting significant degrees of semilunar valve stenosis (Fig. 48–30). Aortic or pulmonary velocity can be successfully obtained in approximately 60% of fetuses.[47] When aortic and pulmonary flow are calculated from angle-corrected velocity, pulmonary flow exceeds calculated aortic flow by approximately 30%.[44,47] With fetal growth, increasing atrioventricular and semilunar valve flows occur largely as the result of increasing valve diameter, since velocity and heart rate changes are relatively minimal during gestation and increases in valve diameters are at least twofold.[47,48]

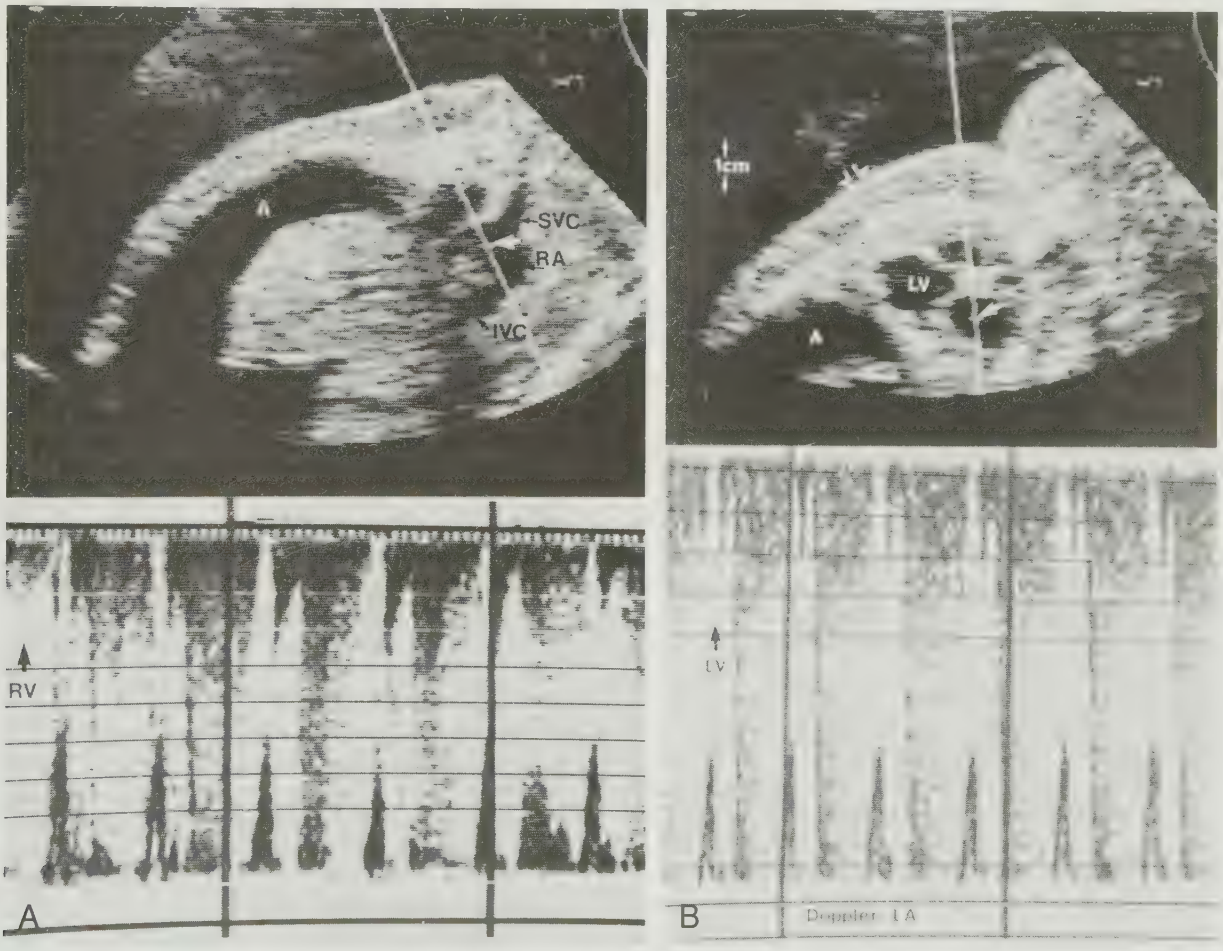

Fig. 48–27. (a) Tricuspid insufficiency detected by pulsed Doppler in a fetus with nonimmune hydrops. In the upper panel, the Doppler sample volume is positioned in the right atrium (RA). The presence of ascites (A) is an indication of fetal hydrops. In the lower panel, the high-velocity jet of tricuspid insufficiency is demonstrated. RV = right ventricle; IVC = inferior vena cava; SVC = superior vena cava. (b) Mitral insufficiency demonstrated by Doppler sampling in the left atrium (LA) in a fetus with nonimmune hydrops (upper panel). The arrow is directed at fetal chest wall edema. The presence of edema and ascites (A) indicates advanced fetal hydrops. In the lower panel, the high-velocity jet of mitral insufficiency is directed from the left ventricle (LV) to left atrium (LA).

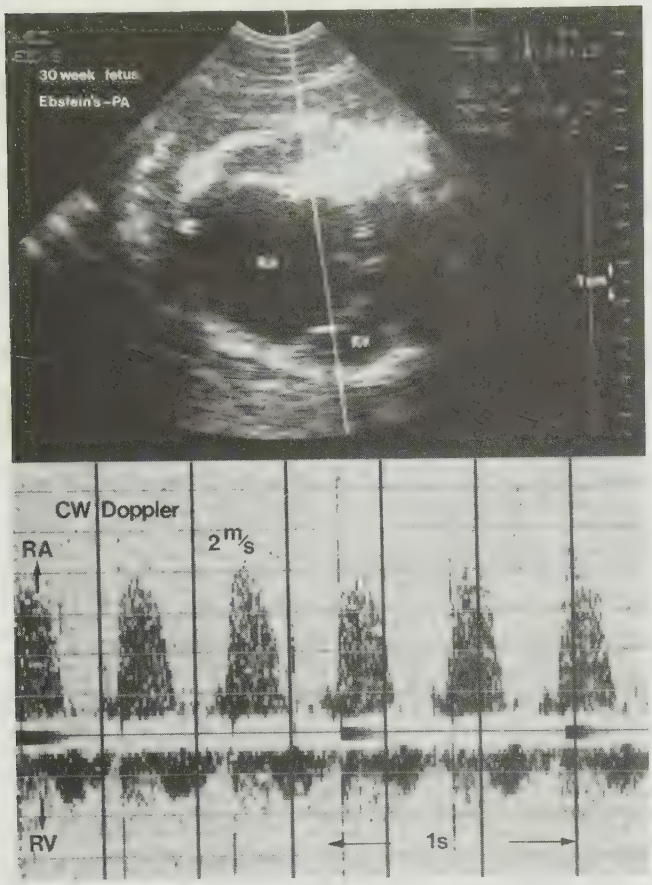

Fig. 48–28. Continuous-wave (CW) Doppler sampling of tricuspid insufficiency in a 30-week fetus with Ebstein's anomaly. The two-dimensional scan (upper panel) is in a transverse plane from posterior to anterior (PA) and demonstrates massive right atrial enlargement with inferior displacement of the tricuspid valve. The line of continuous-wave Doppler sampling is also illustrated in the upper panel. In the lower panel, the jet of tricuspid insufficiency peaks at 2 meters per second (m/s). RA = right atrium; RV = right ventricle; s = second.

Sagittal imaging allows demonstration of the ductus arteriosus in continuity with the descending aorta. Sampling in the ductus arteriosus (Fig. 48–29) generally reveals the highest flow velocities recorded in the fetus. Ductal velocities are higher than either ascending aorta or pulmonary artery velocities, range from 0.6 to 1.2 m/s, and increase with increasing gestational age. Diastolic velocities of 0.1 to 0.2 m/s toward the descending aorta are characteristic of ductal flow. Huhta and associates[50] have recently demonstrated ductal constriction in fetuses exposed to indomethacin in utero. A characteristic pattern of increased peak ductal velocity and exaggerated diastolic runoff toward the descending aorta was demonstrated. This pattern was similar to the velocity profile obtained by continuous-wave Doppler in coarctation of the aorta. Since the greatest portion of cardiac output in the fetus flows through the ductus arteriosus, changes in ductal velocity would reflect either ductal constriction or changes in right ventricular output. Therefore altered ductal flow velocity may be a useful parameter for assessment of right ventricular function and ductal constriction.

In addition to measurement of cardiac and great vessel flow velocity, pulsed and continuous-wave Doppler methods have been applied directly to the measurement of placental blood flow and indirectly to the estimation of placental resistance.[51–68] By using duplex pulsed Doppler echocardiography and continuous-wave Doppler, umbilical artery and vein flow velocities may be measured at the insertion of the umbilical cord on the surface of the fetal abdomen (Fig. 48–31). Umbilical vein flow velocity can also be sampled in the fetal abdomen as the umbilical vein courses toward the liver (Fig. 48–32). Flow in the descending aorta may be sampled at the level of the fetal diaphragm in the sagittal plane with measurement of the angle to flow. Continuous-wave Doppler has also been used with and without two-dimensional imaging to measure umbilical vein, descending aorta, and umbilical artery flow velocities.

The accuracy of calculated placental blood flow using the measurement of velocity of blood flow in the umbilical artery or vein is affected by several factors. First, an accurate measurement of vessel diameter in small fetuses is difficult to obtain within the limits of resolution of two-dimensional ultrasound. In small subjects, a small error in measurement of vessel diameter results in a proportionately large error in calculation of vessel cross-sectional area. The umbilical vein and descending aorta are assumed to be circular in cross section, and phasic changes in vessel cross-sectional area are not taken into account. Second, the calculation of spatial mean velocity of blood flow from spectral velocity wave forms depends on the assumed shape of the spatial velocity profile in the insonated vessel. The velocity profile in the descending aorta is presumed to be parabolic in the fetus, the highest velocity being in the center of the vessel. Third, the angle between the umbilical artery or vein and the ultrasound beam may not be estimated accurately.

With these limitations in mind, it is not surprising that there is considerable variation among individual measurements of fetal blood flow at any gestational age. Nonetheless, some hemodynamic trends can be observed during gestation. In general, umbilical and aortic flows increase with increasing gestational age with a slight reduction in flow in the two weeks prior to term.[52–57,61,62,67] The increase in flow occurs as a result of increasing vessel diameter with umbilical venous mean velocity remaining constant. Mean calculated umbilical vein flow in most studies ranges from 100 to 120 mL/kg/min with descending aorta flow averaging approximately 200 mL/kg/min. Thus the ratio of umbilical flow (or placental flow) to descending aortic flow determined by Doppler in human fetuses is approximately 60%. Increased umbilical flow has been observed in the presence of maternal anemia, maternal hemorrhage, and fetal isoimmune hemolytic disease,[57] with decreasing flow in fetal subjects with imminent asphyxia.[62] Descending aortic mean velocity is also decreased in the presence of maternal hypertension with fetal growth retardation, particularly in the presence of fetal distress.[60] This is both a result of reduced peak velocity and a result of the virtual absence of normal forward diastolic flow velocity.

Forward diastolic flow in the descending aorta and umbilical artery probably results from diastolic runoff to the low-resistance placental circulation. A number of indices of diastolic flow have been developed in an attempt to quantitate changes in placental resistance.[51,58,60,62,63,65,66,68] These include the ratio of maximal systolic to maximal diastolic flow and the pulsatility index ($V_{peak} - V_{min}/V_{mean}$). There is a general trend for the pulsatility index to

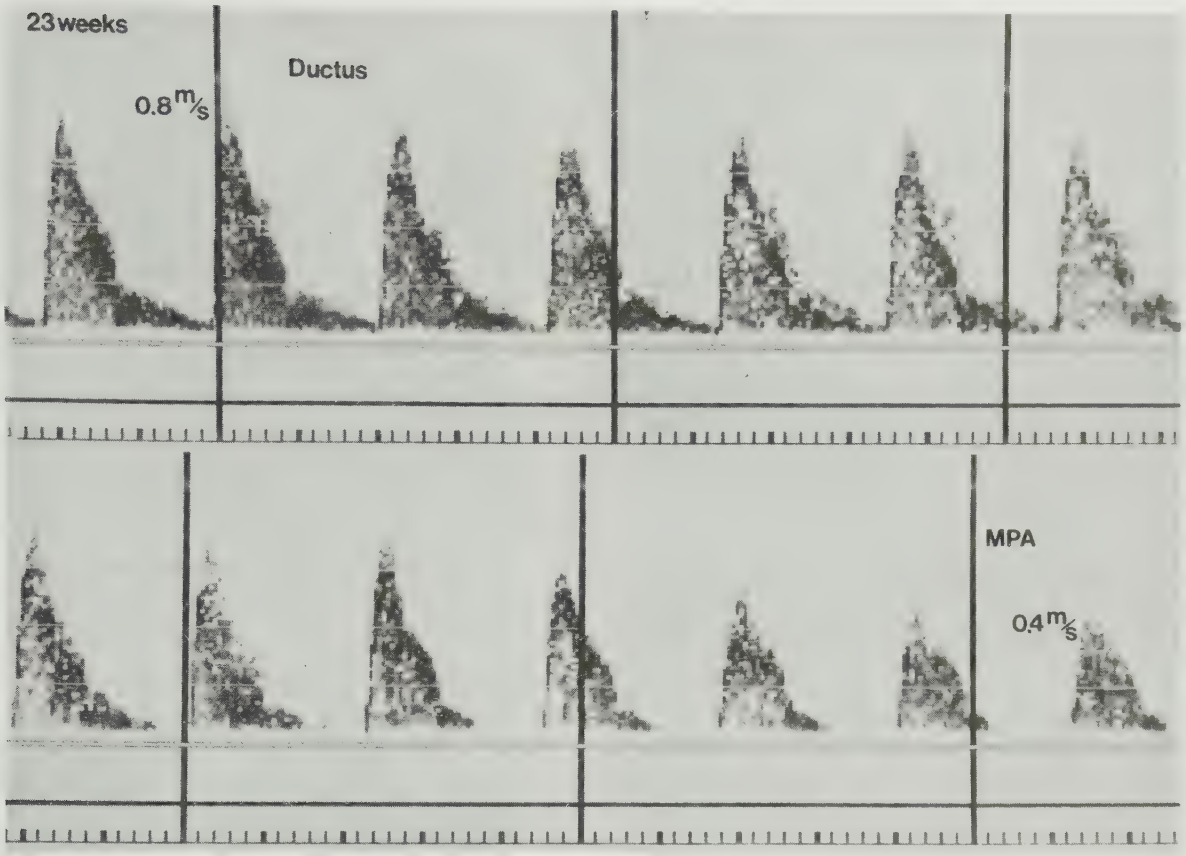

Fig. 48–29. Pulsed Doppler sampling of ductus arteriosus flow and main pulmonary artery (MPA) flow in a 23-week fetus. Ductal peak velocity is 0.8 meter per second (m/s) with continuous diastolic runoff. As the sample volume is withdrawn to the main pulmonary artery, peak velocity decreases and the pattern of continuous diastolic runoff is lost.

decrease with increasing gestational age in some studies,[58] whereas in others there is essentially no change with increasing gestational age.[65,66] In general, as placental resistance increases—for instance, in the fetus with intrauterine growth retardation—diastolic flow is reduced, and the pulsatility index or ratio of systolic to diastolic flow increases.[51,58,60,63,65,68] An increased pulsatility index has been observed in fetal subjects with imminent asphyxia.[62] Diastolic velocity may approach zero, and reversal of flow has been observed in some cases (Fig. 48–33). In contrast, maternal hypertension without growth retardation and isoimmune hemolytic disease do not appear to affect the pulsatility index.[60] The normal pulsatility index is usually less than 2, with some overlap between normal and abnormal subjects in the range from 2 to 3. A pulsatility index greater than 3 is abnormal and may indicate high placental resistance. Although these parameters of placental blood flow and resistance are provocative and provide some insight into fetal hemodynamics, their contribution to the early detection and treatment of the fetus at risk for significant asphyxia remains to be determined.

COLOR DOPPLER FLOW IMAGING

Color Doppler flow imaging may enhance the fetal echocardiographic examination in a number of ways.[69] Because of the lower pulse repetition frequency of color flow systems, energy intensity is less at any given area and therefore is less likely to be harmful to the fetus than conventional pulsed Doppler or continuous-wave Doppler. Poor two-dimensional imaging may be encountered in a number of situations including maternal obesity, polyhydramnios, and advanced fetal gestational age. The addition of color Doppler to the examination may allow differentiation of structures that are not readily identified by two-dimensional echocardiography alone. The use of color Doppler may shorten the duration of conventional Doppler examination by allowing quick recognition of normal and potentially abnormal flow. Identification of pathologic jets, such as tricuspid insufficiency or turbulent jets of semilunar valve stenosis, may allow directed conventional pulsed Doppler examination to the area of interest. In addition, color Doppler may allow identification of direction of flow and improve angle correction of velocities. There are some limitations to the color Doppler examination in the human fetus. The lower pulse repetition frequency of color Doppler, as well as the greater depth of sampling in the fetus, leads to frequency aliasing at lower velocities. Sampling at greater depths with the small volume flows encountered in the fetus may lead to low signal amplitude because of the reduced intensity of backscattered ultrasound. Current color Doppler systems have reduced spatial resolution because of the relatively low carrier frequencies employed and reduced temporal resolution because of the slow frame rates required for color Doppler signal processing. Since Doppler signal amplitude is greatest in the axis

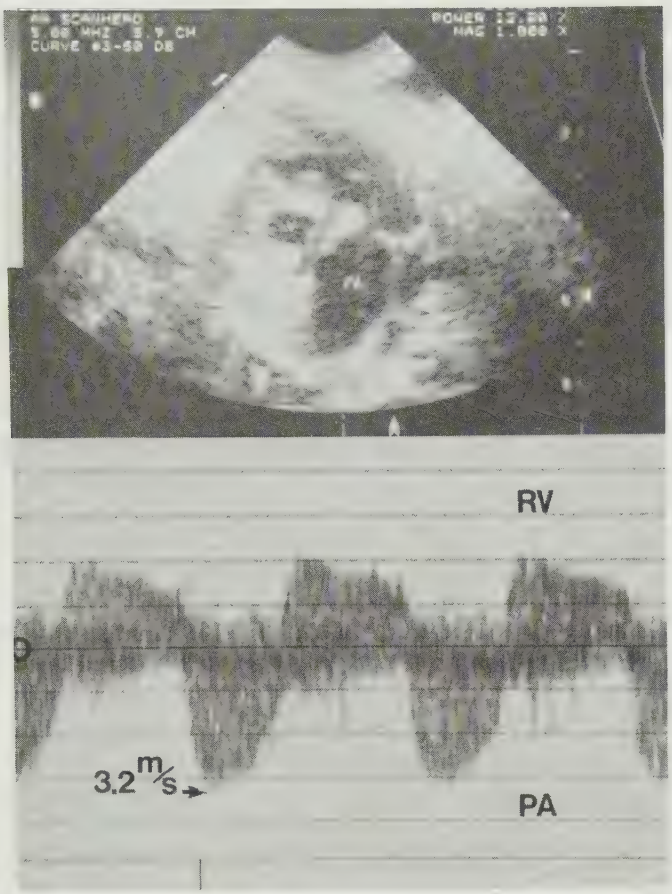

Fig. 48–30. Pulmonary stenosis and insufficiency in a fetus with absent pulmonary valve syndrome. In the upper panel, the arrow is directed at the pulmonary anulus, and massive enlargement of the pulmonary artery (PA) is easily appreciated. The continuous-wave Doppler recording in the lower panel demonstrates pulmonary stenosis with a peak velocity of 3.2 meters per second (m/s) and pulmonary insufficiency with a peak velocity of 2 meters per second. RV = right ventricle; LV = left ventricle.

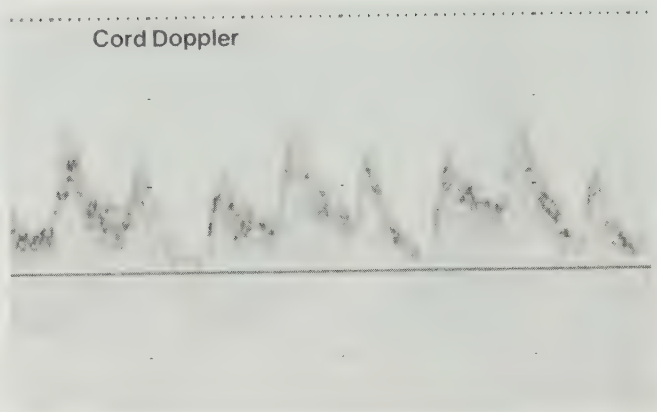

Fig. 48–31. Continuous-wave Doppler recording of umbilical cord flow. The pulsatile "sawtooth" pattern of umbilical arterial flow is upward, directed toward the transducer, and varies with fetal breathing. Note the continuous nature of normal umbilical arterial flow. Umbilical venous flow, which is downward, directed away from the transducer, also varies with fetal breathing but is not pulsatile.

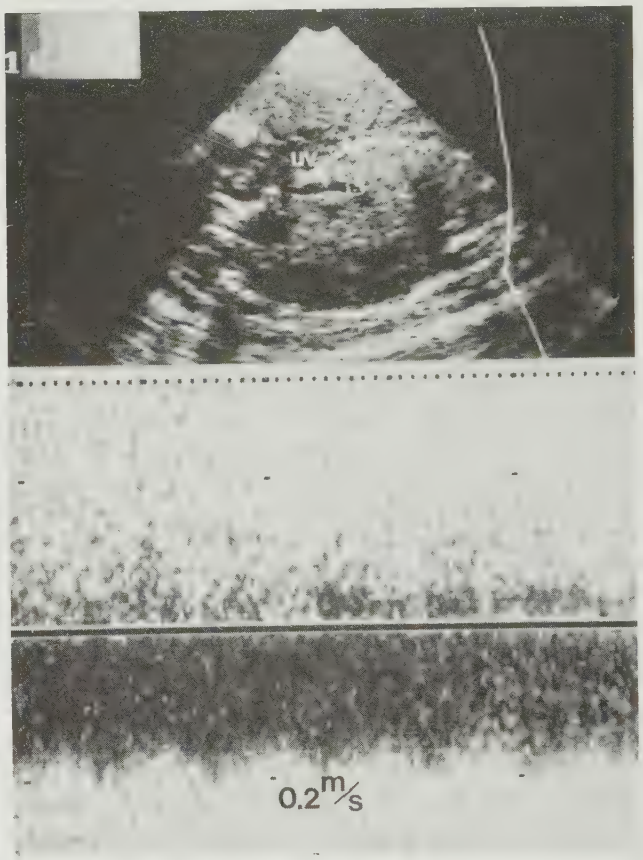

Fig. 48–32. The site of pulsed Doppler sampling of the umbilical vein (UV) as it enters the fetal liver (upper panel). Flow in the umbilical vein (lower panel) is of low peak velocity and demonstrates significant spectral dispersion, reflecting nonlaminar flow conditions.

of flow, the optimal images for color Doppler sampling are often at right angles to the best plane of imaging for two-dimensional echocardiography.

Since standard image orientation is often not obtained in the fetus, the usual color patterns of intracardiac flow are not seen in many cases. The color of the Doppler flow signal depends on the orientation of the heart relative to the scanhead. For instance, in the normal fetus, atrioventricular valve flow is seen as a red jet in diastole when recorded from an apical position in the four-chamber plane. However, atrioventricular valve flow is depicted as blue if the four-chamber view is recorded from base to apex. The blue jet of semilunar valve regurgitation may be seen in the apical four-chamber plane or in a modified long-axis scan from the apex. Enhanced recognition of atrioventricular valve insufficiency may aid in the early diagnosis of congestive heart failure in the fetus and in differentiation of degrees of tricuspid insufficiency associated with progression to fetal hydrops.[49] In the modified long-axis view, great vessel flow demonstrates contrasting colors, pulmonary and ductal flow away from the transducer being

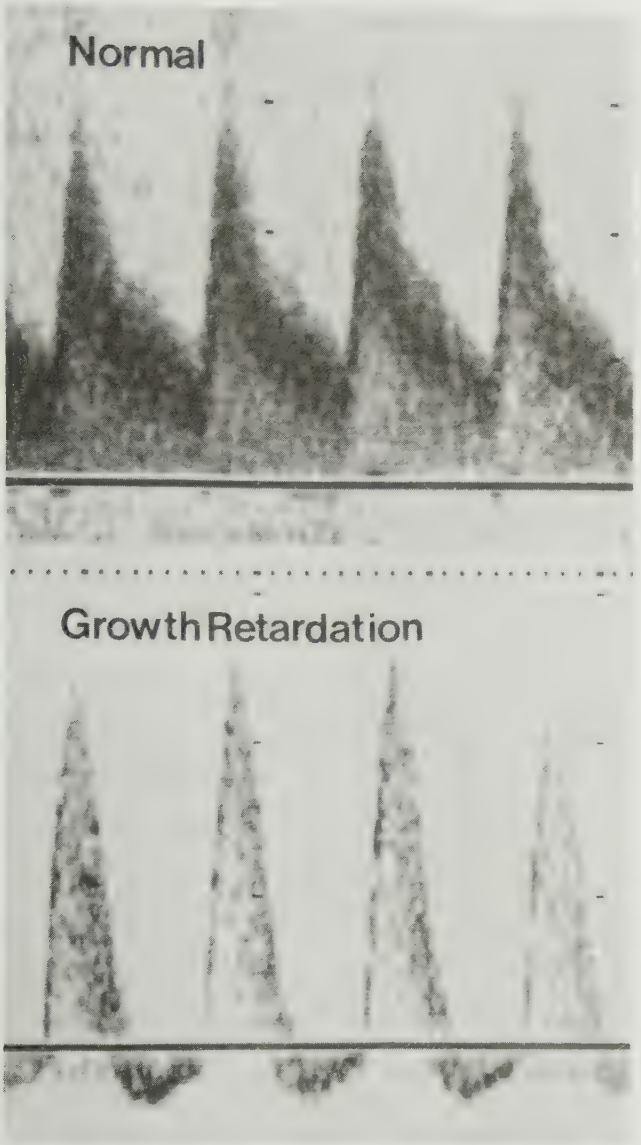

Fig. 48–33. Pulsed Doppler sampling of flow in the umbilical artery. In the upper panel, the typical "sawtooth" pattern of normal umbilical arterial flow is seen with continuous diastolic runoff and relatively high end-diastolic velocity. A markedly abnormal pattern of umbilical arterial flow is seen in the lower panel with flow reversal during diastole. Reduced umbilical arterial diastolic velocities or flow reversal is often detected in the fetus with intrauterine growth retardation or imminent asphyxia.

encoded blue and ascending aortic flow toward the transducer encoded red. Ductal flow may demonstrate aliasing as a result of the relatively high velocity of ductal flow in the fetus. Right-to-left flow across the foramen ovale is usually easily demonstrated in the fetus. Left-to-right flow implies a severe degree of obstruction to inflow at the mitral valve and may suggest the presence of mitral atresia or stenosis. The streaming of inferior vena caval flow to the left atrium and of superior vena caval flow to the right ventricle can be demonstrated in some subjects. The characteristic spiral course of the umbilical vessels with alternating red and blue color is easily demonstrated. With improvements in technology, the contribution of color Doppler flow imaging to cardiac diagnosis in the fetus should continue to increase.

RISKS AND BENEFITS OF FETAL ECHOCARDIOGRAPHY

The potential for damage to the fetus by ultrasonic examination is related to many factors.[70–72] The frequency of ultrasound, commonly from 2 to 10 mHz in echocardiography, is probably a major determinant of adverse tissue effects. The duration of exposure and the pattern of exposure, such as pulsed versus continuous ultrasound, also have a major impact on the amount of ultrasonic energy delivered to fetal tissues. The duration of exposure when using pulsed ultrasound varies with the pulse repetition frequency and the duration of the pulse. Thus the greatest tissue effects at a given carrier frequency would be expected with continuous ultrasound exposure and would be least with low pulse repetition frequencies of sort pulse duration. Tissue effects result from absorbed ultrasound and therefore decrease with increasing distance from the ultrasound source. The amount of energy transmitted is also altered by differences in tissue characteristics between the ultrasound source and the area of potential damage. Biologic mechanisms that come into play under conditions of ultrasound exposure also modify tissue effects. Thus the problem of assessing risk of fetal exposure is very complex and varies greatly depending on choice of instrumentation, fetal and maternal size, presence of edema or altered quantities of amniotic fluid, type of ultrasound examination performed, and duration of examination among other variables.

Ultrasound exposure may damage tissue in a number of ways. As ultrasound energy is absorbed by tissue, heat is generated. The amount of heat generated decreases with increasing depth from the source. However, the degree of local heating that induces damage depends on the temperature threshold for cellular damage and the mechanisms for heat removal at the area of exposure. The ability to remove heat is a function of blood flow and the time between exposures to ultrasound to allow for heat removal. In addition, ultrasound exposure generates or adds to gas bubbles in tissue, called cavitations. The development of cavitations also depends on ultrasound frequency and duration of exposure. Both increasing temperatures and increased gaseous cavitations can lead to cell death.

It should be apparent that there is no simple way to estimate the risk of tissue damage from diagnostic ultrasound. There are threshold intensity levels that appear to be safe to the human fetus even with continuous exposure. Higher threshold intensities are tolerated with pulsed ultrasound. There appears to be little risk with carrier frequencies and pulse repetition frequencies employed for two-dimensional and M-mode echocardiography. However, evaluation of the fetal heart by Doppler echocardiography requires higher-energy exposure than imaging alone because of higher pulse repetition frequencies. The exposure may exceed the current federal guideline of 100 mW/cm^2 spatial peak temporal average. Although it is difficult to estimate exposure, ultrasonic examination should be kept to the minimum time required using the lowest possible energy output, with particular attention to limiting the amount and duration of Doppler examination. Doppler examination should be performed only when clinical indications exist and not as a routine screening method. Continuous-wave Doppler ex-

amination should not be performed when pulsed Doppler examination will yield equivalent information. When repeated examinations are required, Doppler should be performed only when a potentially life-threatening abnormality exists. Direct Doppler sampling should be confined to the heart, great vessels, and umbilical vessels with strict avoidance of the central nervous system, the eyes, and the gonads.

The potential benefits of fetal ultrasound, except as noted above, greatly outweigh the risks. It is difficult to measure the positive physical and psychologic effects of excluding serious fetal congenital heart disease with a prior history of major congenital heart defects in a sibling or parent. When significant structural defects are detected, the physician's responsibility is to inform the parents of the natural history of the defect in the fetus and in the child with a review of the available options. Unfortunately, the natural history of some defects in utero is not clear. The ultimate severity of a defect detected in utero can be overestimated or underestimated. This is particularly likely to occur when a combination of defects is present, such as atrioventricular canal and tetralogy of Fallot. In addition, the medical and surgical treatment for many forms of congenital heart disease is evolving. Likewise, the current approach to in utero treatment of the fetus is evolving and holds promise for developments that will directly affect treatment of the infant with congenital heart disease. If the fetus with a significant defect survives pregnancy, delivery at a medical center that is equipped to care for critically ill neonates can be planned, and preparations can be made for early intervention by a pediatric cardiologist. The decision to terminate pregnancy depends on all of the above considerations and is ultimately an ethical decision calling for an assessment of the potential quality of life and longevity of the affected human fetus.[16]

The benefits of accurate diagnosis of fetal arrhythmia are clear and include (1) the ability to institute specific therapy in utero, (2) the avoidance of unnecessary cesarean section, and (3) the ability to plan for delivery at a medical center that is equipped to manage neonates with abnormalities of heart rhythm. Recognition of heart failure in utero allows treatment that may prolong fetal survival until delivery can be accomplished. Evolving methods of evaluating cardiac function may lead to early recognition of congestive heart failure in utero. Abnormal patterns of descending aorta, umbilical artery, or umbilical venous flow imply reduced placental blood flow and increasing placental resistance and, in some instances, precede changes in other indices of placental insufficiency or impending fetal asphyxia. Recognition of these abnormal patterns promises to allow early diagnosis of fetal distress and may be useful in identifying the fetus at risk for asphyxia.

CHAPTER 49

Exercise Testing

Frank M Galioto, Jr

Exercise testing has become increasingly important in pediatric cardiology centers.[1–4] Such testing is most recognized as useful in detecting cardiac abnormalities that are silent at rest and become manifest only with physiologic stress. Yet in combination with other modalities, exercise testing can lead to a more precise definition of the extent of heart disease in a child or adolescent with known cardiac abnormalities. Stress testing may be an effective screening tool for children in the appropriate setting and is the major tool for assessing the physiologic responses to exercise in normal children.[5,6]

Monitored exercise testing is useful for an objective assessment of symptomatology that the patient senses during physical activity. Since physical activity is an important part of each child's life, it is common that various forms of heart disease may become manifest during these periods of activity. It is therefore important to be able to reproduce the stress of exercise in the controlled, safe environment of the exercise laboratory to ascertain the exact cause of the symptoms perceived by the patient.

The extent to which the exercise test discloses abnormalities in cardiac function is directly related to the number of parameters assessed during exercise. To assess an impairment of cardiac output in a patient who has had surgery for congenital heart disease, cardiac output should be measured during exercise. Indirect measures of cardiac output, for example, the measurement of a ventilatory parameter such as oxygen consumption, are less precise and may lead to erroneous conclusions.[7]

INDICATIONS

The usefulness of exercise testing as a screening tool is subject to much debate. The results of mass screening should be judged according to the specificity and sensitivity of the tool used. If one measures the exercise capabilities of a group of seemingly normal children, there will be a range of "normal" findings. In normal children, the most common "diagnosis" will be that of exercise intolerance due to a lack of conditioning. These children are not abnormal, and the data should be interpreted only in reference to a range of normal responses. If one is interested in screening individuals for hypertrophic cardiomyopathy, which is a common cause of sudden death during exercise in young individuals, the most useful tool should be echocardiography and not stress testing.[8] On the other hand, if one is most interested in exercise-induced ventricular tachycardia, then there is no substitute for exercise testing. Similarly, the exercise test is useful for that small group of individuals with congenital abnormalities of the coronary arteries that predispose them to ischemia.[9] In these individuals, an exercise test will produce changes on the exercise electrocardiogram and will yield diagnostic information. However, for the overwhelming majority of patients, the exercise test will be a screening test for conditioning and not for congenital heart disease.[10,11]

Exercise testing is used most often in evaluating exercise-induced symptoms such as chest pain or syncope when heart disease is considered part of the differential diagnosis. Studies in which the test has been diagnostic include those for the diagnoses of exercise-induced asthma, coronary artery abnormalities, and exercise-induced arrhythmia. Exercise testing is considered especially valuable in the assessment of patients with known problems such as those following repair of structural congenital heart dis-

ease, with valvar heart disease that has not yet been repaired, with systemic hypertension, and with exercise-related arrhythmia.

Each pediatric exercise laboratory has a slightly different methodology, depending upon the personnel involved and the equipment selected for use. Because of these differences, each exercise laboratory must develop its own series of normal values for children and adolescents of different ages. The results obtained in the testing of children with abnormalities should be compared against the results obtained from normal subjects in one's own laboratory rather than to a series of patients in the literature. Often the testing modalities and the patient selection from the literature are quite different from the equipment in and population served by an individual exercise laboratory; thus it is inappropriate to use published norms.

METHODOLOGY

Exercise Inducers: Bicycle Versus Treadmill

The initial key selection of equipment in establishing the pediatric exercise laboratory is that of the exercise inducer. Generally, there are two types of exercise inducers: the motorized treadmill and the bicycle ergometer.[12] Each has its advantages and disadvantages. The treadmill is larger, is somewhat more costly, and does not allow for a precise determination of the amount of work induced. It is, however, more easily adaptable to patients of various sizes, and children as young as 2 years of age have successfully completed treadmill exercise-testing protocols. Testing of very young subjects is usually not possible with a mechanically or electrically braked bicycle ergometer. The treadmill induces slightly more work in terms of oxygen consumption than the bicycle ergometer because a greater number of muscle groups are active during running than during pedaling the ergometer. The use of the treadmill makes the measurement of blood pressure more difficult because of the motion of the arm during running.

A bicycle ergometer is often less expensive than a treadmill and occupies a smaller area of the exercise laboratory than the treadmill. The bicycle can be calibrated precisely, and therefore the exact number of watts accomplished by the subject can be precisely measured.[13] The ergometer is also more useful for individuals who cannot use their legs effectively for exercise. In these cases, the device can be arranged into an arm crank apparatus that will allow for exercise testing. The major drawback to the commercially available bicycle ergometers is that these machines often call for a starting cranking power greater than that achievable by many small children. This is a special problem in laboratories in which a large segment of those to be studied are under 8 years of age. This problem is most acute in laboratories where there are no mechanically braked bicycles but only an electrically braked apparatus. The electrically braked bicycles are all designed for adults and have high initial power levels that are often not achievable by small children. This problem can be overcome by starting the crank of the ergometer with the aid of an assistant and having the patient only maintain appropriate cranking speed, but this maneuver alters the work calculations.

The bicycle ergometer has found most favor in Europe, while the treadmill is used more extensively in the United States. The European investigators[13] have spent considerable effort standardizing the ergometer. Their studies have led to a crank length of 33.3 cm with a crank axis height from the floor of between 80 and 120 cm. The flywheel of the ergometer has been standardized to 100 kg. For adult usage, the work calculations call for different numbers of revolutions per minute per unit of resistance. Because these settings are beyond the capability of most children, any pediatric laboratory that uses bicycle ergometers or arm crank devices should establish its own standards. Modifications to crank arm length are mandatory, given the range of sizes of children's legs.

Bicycle ergometry protocols usually call for starting power levels of 25 W and increments of 5, 10, or 25 W. The more fit adolescent may start at levels of 50 W, but the small child should be started at lower levels if the ergometer can be set below 25 W. The most commonly used protocol in Europe was described by Sjostran and calls for three stages with work intervals of 6 min each. In the United States, James and co-workers have described a 3-min incremental protocol in which the work load is based on the subject's body surface area.[14] (See Table 49–1.)

It is important that the ergometer be calibrated frequently for accuracy. Calibration is relatively simple in the mechanically braked device. An inexpensive calibration set is usually made available at the time of purchase of the ergometer. Calibrating an electrically braked system is much more difficult and often requires a service call by the manufacturer's representative to ensure that the device remains accurate.

Table 49–1. Fixed Continuous Bicycle Protocol with Three Exercise Programs

Exercise Level (3 min spent at each level)	*I (BSA < 1 m²) Workloads (kg-m/min)*	*II (BSA = 1–1.9 m²) Workloads (kg-m/min)*	*III (BSA > 1.2 m²) Workloads (kg-m/min)*	*Cumulative Time (min)*
1	200	200	200	3
2	300	400	500	6
3	500	600	800	9
4	600	700	1000	12
5	700	800	1200	15
6	800	900	1400	18
7	900	1000	1600	21
8	1000	1100	1800	24
9	1100	1200	2000	27
10	1200	1300	2200	30

BSA = body surface area in square meters.

From James, F.W., et al.: Responses of normal children and young adults to controlled bicycle exercise. Circulation, *61*:902–912, 1980.

Table 49–2. Bruce Protocol

Stage	Duration (min)	Speed (mph)	Grade (%)	Mets
Rest/recovery		0.0	0.0	
1	3:00	1.7	10.0	4.5
2	3:00	2.5	12.0	7.0
3	3:00	3.4	14.0	10.0
4	3:00	4.2	16.0	12.9
5	3:00	5.0	18.0	15.0
6	3:00	5.5	20.0	16.9
7	3:00	6.0	22.0	19.1

From Bruce, R.A., and McDonough, J.R.: Stress testing in screening for cardiovascular disease. Bull. N.Y. Acad. Med., *45*:1288–1305, 1969.

The treadmill does not have a similar calibration because the number of steps that a child takes during running exercise to keep up to the speed of the treadmill varies from one individual to the next. This variability makes much more difficult an assessment of the amount of work done. However, standard protocols have been developed by a series of investigators. The most commonly used protocol is that described by Bruce and McDonough.[15] (See Table 49–2.) The treadmill speed and incline are increased every 3 min with the Bruce protocol. The initial speed is set at 1.76 mph and the grade at 10%. After 3 min, the speed is increased to 2.5 mph and the incline to 12%. After another 3 min, the speed is further increased to 3.4 mph and the grade to 14%. In the fourth stage, after 9 min have elapsed, the speed is increased to 4.2 mph and the grade to 16%.

In the exercise laboratory at Children's Hospital National Medical Center, it has been found that most children cannot exercise consistently above 3.4 mph because of the number of strides required. Therefore the Bruce protocol has been modified to be more suitable for the child. The speed of the treadmill is maintained at 3.4 mph past the third stage, and only the grade is increased. (See Table 49–3.)

Other commonly used protocols for the treadmill are those designed by Balke[16] and Astrand.[12] Astrand's method calls for a stepwise increase in grade while keeping the speed constant. The speed is determined by the subject's ability to run and ranges between 5 and 8.5 mph. In Balke's protocol, a constant speed of 3.3 mph is used, the grade increasing to a maximum of 22% after 22 min. It has been found that the Balke protocol allows for the longest test duration, while the Bruce protocol allows for a shorter test but with a slightly higher maximal oxygen consumption. It is clear from this wide range of results that individual children will respond differently to various protocols. In the pediatric laboratory with a treadmill, the physicians should become proficient in applying just one protocol, and that protocol should be used consistently to allow for uniform comparison between subjects. There may have to be modifications for extremely small children or those who are especially unfit to allow for a long enough exercise test to make various physiologic measurements, but these modifications should be kept to a minimum, since they will produce results that will be difficult to interpret.

Table 49–3. Modified Bruce Protocol for Young Children

Stage	Duration (min)	Speed (mph)	Grade (%)	Mets
Rest/recovery		0.0	0.0	
1	3:00	1.7	0.0	2.3
2	3:00	1.7	5.0	3.5
3	3:00	1.7	10.0	4.5
4	3:00	2.5	12.0	7.0
5	3:00	3.4	14.0	10.1
6	3:00	3.4	16.0	12.9
7	3:00	3.4	18.0	15.0
8	3:00	3.4	20.0	16.9
9	3:00	3.4	22.0	19.1

Electrocardiography

Electrocardiographic monitoring is mandatory during all exercise tests.[17] The patient should have electrodes firmly fastened to his skin in the standard pattern to allow for the recording of all of the leads of the standard electrocardiogram. It should be possible to switch the monitor from one lead to another so that any electrical plane of interest can be viewed. For constant monitoring during the study, three leads from the three orthogonal vector planes should be selected. It most useful to monitor leads I, aV_F, and V_5. It is often advisable to monitor an anterior chest lead in patients who have had right ventricular surgery or are suspected of having right ventricular dysfunction. In these children, V_1 or V_2 is substituted for V_5. At each stage of exercise, a complete electrocardiogram should be recorded at 25 mm/s speed. During the remainder of the exercise test, we have found it extremely helpful to record the three leads being observed on the oscilloscope at a slow paper speed of 5 mm/s. In this way, if an arrhythmia is noticed during the test, the arrhythmia can be easily identified following the completion of the study during the interpretation phase.

A comprehensive resuscitation cart should be present in the exercise laboratory and checked regularly to make sure that all drugs are in date and all apparatus including a defibrillator is functioning without problem. All personnel present during exercise testing must be certified in cardiopulmonary resuscitation and proficient in the techniques of advanced life support.

Blood Pressure

The measurement of blood pressure during exercise is vital, but it is the parameter most recorded in error in children during exercise testing, especially when a treadmill is used.[18–20] If the major purpose of an exercise test is the evaluation of blood pressure in a subject thought to be hypertensive, it is better for that individual to have his exercise test on a bicycle ergometer until more accurate equipment becomes available for assessment of blood pressure during running.

The most commonly used blood pressure device is still the mercury sphygmomanometer and stethoscope. The Korotkoff sounds are auscultated, and the resultant values are recorded manually. Several other methods are available. Doppler detection is theoretically useful, since it does not depend upon the amount of blood flow through the arm for determination of the systolic and diastolic pressures. However, Doppler measurement is subject to a large amount of artifact during any arm movement. Because of this problem with motion artifact, Doppler devices have generally not been used in the clinical exercise laboratory.

The oscillometric method of blood pressure measurement has found favor in some manufacturers' products, but a number of

investigators have shown that the movement of the muscles in the arm causes considerable artifact, and this method has also fallen into disuse.

The most promising method is the automated blood pressure device with a sensitive Korotkoff sound microphone and automated sphygmomanometer. The difficulty with this method is that the reduction of the various sound artifacts in the same frequency and amplitude as the Korotkoff sounds often distorts the Korotkoff sounds themselves. However, a series of new prototypes are being developed with programmable acoustic filters so that the Korotkoff sounds may be better detected and extraneous signals reduced.

Respiratory Gas Exchange

The measurement of gas exchange as oxygen consumption (VO_2), carbon dioxide production (VCO_2), and minute ventilation (V_E) during exercise has been used by many investigators as a gauge of the total effort required by the cardiovascular system.[21,22] Maximal oxygen uptake was the first physiologic parameter measured. Work by Astrand and Rodahl[12] has shown that there is a stable relationship between oxygen uptake and increasing work performed during the aerobic phase of exercise with an eventual plateau in oxygen uptake. The point at which rising oxygen consumption changes to a plateau is called the "anaerobic threshold."[23,24] Some workers have used this point as a marker for conditioning. Its applicability in congenital heart disease has not been thoroughly investigated.

The classic method for measurement of oxygen uptake calls for the use of the Douglas bag.[12] The subject inspires room air, and all gases expired during a given period of time during exercise are collected in a container. The gas is analyzed after the test for oxygen content and volume, and the oxygen consumption for that period is calculated. The use of oxygen uptake measurement has been limited in children because of the difficulty in having the child cooperate enough to create a mouthpiece seal for a prolonged period of time during the collection of expired gases to ensure accuracy of the calculations.

The problem of cooperation has been overcome by the use of the respiratory spectrometer and pneumotachygraph, which reduces the time for collection to a single breath. In this method[25] (Fig. 49–1), the patient inspires room air, and all of the expired gases are vented via a one-way valve through a pneumotachygraph in which the capillary portion of a respiratory mass spectrometer is placed. From the pneumotachygraph, one can detect the volume of each expiration, and the respiratory mass spectrometer gives accurate determination of the amount of expired oxygen and carbon dioxide. From these data, it is possible to calculate oxygen consumption, carbon dioxide production, and minute ventilation on a breath-by-breath basis. This technique is made practical in the clinical setting with the use of an on-line microcomputer to manage the data collection, the various calculations required, and the display of the result in real time.

Whereas the basic exercise test requires only an exercise inducer, electrocardiographic monitor, and blood pressure device, most comprehensive pediatric centers where exercise is being studied in a research effort are routinely measuring oxygen consumption, carbon dioxide production, and minute ventilation. The use of these parameters produces a measure of energy expended, rather than a measure of work performed. The most useful and best-understood measure of effort is that of oxygen consumption.[26,27]

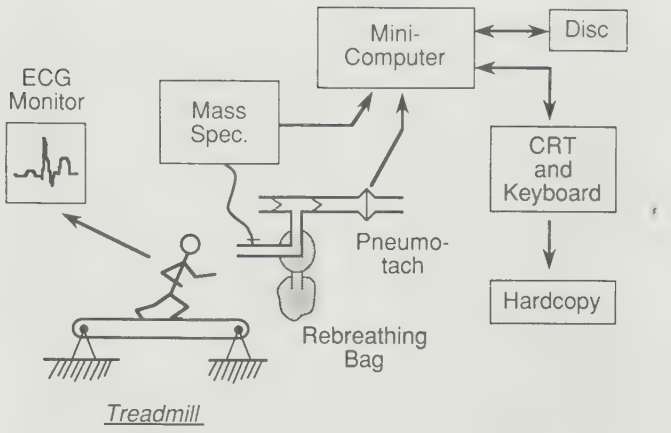

Fig. 49–1. Schematic drawing of the automated exercise laboratory. The patient breathes through the mouthpiece, which is connected to a pneumotachygraph in which the capillary of the respiratory mass spectrometer is placed. The data acquisition and analysis are managed by the on-line computer, which can display the results in real time on the CRT and print them on the hard-copy device.

Obviously, oxygen is needed for muscular work in the locomotion system, for cardiac work, and for the work of respiration in addition to the baseline metabolic processes. These oxygen consumption measurements are those of total oxygen uptake and do not reflect an accurate percentage required by the heart or the musculoskeletal system. For pediatric work, it is important to understand that the limiting aspect for exercise is the amount of oxygen that can be delivered to the tissues of the musculoskeletal system. With the treadmill, the highest amount of oxygen is consumed, since running uses more muscle groups than pedaling the bicycle ergometer.

Maximum oxygen uptake is governed by the ability of the heart to deliver blood to the tissues. Patients with reduced stroke volume and/or heart rate cannot perform as much work as those with normal responses. Similarly, patients with increased peripheral resistance are not able to work to the same level of maximum oxygen uptake.

The practical importance of measuring oxygen consumption is that it is directly related to the performance of the individual. It is well known that the highly trained athlete can achieve much higher oxygen consumption levels than the untrained individual, demonstrating the ability of the isolated measure of oxygen consumption to predict performance. It is important to remember, however, that the maximum oxygen uptake per unit of body weight is greater in a child of 10 years than in an adult for the same amount of work performed.[12] The child is therefore considered a less efficient athlete, since he requires more oxygen to perform the same amount of work.

The use of the carbon dioxide production and minute ventilation allows for better detection of the metabolic "switch" from aerobic to anaerobic mechanisms, the anaerobic threshold.[28] It is assumed that above this level of effort, additional work is being accomplished by the use of nonoxygen-requiring metabolic pathways. Obviously, oxygen is still consumed at a high level, but additional work performed is being done through the use of anaerobic pathways. This threshold is a reflection of the degree of training, since

it has been noted to be higher in the trained athlete and much lower in the less efficient and more sedentary individual.

Cardiac Output

Cardiac output is usually considered to be linearly related to oxygen consumption during submaximal work. Cardiac output at maximal oxygen uptake is less than would be predicted from a linear extrapolation of the cardiac output versus oxygen consumption line.[29] Various investigators have found that children have a low cardiac output in relation to oxygen consumption.[12] In studies in congenital heart disease, it is becoming increasingly apparent that the measurement of cardiac output may be key to the understanding of various exercise responses.

The measurement of cardiac output during exercise is much more difficult than the measurement of other metabolic parameters. The traditional way of measuring cardiac output in cardiovascular practice is in the cardiac catheterization laboratory and utilizes the Fick method. This methodology is unsuitable to the exercise laboratory because of the use of invasive catheters centrally located in the heart during a period of vigorous work and the associated risks of arrhythmia and bleeding. Various noninvasive measures have been developed to meet this need. These methods include the measurement of cardiac output by carbon dioxide rebreathing and by acetylene rebreathing.

The carbon dioxide rebreathing method applies the Fick principle to the exchange of carbon dioxide.[30] It requires the attainment of a steady production of carbon dioxide and requires also the measurement of an arterial sample for carbon dioxide. This can be done by an arterialized capillary blood specimen and the measurement of expired CO_2 for a mixed venous sample. The mixed venous CO_2 sample is obtained by rebreathing from a bag usually containing 5 to 10% carbon dioxide. This requires the subject to be cooperative and willing to withstand some of the discomfort associated with a slightly increased partial pressure of carbon dioxide in the blood. The method has been criticized because the required steady state condition is rarely achieved during exercise. Carbon dioxide is not a physiologically inert gas, and as a result, any increased production because of more work during the period of measurement may lead to an overestimate of cardiac output. Because of these problems, the method is not generally used.

The acetylene rebreathing method for cardiac output measurement is finding increasing use.[31–33,34] The method calls for a closed system of rebreathing achieved with a mouthpiece and noseclip and a prefilled rebreathing bag. The bag is prefilled with known concentrations of helium and acetylene, the balance being oxygen. The helium is used as a marker of uniform distribution of gases, since it is not diffusible across the alveolar–capillary interface, and to ensure that there are no leaks in the system.

With the initiation of breathing from the bag, the helium concentration falls as part of the gas passes into the lungs. On subsequent breaths, helium equilibrates its concentration between the air spaces of the subject's lungs and the bag. At this point, it is assumed that there has been uniform distribution of the gaseous material between the test bag and the subject's lungs. Simultaneous measurement of the acetylene concentration is also made by the mass spectrometer. The acetylene concentration falls with the first breath as acetylene passes into the lungs. Because it is freely soluble in lung tissue and its diffusion is readily accomplished across the alveolar–capillary interface, any disappearance of acetylene from the closed system after the helium achieves equilibrium between the lung and the closed bag indicates that the acetylene is leaving the lung system in the pulmonary blood flow. This rate of disappearance following equilibrium of the helium signal is analogous to the pulmonary capillary blood flow, which is a measure of the cardiac output.

It is important to emphasize that the acetylene rebreathing method will not measure total cardiac output but rather only the amount of blood that (1) reaches the lungs, (2) contacts the alveolar–capillary interface to absorb acetylene, and (3) then leaves the lung. This portion of the cardiac output is referred to as the effective cardiac output (Q_{EP}). If there are right-to-left shunts so that a considerable amount of blood does not reach the alveolar-capillary interface, this portion of the total pulmonary blood flow cannot be detected. Similarly, if there is early recirculation of blood saturated with acetylene as in a left-to-right shunt, the effective pulmonary blood flow measurement by acetylene cannot be accurately measured. It has been shown that the measure of cardiac output by the acetylene method is about 95% of the total pulmonary blood flow in the absence of anatomic shunts (when done simultaneously with Fick measures of pulmonary blood flow in the cardiac catheterization laboratory). Since there is an 18 to 22-s period before recirculation of the gas dissolved in the blood, all measures must be made during this period. Acetylene is tasteless and, in the concentrations used in this type of testing, not flammable. Use of this method is allowing researchers to learn more about cardiac output function during exercise in a variety of pathologic states.

Other Studies During Exercise

Radionuclide angiography[35,36] has been used to assess ventricular function during exercise in many centers. It permits assessment of wall motion of the left ventricle and allows for accurate measurement of ejection fraction. Measurements of right ventricular function are less precise at present. Cardiac output also may be measured by this technique. In children, the major drawbacks to the technique are the total body radiation exposure and the difficulty in keeping the position of the patient's chest constant in relation to the face of the scintigraphy counter for the time required to make enough counts to assure accurate calculations.

The use of echocardiographic and Doppler equipment during exercise is currently under investigation in a number of laboratories.[37,38] Echocardiographic assessment of ventricular performance has been found to be useful in selected individuals with conditions that adversely affect myocardial contractility. The technical problems are those associated with artifact generation because of motion of the transducer against the chest wall and inability to visualize the same area of the heart with each stage of exercise. Because of these problems, many investigators have been using supine exercise with the subject using a bicycle ergometer suspended overhead. This position does not allow for maximal exercise, but in selected individuals this technique has yielded valuable information.

The use of pulsed and continuous-wave Doppler during exercise is undergoing development. The Doppler transducer must be held exactly in the axis of the aortic or pulmonary root during exercise in order to measure velocity accurately. If this position is not achieved, the method is inherently inaccurate. A number of investigators are designing equipment and transducers that will allow

for this measurement; in time, Doppler assessment of cardiac output during exercise may prove to be useful.

Another study that currently has only a research interest is that of pulmonary diffusion during exercise.[39] The pulmonary diffusing capacity is a measure of the gas exchange across the alveolar–capillary interface per unit of pressure. It has been found that athletes with a larger diffusing capacity seem to perform better than their teammates with less diffusing capacity. Physical training does lead to an increase in the maximal diffusing capacity. The role of this measure in patients who have had large left-to-right shunts or cyanotic congenital heart disease remains to be elucidated.

In summary, the simple or basic exercise test should include the use of an exercise inducer, either a treadmill or a bicycle ergometer, electrocardiographic monitoring equipment, and appropriate recording and blood pressure measurement equipment. In a more sophisticated study, oxygen consumption, carbon dioxide production, and minute ventilation are measured in addition to the other parameters. These measurements are usually made at rest, during midexercise, and at peak exercise. If possible, measurements should be made at each stage of exercise. Finally, the most elaborate exercise test calls for the addition of cardiac output measurement. Currently, the use of the cardiac output equipment is not needed for most clinical laboratories and should be reserved for institutions that are conducting research on exercise in children.

CONDUCT OF THE EXERCISE TEST

In the Exercise Laboratory at the Children's Hospital National Medical Center, the usual routine calls for the patient with a parent to be brought to the exercise-testing laboratory. Upon arrival, the exercise technologist reconfirms the height and weight of the patient, as well as judging his psychological maturity and willingness to exercise. Special attention should be given to the very young child, who will need to be encouraged in an age-appropriate manner to exercise to his maximum capability. Parents are cautioned not to overprotect the child. Electrocardiographic electrodes are placed in the usual positions for monitoring during exercise, and leads are attached. All of the electrode and lead apparatus is then covered with a tightly fitting mesh shirt to reduce motion artifact from the leads during exercise (Fig. 49–2). A baseline electrocardiogram is measured with the patient standing on the treadmill and is assessed for rhythm, heart rate, and morphologic features. The baseline parameters for ST segment, QT interval, QRS duration, and PR interval are detemined. A sphygmomanometer or automated blood pressure device is attached to the arm, and the patient is instructed in the operation of the treadmill. The child is shown that the treadmill will increase in speed and in grade and is told that this will take place at various points during the exercise study, and that a maximal effort is expected. The patient is taught how to hold the mouthpiece tight in the mouth. Then baseline measures of oxygen consumption, carbon dioxide production, minute ventilation, and cardiac output are obtained with the output measured by the acetylene rebreathing method (Fig. 49–3). The modified Bruce protocol is usually selected, and when the physician in attendance feels it is appropriate to begin, the test is started. During each phase of exercise, the patient is carefully observed, asked to comment on how he feels, and instructed to report any sensations of chest pain or dizziness. If such events are

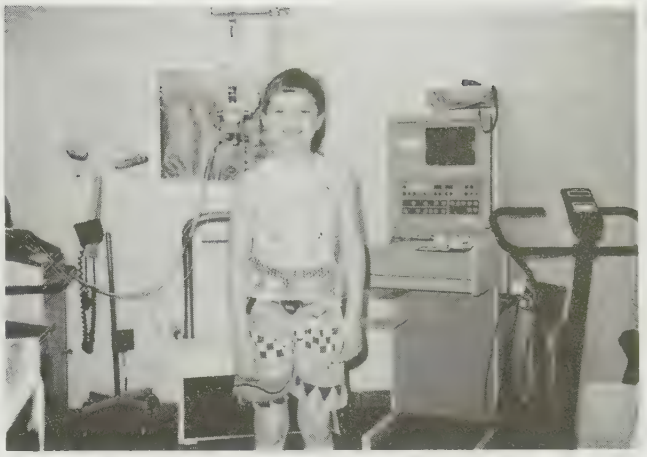

Fig. 49–2. Photograph of a patient on the treadmill illustrating the electrocardiographic electrode placement with the leads held in place by a mesh shirt to reduce motion artifact.

reported and yet there are no signs of any electrocardiographic changes or blood pressure variability, the physician may allow the test to continue. In especially anxious and small children who are not used to sustained exercise, there are commonly complaints of leg fatigue. The patient is encouraged to exercise through these levels of discomfort as long as all other parameters are stable.

If on-line oxygen consumption measures are available, the patient is encouraged to exercise until he is well in the normal range for maximal oxygen consumption for the laboratory. If those parameters are not being measured, the patient is encouraged to exercise to his maximum voluntary effort. A simple way to detect maximal effort is to ask the patient to respond to simple questions. If he is clearly able to take time to speak, then more exercise can be performed. If the child is so engaged with effort that he is unable to speak clearly, this is interpreted as a maximal effort. Cardiac output is measured at what is judged to be midexercise and at the point of maximal exercise.

When it has been determined that the patient can do no more

Fig. 49–3. Photograph of a patient on the treadmill with his mouth tightly around the mouthpiece. For measurement of cardiac output by acetylene rebreathing, breathing is diverted via the valving device into the prefilled bags (white) for 20 seconds.

Table 49–4. Normal Exercise Data in Girls 8 to 12 Years in Age*

	Resting	*Mid Exercise*	*Maximal Exercise*
Heart rate/minute	102.6 ± 16.5 (n=28)	155.6 ± 14.1 (n=28)	194.3 ± 11.7) (n=28)
Blood pressure (mmHg) Systolic	105.4 ± 9.50 (n=28)	120.6 ± 13.3 (n=25)	135.6 ± 13.5 (n=20)
Diastolic	73.0 ± 6.40 (n=26)	74.1 ± 9.90 (n=25)	71.3 ± 10.7 (n=17)
Oxygen consumption (L/min)	0.437 ± 0.23 (n=28)	1.00 ± 0.22 (n=28)	1.29 ± 0.26 (n=26)
Carbon dioxide production (L/min)	0.377 ± 0.18 (n=28)	0.902 ± 0.22 (n=27)	1.28 ± 0.27 (n=26)
Minute ventilation, expiratory (L/min)	12.7 ± 5.05 (n=28)	25.4 ± 6.83 (n=28)	38.9 ± 10.8 (n=26)
Effective pulmonary blood flow, C2H2 (L/min)	3.29 ± 1.32 (n=26)	6.04 ± 1.45 (n=25)	7.87 ± 1.83 (n=22)

*Twenty-eight girls were tested. The average was 10.55 ± 1.00 years; the average weight was 38.64 ± 9.98 kg; and the average standing height was 124.74 ± 9.18 cm.

exercise, the study is terminated by slowing the treatmill gradually and decreasing the grade. Exercise is never stopped abruptly. To avoid peripheral venous pooling and syncope, a recovery period with a slow walk is required for at least 2 min before the patient is allowed to sit. Blood pressure is measured at 1-min intervals during the recovery period, and the electrocardiogram is monitored to observe for signs of arrhythmia or ischemia. The patient is not detached from any of the electrocardiographic or blood pressure apparatus for at least 5 min, or until he has reached within 20% of baseline levels of heart rate and blood pressure.

The criteria for ending an exercise test should be determined before the test is begun. The physician in charge should be familiar with all aspects of the patient's history, diagnosis, and indications for the study. There are certain criteria for premaximal termination that should always be observed. The onset of ventricular tachycardia, defined as three or more consecutive premature beats, should be reason to terminate the test. Exercise-induced hypotension when the systolic blood pressure falls 10 mm Hg or more with an increasing load is another predictor of falling cardiac output. Patients receiving beta-blockers may have an early plateau of heart rate and blood pressure, but even these patients should not have a 10 mm Hg fall in systolic blood pressure. ST-T wave segment depression of 2 mm or more below baseline is caused by ischemia. If these changes are progressive and certainly if accompanied by symptoms such as chest pain or lightheadedness, the test should be terminated. A "maximal" test is one to exhaustion. For pediatric subjects, the heart rate should exceed 180 beats/min and often will approach or even exceed 200 beats/min. The respiratory quotient should attain or exceed 1.0 if metabolic parameters are measured.

Following the study, the data are carefully analyzed, the results are compared to the known tables for the laboratory (Tables 49–4 and 49–5), and a formal report is prepared by the exercise technologist and referring cardiologist.

The incidence of exercise test complications is low even in centers where most patients are being evaluated for heart disease and arrhythmia. In over 2000 consecutive pediatric stress tests at Children's Hospital National Medical Center, there have been no

Table 49–5. Normal Exercise Data in Boys 8 to 12 Years in Age*

	Resting	*Mid Exercise*	*Maximal Exercise*
Heart rate/minute	95.5 ± 13.2 (n=44)	147.6 ± 8.70 (n=44)	185.4 ± 11.2 (n=44)
Blood pressure (mmHg) Systolic	105 ± 7.80 (n=41)	125 ± 14.8 (n=39)	134 ± 16.1 (n=33)
Diastolic	73.1 ± 8.70 (n=40)	66.4 ± 7.20 (n=33)	66.1 ± 8.90 (n=28)
Oxygen consumption (L/min)	0.302 ± (n=43)	1.17 ± 0.314 (n=44)	1.61 ± 8.90 (n=28) (n=39)
Carbon dioxide production (L/min)	0.250 ± 0.07 (n=43)	1.01 ± 0.311 (n=44)	1.55 ± 0.54 (n=39)
Minute ventilation, expiratory (L/min)	9.42 ± 3.3 (n=43)	27.7 ± 7.13 (n=44)	43.84 ± 14.1 (n=39)
Effective pulmonary blood flow, C2H2 (L/min)	3.85 ± 1.23 (n=41)	7.17 ± 2.52 (n=39)	9.08 ± 3.3 (n=34)

*Forty-four boys were tested. The average age was 10.53 ± 1.68 years; the average weight was 37.71 ± 11.40 kg; and the average standing height was 143.82 ± 12.95 cm.

deaths associated with the studies. Three patients have had ventricular tachycardia causing syncope. All were successfully treated in the exercise laboratory with control of their arrhythmia.

Exercise testing is a relatively new tool in the field of pediatric cardiology but one of increasing importance. It is useful not only in assisting physicians to make the diagnosis of heart disease, but it is the one discipline that allows for a total assessment of the patient's cardiopulmonary status during activity when many postoperative problems become apparent. Future work in exercise testing will draw upon many other diagnostic disciplines and will add to the available knowledge of the child with heart disease during the active portion of his life.

CHAPTER 50

Nuclear Cardiology

Henry B Wiles

Blumgart, Weiss, and Yens introduced clinical nuclear cardiology in 1927 with their elegant studies on the velocity of blood flow.[1,2] They measured the circulation time from the right arm to the left arm using injections of radium C and a cloud chamber detector. Prinzmetal et al.[3] described the radiocardiogram, a time-activity curve of a radionuclide traversing the cardiac chambers. Goldring et al.[4] reported the results of 100 radiocardiograms in children with congenital heart disease. Improvements in radiopharmaceuticals and detection instruments, especially the Anger camera (see Chapter 36), led to the report by Van Dyke et al.[5] of "quantitative radioisotope angiocardiography." Further developments in pharmaceuticals, instruments, and computers during the 1970s have established nuclear cardiology as an important tool in the diagnosis and management of patients with cardiovascular disease.[6–8]

Although nuclear techniques are widely used in adult cardiovascular medicine, pediatric cardiologists have limited experience with these techniques. Nuclear cardiology is a physiologic modality that gives information on ventricular function, myocardial perfusion, and myocardial integrity. A study performed with a radionuclide is a physiologic study, not an anatomic study. Students of cardiovascular medicine are often confused by scintigraphic images because they try to visualize anatomic structures and details. An attempt to visualize a scintigraphic study as a "physiologic picture," as one would visualize a "Doppler picture," will increase the understanding and use of nuclear cardiology techniques.

Today the success of therapy for children with heart disease is measured not only in terms of survival or lifestyle, but also in terms of myocardial function and preservation; therefore, nuclear cardiology is important in the evaluation and management of children with heart disease. Pediatric nuclear cardiology is not simply determination of shunt flow; it is the evaluation of global and regional myocardial integrity.[9–12] A nuclear cardiology study is noninvasive and repeatable on an outpatient basis for serial evaluation.

This chapter presents the current techniques and indications for pediatric nuclear cardiology investigations. There are six types of studies available for the child with heart disease.

1. Blood pool imaging, usually done with technetium-99m (^{99m}Tc), gives information on right ventricular and left ventricular function.
2. Myocardial perfusion imaging with thallium-201 (^{201}Tl) investigates myocardial perfusion.
3. Infarct-avid myocardial scintigraphy, using ^{99m}Tc pyrophosphate, localizes recent myocardial infarction.
4. Tracer flow imaging, again using ^{99m}Tc, allows evaluation of blood flow patterns and velocities, including determination of left-to-right shunt flow.
5. Vascular perfusion imaging, using ^{99m}Tc labeled to macroaggregated albumin (MAA), qualitates organ blood perfusion, such as lung perfusion or determination of right-to-left shunts.
6. Inflammatory disease imaging, using white blood cells labeled with gallium-67 (^{67}Ga) or indium-111 (^{111}In), detects myocardial or pericardial inflammation.

BLOOD POOL IMAGING

Blood pool imaging assesses cardiac performance. Ventricular function is assessed by evaluation of wall motion, global and

regional ejection fraction, absolute volume, cardiac output, phase analysis, filling time, and regurgitant fraction. All of these parameters are available at rest and at peak exercise stress. Determination of volume and ejection fraction is based on the count density of radioactivity and not based on geometric assumptions. This count-based method of quantitation is theoretically superior to geometric models.

Two methods for blood pool radionuclide angiocardiography (RNA) are equilibrium studies, known as multiple gated acquisition (MUGA), and first-pass studies. Each method has advantages for both adults and children, while some advantages are unique to children. Either method alone is adequate for RNA assessment of heart disease, but ideally, both methods should be available in order to provide the maximum evaluation of children. Table 50–1 lists the advantages of each method. The main advantages of first-pass RNA in children are temporal separation of small structures (especially important for right ventricular assessment), shunt quantitation, and lower radiation dose with development of short-lived radionuclides.

EQUILIBRIUM RADIONUCLIDE ANGIOCARDIOGRAPHY

Technique

Technetium-99m bound to either albumin or red blood cells (RBCs) is used for equilibrium RNA. Both in vivo[13] and in vitro[14] methods are available for binding ^{99m}Tc to the patient's RBCs. The in vitro method requires removing a small sample of blood from the patient, attaching ^{99m}Tc to the RBCs using a commercially available kit, and injecting the labeled blood back into the patient. The in vivo method requires an injection of stannous pyrophosphate (tin) to form an RBC-pyrophosphate complex. The dose of stannous pyrophosphate is based on the patient's weight (Table 50–2), with a maximum adult dose of 3.5 mg. Fifteen to twenty minutes later, ^{99m}Tc is injected through the same intravenous line. The dose of ^{99m}Tc is again calculated according to the patient's weight (Table 50–2). A full adult dose is 25 to 35 millicuries (mCi). The in vitro method is slightly more efficient at labeling RBCs, but the in vivo method is easier and safer: there is no chance of injecting blood clots or the wrong blood specimen.

Table 50–1. Advantages of Equilibrium and First-Pass Blood Pool Methods

Equilibrium
Radionuclide bolus not important
Any vein used for injection
Multiple views from one injection
Camera easy to position
Data available for hours (exercise, intervention)
Conventional Anger camera used
Better spatial resolution
Short processing time (5 to 20 min)
Phase analysis
Left ventricular volumes more reliable
First-Pass
Short acquisition time: patient cooperation, exercise staging
Temporal separation of structures in all views
Right ventricular performance assessment
Higher photon flux for better statistical accuracy
Real-time tracer flow analysis
Shunt detection and quantification
Individual heart beats analyzed

Table 50–2. Dosage Schedule Based on Patient Weight

Weight (kg)	*Multiplier for Adult Dose*

Imaging the cardiac chambers requires a conventional Anger camera with a standard field-of-view crystal (approximately 10 in. in diameter). A large field-of-view camera (20 in.) may be necessary for studies that include both lung fields. A general purpose parallel hole collimator, with or without slants (see Chapter 36, Fig. 36–11), is used for most studies. The slant hole collimator can improve left atrial–left ventricular separation. An infant with a small heart may require a pinhole collimator (Fig. 50–1) to enlarge the structures for accurate measurements.[15] A pinhole collimator has low sensitivity and requires a long acquisition time of 6 to 8 min. Patient cooperation during this acquisition is extremely important since motion artifact is magnified.

A gating mechanism using the patient's R wave is necessary to acquire an equilibrium study. A computer divides the cardiac cycle (R wave to R wave) into nearly equal segments; the number of segments (generally 16 to 30) depends on the software supplied with the camera. The R wave triggers the camera, opens the "gates," and begins acquisition. The computer stores all radiation events occurring within each segment of the cardiac cycle. All counts recorded in the first segment of all triggered cardiac cycles are combined into one picture (Fig. 50–2). Likewise, all counts in segments 2,3,...N are added into one picture for that segment. The final "representative" cardiac cycle is a composite of several hundred heart beats. The number of heart beats used to make the composite picture can be based on time (e.g., 2½ minute acquisition), count density (acquisition continues until a predetermined number of counts are recorded), or simply a predetermined number of beats. An R-to-R interval that varies by greater than 10 to 20% is rejected by the computer. Any cardiac rhythm that has a widely varying R-to-R interval, e.g., bigeminy, makes gated equilibrium studies difficult or impossible. In this situation, list mode acqui-

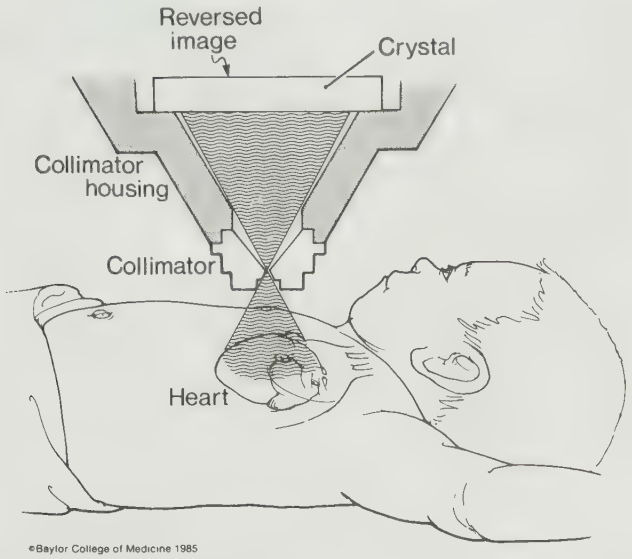

Fig. 50–1. A pinhole collimator magnifies small structures with a minimum of distortion. The small heart of an infant is often best imaged with this collimator. Since there is only one hole for gamma rays to enter, long acquisition times are required. Patient cooperation often requires mild sedation.

sition can be used to analyze individual, operator-determined heart beats.

Images are usually obtained in the anterior, 45° left anterior oblique (LAO), and 70° left anterior oblique positions. The anterior view shows the apex and anterolateral walls of the left ventricle. The 45° LAO view usually provides the best separation of right and left ventricles. The septal, inferoapical, and inferolateral walls are seen on this view. Children with complex congenital heart disease often require individualization of this view to maximize ventricular and atrial separation. The 70° LAO projection brings the inferior and anterolateral walls into view.

The data collected during an equilibrium study are stored in frame mode or list mode by a dedicated computer. Disk storage is helpful in a large center since studies can be analyzed at a different work station while additional studies are collected. The disk storage can then serve as an archival system for later retrieval of records.

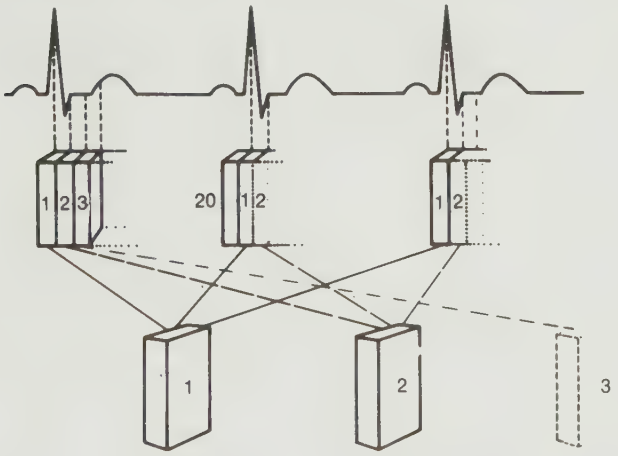

Fig. 50–2. A multiple gated acquisition (MUGA) study requires equilibrium of the radionuclide throughout the blood pool and a constant R-to-R interval. All radiation events in frames 1,2,...*N* are added into one "composite" image. This image is sequenced with subsequent "composite" images to form a representative cardiac cycle. The first frame is triggered by each successive R wave. (Holman, B.L., and Parker, J.A.: Computer Assisted Cardiac Nuclear Medicine. Boston, Little, Brown, 1981. Reprinted with permission.)

Functional Assessment

Ejection Fraction

The data collected during an equilibrium RNA study are manipulated by a computer program with operator intervention. Frames representing end diastole and end systole are examined separately by drawing regions of interest (ROI) around the ventricle (Figs. 50–3 and 50–4). Total radiation counts in the defined ROI are calculated after appropriate background subtraction. Ejection fraction (EF) is determined by:

$$EF = \frac{EDC - ESC}{EDC}$$

where EDC = end-diastolic counts
ESC = end-systolic counts
EF = ejection fraction

(Eq. 50–1)

Normal resting adult left ventricular ejection fraction (LVEF) is considered to be 55% or greater.[16,17] Normal children generally have a higher ejection fraction[18,19] (Table 50–3). Normal exercise

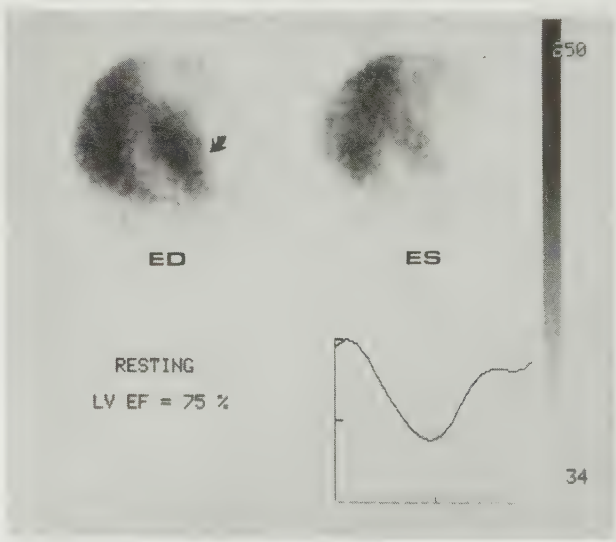

Fig. 50–3. A resting equilibrium blood pool study. The arrow indicates the left ventricle in the 45° left anterior oblique view. The ejection fraction is normal at 75%. The time–activity curve (lower right corner) from a left ventricular region of interest graphs the changing count density. The slope of this curve indicates changing volume versus time (dV/dt). ED = end diastole, ES = end systole, LVEF = left ventricular ejection fraction.

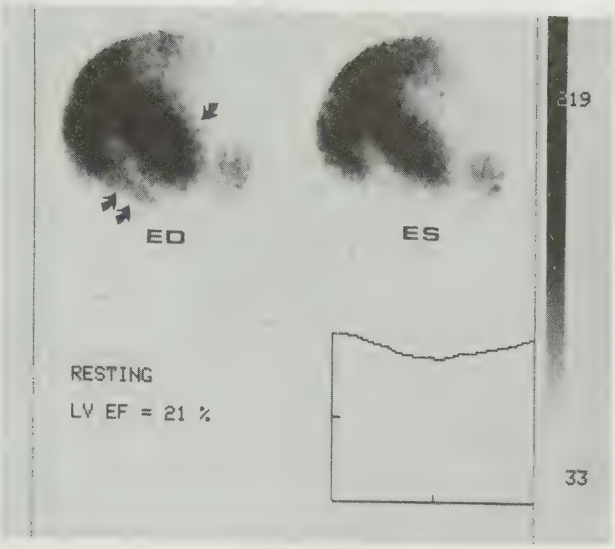

Fig. 50–4. A resting equilibrium blood pool study in a patient with dilated cardiomyopathy. The single arrow indicates a dilated left ventricle with poor contractility. The resting ejection fraction is decreased to 21%. Note that the right ventricle (double arrows) has well-preserved function. The time–activity curve (lower right corner) shows decreased ejection counts and decreased slope (dV/dt).

EF should increase by five or more ejection fraction points (e.g., 60% at rest to 65% at peak stress). Failure to increase EF with exercise (''flat response'') is mildly abnormal, and a decrease in EF is clearly abnormal.

The accuracy and reproducibility of equilibrium RNA-determined ejection fraction is well established.[20] Correlation coefficients between RNA and contrast ventriculography EF range from 0.84 to 0.93.[8,16,21–26] Intraobserver and interobserver variability is minimal[16] and less than that found with contrast ventriculography.[27] Validation of RNA-determined left ventricular (LV) and right ventricular (RV) ejection fraction in children was established by Parrish et al.[28] Correlation coefficients were 0.90 and 0.83, respectively.

Regional EF and ''first-third'' EF (percent of counts ejected in the first third of systole) may be more sensitive predictors of ventricular function than global EF.[29,30] Regional EF has been shown to correlate with regional abnormalities seen with contrast angiocardiography.[31] Since coronary arterial supply to the myocardium is regional, evaluation of regional EF may be more sensitive than global EF for ischemia. Regional EF has not been proven clinically useful in children with heart disease, but evaluation of diseases with possible regional myocardial ischemia (e.g., Kawasaki disease and anomalous left coronary artery from the pulmonary artery) may prove useful. First-third EF is best determined by first-pass RNA. Right ventricular EF can be determined by equilibrium RNA,[24,26,32,33] but overlying structures produce less accurate results. First-pass RNA is the preferred method in our laboratory for RVEF determination.

Table 50–3. Mean RVEF and LVEF in Children[19]

Age (yr)	*RVEF (+SD)*	*LVEF (+SD)*
<1	0.54±0.09	0.68±0.13
1–5	0.53±0.07	0.62±0.09
6–10	0.52±0.05	0.69±0.08
11–15	0.54±0.03	0.65±0.09
16–20	0.53±0.06	0.70±0.08

Cardiac Output

Absolute end-diastolic volume and end-systolic volume are calculated from the count density in the left ventricular ROI when compared to the count density in venous blood. The theoretical basis for this comparison is that the known concentration (count density) of radioactivity in venous blood must be proportional to the concentration and volume of blood in the ventricle. Cardiac output is determined by multiplying stroke volume (end-diastolic volume minus end-systolic volume) and heart rate. Validation of equilibrium RNA determined ventricular volumes and cardiac output has been established when compared to contrast angiocardiography,[34–36] thermodilution techniques,[37] and Fick cardiac output measurements.[38,39] This method is also validated for evaluation of right ventricular volumes in children,[40] during exercise,[38,39] and with pharmacologic intervention.[37,38]

Wall Motion

Visual inspection of a cine-like continuous loop image is important in the evaluation of ventricular function. Global and regional wall motion abnormalities are appreciated at rest and during exercise.[41,42] Anterior, 45° LAO, and 70° LAO views are evaluated at rest, and 45° LAO views evaluated at peak stress. The screen used for visual inspection should have adequate contrast and brightness controls to maximize edge detection. A finger or pointer placed at the ventricular edge often helps determine whether there is significant wall motion abnormality. Hypokinesis means the wall excursion is less than normal, akinesis means no wall excursion is detectable, and dyskinesis means wall excursion is opposite of the normal pattern. Visual wall motion evaluation is subjective and should be combined with quantitative evaluation (e.g., ejection fraction or cardiac output).

End-Systolic Pressure/Volume Loops

The use of end-systolic pressure and end-systolic LV volume is considered the best method of assessing myocardial contractility independent of preload and afterload conditions.[43] Pressure/volume loops generated from absolute ventricular volumes using equilibrium RNA studies have been shown to correlate with contrast cineangiocardiographic determinations at rest, during exercise, and with drug interventions.[44–46] A major problem with producing accurate pressure/volume loops is determination of end-systolic pressure. This technique may be most applicable to children in an intensive care environment where an arterial monitoring line is in place. Therapeutic effects on contractility can be monitored serially in children after open heart surgery or in children who are critically ill.

Filling and Ejection Times

The rate of volume change versus time (dV/dt) has been suggested as a useful measure of systolic and diastolic ventricular function[41] (see Fig. 50–3). Equilibrium RNA can provide these variables from the slope of the time–activity curve. The time to peak ejection or filling and the rate of peak ejection or filling are easily calculated. The peak ejection and filling rates are standard-

ized by relating them to end-diastolic volume. Thus, rates are expressed as end-diastolic volumes per sec (EDV/sec). Bonow et al.[47] documented abnormal peak filling rates of < 2.5 EDV/sec in 91% of 231 patients with coronary artery disease. The clinical role of systolic and diastolic filling rates in children remains to be investigated.

Regurgitant Fraction

The degree of valvular regurgitation is determined by comparing the number of counts ejected from the LV (stroke counts) to the number of counts ejected from the RV. Stroke counts are determined by subtracting end-systolic counts from end-diastolic counts. The stroke count ratio is

$$SCR = \frac{LVSC}{RVSC}$$

where SCR = stroke count ratio
LVSC = left ventricular stroke count
RVSC = right ventricular stroke count

(Eq. 50–2)

For aortic and mitral regurgitation, the SCR will be large and for tricuspid and pulmonic regurgitation, the SCR will be small. The severity of aortic and mitral regurgitation has been validated in children by this method,[48,49] as has tricuspid regurgitation in children and adults.[49,50] The range for the SCR in children without valvular regurgitation is wide: 0.70 to 1.38.[49]

Phase Analysis

The time-activity curve generated from an equilibrium RNA study approximates a sine wave. Phase analysis, using Fourier transformation of time-activity curves for each pixel within a ROI, gives onset and timing of pixel-by-pixel ejection. Since regional ejection of blood must be preceded by electrical activation, phase analysis of ejection time approximates onset of electrical activation. Using list mode acquisition techniques to eliminate any irregular R to R intervals, phase analysis activation sequences have been used to evaluate accessory bypass connections in Wolff-Parkinson-White syndrome,[51,52] right and left bundle branch block,[53] ventricular tachycardia,[54] RV dysfunction after tetralogy of Fallot repair,[55] and coronary artery disease.[56] This technique requires considerable computer power and time.

FIRST-PASS RADIONUCLIDE ANGIOCARDIOGRAPHY

Technique

First-pass RNA differs from equilibrium RNA in that the radiotracer is imaged only during the first transit through the cardiac chambers and central vessels (Fig. 50–5). Imaging the first transit produces temporal separation of right and left sides of the heart, making assessment of the right ventricle more accurate. The problem of right atrial and right ventricular separation still exists, but the camera can be positioned in a slight right anterior oblique (RAO) position to maximize separation. Another major difference afforded by first transit imaging is the short acquisition time. Ventricular function is evaluated on a beat-by-beat basis. For example, peak exercise ventricular function is measured at peak exercise, not as an average of the last 2 to 3 min. of exercise obtained with stress equilibrium RNA. Disadvantages of first-pass RNA include bolus integrity, injection technique, special camera and software requirements, and unnecessary radiation exposure with relatively long-lived radiotracers (i.e., ^{99m}Tc with a half-life of 6 hours).

The bolus of radionuclide must reach the cardiac chambers in a compact form to produce statistical accuracy. This is achieved by rapidly flushing the radiopharmaceutical through a large-bore needle or catheter positioned in a relatively large vein. The best veins for use are either the external jugular vein or the right antecubital vein. Hand, leg, and left antecubital veins are generally too distal from the cardiac chambers to assure a compact bolus. Distal veins also branch during their course to the heart, resulting in a fragmented bolus. The patient should breathe quietly during the injection since a Valsalva maneuver or crying often causes the bolus to "hang up" and produce a fragmented bolus. Bolus integrity is analyzed by placing a ROI over the right superior vena cava and evaluating the time-activity curve. The bolus should be approximately 0.5 sec or less in duration. Deconvolution analysis is a mathematical method of improving the statistical accuracy of a prolonged or fragmented bolus.[57,58]

The radiopharmaceutical used for first-pass RNA is ^{99m}Tc as sodium pertechnetate or ^{99m}Tc-labeled tracers. The use of ^{99m}Tc pertechnetate requires premedication with perchlorate to block excessive uptake of ^{99m}Tc in the thyroid, salivary glands, and stomach. The dose of ^{99m}Tc pertechnetate is 15 to 20 mCi for a patient weighing 70 kg or more. A child's dose is based on body weight and calculated from Table 50–2, with a minimum dose of 2 to 3 mCi. Technetium-99m has a half-life of 6 hours and will often not disappear from the body before another first-pass is necessary (e.g., during an exercise test). Repeat studies require correction for increased background activity that reduces statistical accuracy (see Chapter 36). Labeling ^{99m}Tc to diethylenetriamine pentaacetic acid (DTPA) or sulfur colloid helps facilitate removal of the radiotracer from the blood pool by increasing urinary excretion or increasing uptake in the liver and spleen. Injection of in vitro ^{99m}Tc-labeled RBCs or in vivo labeling after stannous pyrophosphate (see previous section on equilibrium RNA techniques) can be used for a first-pass study followed by a standard gated equilibrium study.

An ideal radionuclide for first-pass RNA should have a short half-life since imaging is acquired for only 20 to 40 sec. A short-half-life radionuclide has the advantages of decreased radiation dose to the patient and rapid disappearance from the body resulting in decreased background activity. Radionuclides currently under development are gold-195m ($T_{1/2}$, 30 sec), iridium-191m ($T_{1/2}$, 5 sec), and tantalum-178 ($T_{1/2}$, 9 min) (see Chapter 36). Perhaps the most promising of these radionuclides is ^{178}Ta, since the 9-min half-life makes it easy to work with, gated equilibrium studies can be performed after each injection, and production costs are favorable. The last section in this chapter, Future Directions, provides more information on these radionuclides.

The gamma camera is usually positioned in a 20 to 30° RAO or anterior position. Acquisition occurs for 20 to 40 sec with a rate of 10 to 40 msec per frame. Data are recorded event by event or by list mode and reformatted or regrouped by the computer for visual and analytical analysis. Regions of interest are placed over the superior vena cava for bolus analysis, RV and LV for function analysis, and lungs for shunt analysis. The best method for back-

The radionuclide bolus is seen traversing the right subclavian vein, right superior vena cava, right atrium, right ventricle, lungs, and left ventricle. Operator-defined regions of interest are outlined for analysis. This study demonstrated a normal Q_p/Q_s (1.06/1).

ground subtraction for LV analysis is not known, but a paraventricular region from a representative cycle is adequate.[59]

Functional Assessment

Ejection Fraction

Ejection fraction is calculated in a similar way to equilibrium RNA. Regions of interest are placed around the RV and LV, being careful not to include atria or great vessels (Fig. 50–6). End-diastolic and end-systolic counts are used for calculating the EF (see Eq. 50–1). Validation studies have documented excellent correlation with contrast cineangiography.[18,36] Normal ejection fractions in children were reported by Hurwitz et al. (see Table 50–3).[19] First-third EF may be more sensitive for detecting ventricular dysfunction caused by coronary artery disease.[37] Whether this is true for ventricular dysfunction caused by congenital heart disease is unknown.

Cardiac Output

Cardiac output determination with first-pass RNA requires that the radiotracer reach equilibrium after the first transit through the heart. Though good correlation has been found with the Fick method ($r = 0.88$),[60] equilibrium RNA-determined absolute volumes and cardiac outputs are more reliable.

Wall Motion

Visual inspection of wall motion from individual or combined beats is used for wall motion analysis. The number of counts recorded during first-pass RNA is lower than the total counts from equilibrium studies, so wall motion, especially LV wall motion, is less well defined.

Filling and Ejection Times

Calculation of the peak filling and ejection times is easily done from first pass RNA. The methodology and indications are the same as for equilibrium studies.

Regurgitant fraction and end-systolic pressure volume loops require forward stroke counts and absolute volumes. Calculations of these parameters from first-pass RNA requires many assumptions. They are best determined from equilibrium studies. Phase analysis for accurate activation sequencing also requires the statistical accuracy of equilibrium data.

Clinical Indications

The clinical indication for any blood pool RNA study is a need to know global and regional ventricular function with or without the stress of exercise. Ventricular function may be normal at rest but have limited reserve when challenged with the demands of exercise. Both equilibrium and first-pass RNA are well suited for stress studies. This advantage is in contrast to echocardiographic evaluation of ventricular function, which is technically difficult during exercise. Furthermore, echocardiographic evaluations of RV function and ventricular volumes are based on geometric assumptions, whereas RNA studies are based on count densities.

Acquired and congenital heart disease in children, including volume and pressure overload, decreased myocardial perfusion,

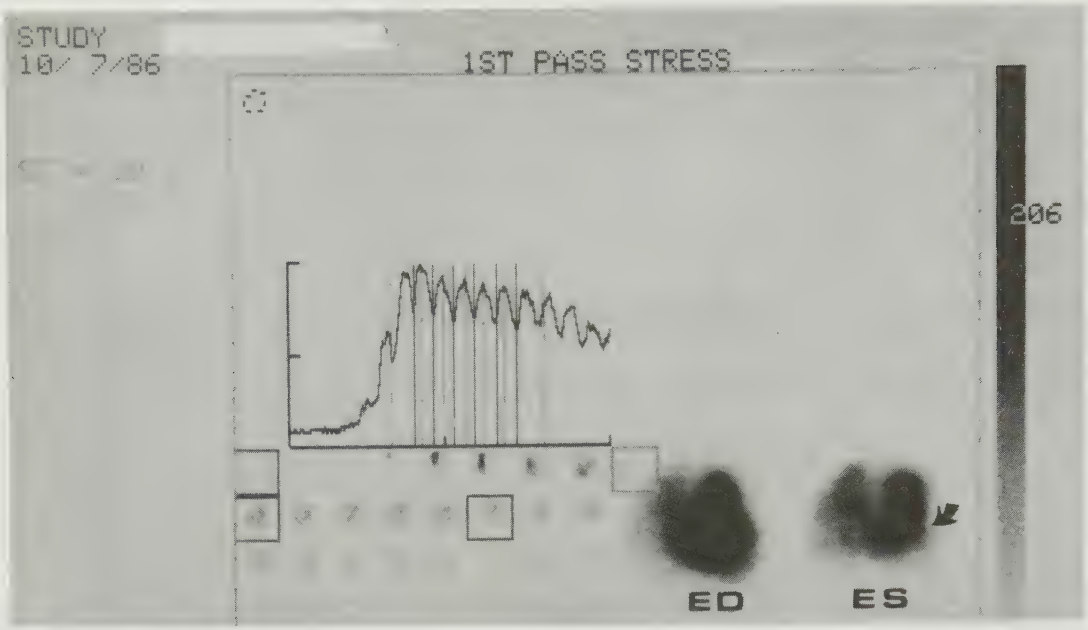

Fig. 50–6. A first-pass blood pool study during exercise stress in a patient status post tetralogy of Fallot repair. The arrow indicates the right ventricle, which has a dilated pericardial patch in the outflow tract. Right ventricular function is abnormal with an exercise ejection fraction of 29%. The time–activity curve (middle left) shows the count density in the right ventricle for each imaged heart beat. ED = end diastole, ES = end systole, EF = ejection fraction.

metabolic disturbance, cardiomyopathy, pericardial disease, systemic hypoxemia, surgical injury, and conduction disturbance, may affect ventricular function. Every child with heart disease has one or more of these features and may be an appropriate candidate for a nuclear cardiology study. Appropriate selection of patient and nuclear test requires a knowledge of the physiology of heart disease and experience with nuclear medicine compared to other modalities.

Volume Overload

Volume overload of a ventricle causes increased myocardial work, myocardial hypertrophy, and metabolic changes. Severe volume overload, especially long-standing overload, will affect ventricular function. Both RNA techniques are excellent tools for evaluating this decreased function. Since RNA may be done with exercise, this test may be a more sensitive indicator of myocardial dysfunction than either echocardiography or catheterization. Hurwitz et al.[48] showed that children with aortic or mitral regurgitation can be classified into groups with mild, moderate, and severe regurgitation and that these groups were similar to those determined by invasive means. Parrish et al.[49] further validated RNA stroke count evaluation of volume overload when compared to cineangiographic stroke volume ratios ($r = 0.88$). They concluded that RNA is an excellent tool for qualitative and quantitative assessment of valvular regurgitation in children.

Clinical Case: R.P. was a 12-year-old male with aortic regurgitation and occasional premature ventricular contractions (PVC). Echocardiography showed a moderately enlarged LV end-diastolic diameter with low-normal shortening fraction at rest. He was asymptomatic. PVCs persisted despite treatment with phenytoin. A rest-stress equilibrium RNA evaluation showed low-normal LV function at rest but a significantly abnormal response to exercise with a decreased ejection fraction. He underwent aortic valve replacement with subsequent elimination of his PVCs. The RNA test was instrumental in recommending valve replacement in this preadolescent male.

Adults with persistent small ventricular septal defects (VSD) ($Q_p/Q_s < 2:1$), surgically closed VSDs, and Eisenmenger's complex show abnormal LV function with exercise.[61] Furthermore, those patients with surgically closed VSDs had resting LV function significantly different from normal controls. Adults with VSDs and atrial septal defects (ASD) have altered mechanisms for augmenting cardiac output during exercise.[62] These findings from RNA investigations show that successful therapy for congenital heart disease may not result in a "normal" cardiovascular system. The clinical significance of these findings requires further investigation.

Nishioka et al.[63] found LV dysfunction (increased end-diastolic volume and decreased ejection fraction) in preoperative patients with tricuspid atresia. Other investigators have found persistent LV dysfunction after the Fontan procedure,[64] however, Peterson et al.[65] found a significant increase in cardiac output after the Fontan procedure. RNA evaluation of LV function after the Fontan procedure is useful in evaluating the results of surgery. The usefulness of RNA evaluation before surgery to help determine the appropriate age for the Fontan proecedure (based upon LV function) is yet to be answered.

Pressure Overload

Evaluation of LV function in the presence of pressure overload due to left-sided obstruction usually shows normal or above normal indices. The value of RNA in this setting is limited. The evaluation of a pressure overloaded RV, however, is quite useful. RNA evaluation after intra-atrial repair of d-transposition of the great arteries shows a high incidence of ventricular dysfunction. Murphy et al.[66]

showed 11 of 26 patients had abnormal RVEF or LVEF at rest while 18 of 26 had abnormal responses to exercise. In addition, Parrish et al.[67] found abnormal RV response to exercise in 6 of 11 patients and abnormal LV response in 10 of 11. Assessment of the RV in patients with congenitally corrected transposition of the great arteries (l-TGA) also showed abnormal responses to exercise in 5 of 5 patients.[67] Contrast angiographic evaluation of RV function confirmed this decreased RV function, especially in older patients with l-TGA.[68]

The results of total surgical correction of tetralogy of Fallot are generally excellent. A small group of patients, however, remain at risk for significant morbidity or mortality, probably related to ventricular arrhythmias. Identifying the entire group at risk is not yet possible. RV dysfunction may contribute to the late problems after tetralogy of Fallot repair. Reduto et al.[69] used first-pass RNA and found RV dysfunction with exercise in 13 of 16 patients after surgical repair. This RV dysfunction may be caused by surgical injury or persistent RV pressure overload.

Cardiomyopathy

Ventricular function is nearly always affected in patients with cardiomyopathy, regardless of the cause of the cardiomyopathy (see Fig. 50–3). RNA assessment of myocardial function in patients with cardiomyopathy is useful in the diagnosis, functional classification,[70] and followup of treatment efficacy. Idiopathic dilated cardiomyopathy has a variable degree of biventricular dysfunction that may be followed serially by RNA investigations.[71] Children with anomalous left coronary artery from the pulmonary artery have abnormal resting LVEF and may be followed for improvement after medical or surgical treatment.

The cardiomyopathy associated with the use of doxorubicin is often irreversible and requires termination of use of this drug. The cumulative dose necessary to produce cardiotoxicity is widely variable between patients. Serial evaluation of LVEF by RNA techniques has proven useful in determining the maximum cumulative dose for an individual patient.[72] A decrease of 15% or more in baseline LVEF predicts a high incidence of severe cardiotoxicity with clinical congestive heart failure. A decrease of 10 to 15% in LVEF does not usually result in congestive failure but probably warrants discontinuation of the drug. A decrease of less than 10% in LVEF predicts a low incidence of failure and allows for continuance of doxorubicin administration. Serial evaluation can also be used in patients with abnormal LVEF before beginning chemotherapy.[73] Exercise LVEF increases the sensitivity of detecting significant cardiotoxicity but decreases the specificity.[74] In children we begin using resting LVEF for detection of cardiotoxicity after a cumulative dose of 300 to 350 mg/m^2.

Conduction Disturbance

Nuclear imaging and phase analysis can detect and localize abnormal conduction pathways.[51–54] The ability to localize bypass tracts in Wolff-Parkinson-White syndrome may be an adjunct to electrophysiologic catheterization. The situation in which this localization may be most useful is in the patient with persistent supraventricular tachycardia after attempted surgical disruption of a bypass tract. The decision for early reoperation would benefit from the noninvasive localization of a persistent bypass tract.

MYOCARDIAL PERFUSION SCINTIGRAPHY

Technique

Coronary artery patency is important for the adequate supply of oxygen to the myocardium. Thallium-201, as thallous chloride, follows potassium kinetics. Uptake in myocardial cells is dependent on blood flow to and extraction by the myocardium. Canine myocardium under basal conditions extracts 88% of ^{201}Tl during the first transit.[75] Decreased accumulation of ^{201}Tl indicates underperfusion relative to other areas of myocardium. During exercise stress the coronary blood flow can increase by five- to sixfold.[76] Blood supply and oxygen delivery distal to an area of coronary stenosis may be adequate at rest but unable to meet the increased oxygen demands during exercise. A single dose of ^{201}Tl with immediate postexercise and redistribution rest imaging is capable of detecting exercise-induced myocardial ischemia.[77–79]

The patient should achieve maximum exercise during a standard treadmill exercise protocol (see Chapter 49). An intravenous line, established before the exercise test begins, is used for injection of 1.15 mCi/m^2 (minimum 0.15 mCi, maximum 3.5 mCi) of ^{201}Tl approximately one minute before anticipated maximum exercise effort. This early injection allows myocardial uptake of ^{201}Tl during peak myocardial blood flow. Planar imaging consists of three static views—anterior, 45° LAO, and 70° LAO—each lasting 3 to 5 min (Fig. 50–7). Within 10 min of exercise termination the patient is positioned under the gamma camera for myocardial imaging; this

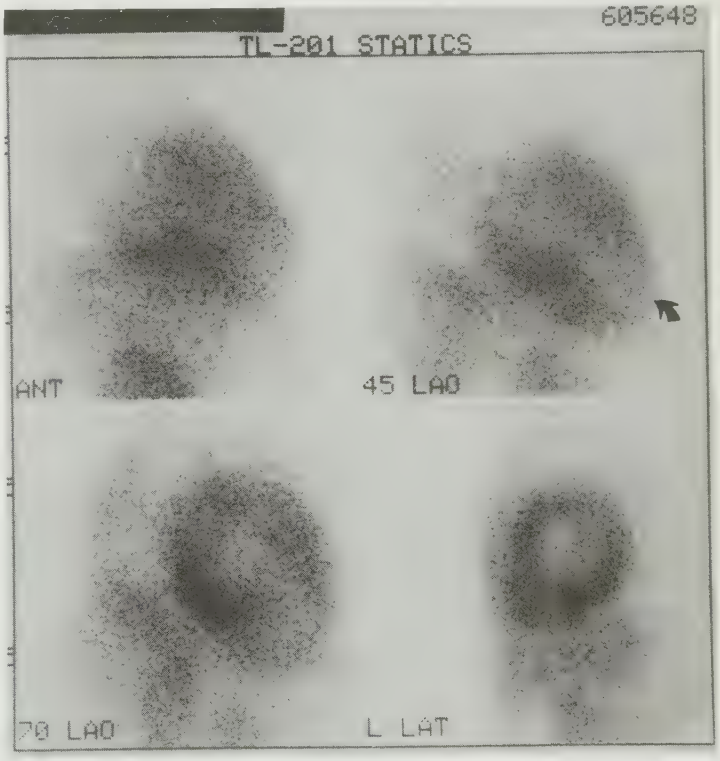

Fig. 50–7. A normal planar thallium-201 myocardial perfusion scan. Uptake is even throughout the myocardium. Note the normal decreased counts or "apical thinning" (arrow) at the left ventricular apex. Decreased counts are also normal at the mitral annulus. ANT = anterior view, LAO = left anterior oblique view, LAT = left lateral view.

image reflects the perfusion during exercise stress. Redistribution images are obtained 3 to 4 hours later in the same positions. Visual comparison of the stress and redistribution images detects relative underperfusion. A "cold spot" indicates decreased delivery of the radiotracer to that segment of myocardium. If a "cold spot" is visible on the stress image and not on the redistribution image, then stress-induced ischemia is present (Fig. 50–8). If the "cold spot" is visible on both sets of images, that region is relatively underperfused at all times and represents a scar.

Visual inspection of planar images takes considerable skill since anatomic definition is poor. This is partly due to the low energy resolution with ^{201}Tl (70 keV x-ray) (see Chapter 36) and motion of the heart during acquisition. Gating the acquisition would improve spatial resolution but make the acquisition time prohibitively long. Another method of improving the accuracy of ^{201}Tl scintigraphy is quantitative analysis of count densities in defined regions of the myocardium. Many different computer algorithms have been devised for this purpose. Quantitative analysis of count densities and washout rates generally improves the sensitivity and specificity of planar ^{201}Tl images.[80–82]

Planar imaging produces significant overlap of myocardial regions. Areas of relative underperfusion may be missed. Single photon emission computerized tomography (SPECT) produces a series of axial images, much like a CT scanner, and allows for expanded regional evaluation.[83] The gamma camera is mounted on a special gantry and rotates 180° from an RAO to LPO position. Images are obtained for approximately 25 sec at 3-sec intervals. Computer algorithms reconstruct the heart in planes aligned with the axis of the heart. Images are analogous to echocardiographic planes: parasternal long axis, parasternal short axis, and apical four-chambered views. Quantitative analysis of these images is possible with a common presentation called the "bullseye."

Thallium-201 images can be obtained at rest if the patient is unable to exercise due to age, deconditioning, or physical handicap. Resting images alone will not differentiate ischemia from a scar. Alternative methods for simulating stress-induced myocardial underperfusion have been developed using pharmacologic intervention. Intravenous dipyridamole at a dose of 0.142 mg/kg/min for 4 min is a potent coronary vasodilator, producing increases in coronary flow adequate to detect relative differences with ^{201}Tl scintigraphy.[84] This protocol is safe[85,86] and highly sensitive for detection of coronary artery stenosis.[87,88] Other methods for increasing myocardial oxygen demand include dobutamine infusion,[89] epinephrine infusion,[90] and cold pressor test.[91] We have used both dipyridamole and dobutamine infusions in infants and children who are too young to exercise. This allows utilization of the diagnostic power of ^{201}Tl imaging for detection of stress-induced myocardial ischemia. Infants and young children are sedated with chloralhydrate (50 mg/kg PO) or meperidine (2 mg/kg IM) and promethazine (1 mg/kg IM).

Clinical Indications

Myocardial perfusion scintigraphy using ^{201}Tl is indicated whenever there is a question about adequate myocardial perfusion.[92] Anomalous coronary anatomy, atherosclerotic disease, sequela of inflammatory disease (Kawasaki disease), and altered muscle func-

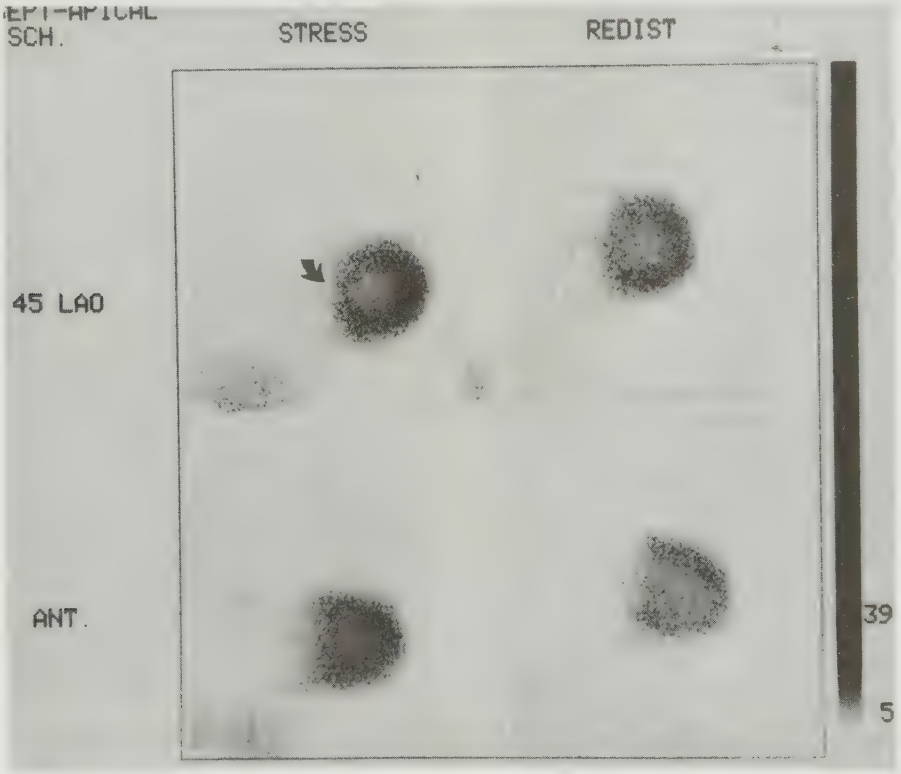

Fig. 50–8. A stress-redistribution thallium-201 myocardial scintigram showing septal ischemia and partial scar formation. The arrow indicates the septal area with decreased uptake at peak stress. With redistribution the septal area still has decreased activity compared to other areas of myocardium (scar formation) but is more homogeneous than at peak stress. LAO = left anterior oblique view, ANT = anterior view, REDIST = redistribution.

tion (cardiomyopathy and hypertrophy) can interrupt normal myocardial perfusion. The use of stress testing adds an additional dimension to myocardial perfusion scintigraphy and should be used whenever possible (see section on Techniques).

Atherosclerosis

Thallium-201 scintigraphy is widely utilized for diagnosis and management of adults with atherosclerotic coronary artery disease. Though rare in children, atherosclerosis may be accelerated in families with genetic disorders of lipid metabolism, after coronary artery aneurysms, and after cardiac transplantation. The widespread use of stress ^{201}Tl scintigraphy in children and adolescents presenting with chest pain is not indicated. Stress ^{201}Tl scintigraphy is indicated, however, in the selected young patient with severe pain, debilitating symptoms, or other physical and laboratory abnormalities of the cardiovascular system. The reassurance of a normal ^{201}Tl study may negate the need for coronary arteriography.

Anomalous Left Coronary Artery from the Pulmonary Artery (ALCA)

Patients with ALCA often present with symptoms and signs of myocardial infarction.[93] Gutgesell et al.[94] found ^{201}Tl perfusion defects in 7 of 7 children with ALCA. They also found perfusion defects in 4 of 9 children with congestive cardiomyopathy. They concluded that ^{201}Tl scintigraphy was sensitive for detecting ALCA but was not specific. They did not use any method of cardiac stress, however, and were unable to differentiate scar from ischemia. Finley et al.[95] found perfusion defects using resting ^{201}Tl images in 2 of 3 children with ALCA treated medically. Others have shown normal stress ^{201}Tl scans in patients years after surgical repair.[95,96] We have used dipyridamole and dobutamine infusions to evaluate stress and redistribution perfusion images in children with ALCA. One child had stress-induced ischemia, and one had a fixed scar. Further studies using physical or pharmacologic stress are needed to determine the best therapy for this lesion.

Kawasaki Disease

The longterm sequelae of Kawasaki disease are coronary artery aneurysm and stenosis. Approximately 1% of children with Kawasaki disease die from coronary underperfusion and myocardial infarction. Kato et al.[97] found normal resting ^{201}Tl scintigrams in children after total regression of previous aneurysms. Six of 19 children with persistently abnormal coronary angiograms had perfusion defects. Again, no method of myocardial stress was employed, and a scar was not differentiated from stress-induced ischemia.

We have applied stress to the myocardium using dipyridamole or dobutamine infusion in five asymptomatic children with coronary aneurysms.[98] Two children had stress-induced ischemia demonstrated on stress/redistribution SPECT images. One child had a fixed scar in the exact distribution of her aneurysmal coronary artery. One child had ''normal'' coronary arteries documented by angiography two years after previously demonstrated aneurysms. Her ^{201}Tl study was normal. One child with only perivascular cuffing and no aneurysm had a normal stress/redistribution study. These studies demonstrated stress-induced myocardial ischemia in certain children with coronary aneurysms who do not have evidence of coronary stenosis. One possible explanation for this finding is that the aneurysm or vessel near the aneurysm has lost the functional ability to dilate in a normal manner. The longterm prognosis for these coronary defects is uncertain.

Hypertrophy

Ventricular hypertrophy will increase ^{201}Tl uptake because of increased muscle mass and blood flow. The normal right ventricle has little or no ^{201}Tl uptake because of its thin muscular wall. Right ventricular hypertrophy due to pressure or volume overload will cause the RV to become evident on ^{201}Tl images. The clinical utility of this effect is limited. Left ventricular hypertrophy will also be evident on ^{201}Tl images. Patients with left-sided obstruction and idiopathic hypertrophic subaortic stenosis may have chest pain and ST segment depression during exercise. If these changes are due only to subendocardial ischemia, ^{201}Tl scintigraphy will not detect this perfusion defect. The resolution of ^{201}Tl images is not sufficient to differentiate subendocardial perfusion.

INFARCT-AVID MYOCARDIAL SCINTIGRAPHY

Technique

Technetium-99m stannous pyrophosphate (^{99m}Tc-PYP) localizes in irreversibly damaged myocardial tissue in a manner similar to calcium accumulation. Recent myocardial infarction can be imaged as a ''hot spot'' on ^{99m}Tc-PYP scintigrams. Technetium-99m is labeled to pyrophosphate in vitro using a commercially available kit. Injection of ^{99m}Tc-PYP is best done 48 to 72 hours after onset of infarction. Imaging with a standard gamma camera in anterior, LAO, and left lateral projections begins 3 to 6 hours after injection to allow the radiotracer to accumulate in damaged tissue.[99] Scans are graded on a 0 to 4+ scale: 0 = no tracer seen in the myocardium, 1+ = uptake less intense than rib uptake, 2+ = uptake equal to rib uptake, 3+ = uptake equal to sternal uptake, and 4+ = uptake greater than sternal uptake. Grade 2+ uptake is generally considered equivocal while 3+ and 4+ uptake are considered specific for myocardial necrosis. Free ^{99m}Tc will often label the blood pool, and one must be careful not to identify blood pool activity in the heart as a positive ^{99m}Tc-PYP scan.

Clinical Indications

Technetium-99m pyrophosphate scanning of myocardial infarction has limited use in children. Sensitivity is adequate but specificity is low. Furthermore, children rarely have acute myocardial infarction that cannot be easily diagnosed by other means. The young child or adolescent who presents with sudden, unexpected cardiac decompensation with possible acute myocardial infarction may benefit from a ^{99m}Tc-PYP scan for documentation. Identification of postoperative infarction may also be beneficial. Cardiac amyloidosis will produce positive ^{99m}Tc-PYP scans in 80 to 100% of patients with this disease.[100,101] The clinical utility of this use of ^{99m}Tc-PYP in children is unclear.

FIRST-PASS RADIONUCLIDE ANGIOCARDIOGRAPHY FOR TRACER FLOW ANALYSIS

The use of tracer flow analysis using first-pass radionuclide angiocardiography (RNA) is primarily used for left-to-right (LR) shunt detection and quantification. This use of RNA is often com-

bined with blood pool imaging for analysis of ventricular function (see section on Blood Pool Imaging).

Technique

The technique for first-pass RNA tracer flow analysis is essentially identical to the first pass technique for blood pool imaging. The frame rate during acquisition may be slower (one frame/0.5 to 1.0 sec) if ventricular functional analysis is not required. The camera must be positioned before the tracer injection so that the vascular structures of interest are imaged. Technetium-99m is the radiotracer currently used for flow studies. This radiotracer may be used alone, labeled to other chemicals for more rapid extraction from the blood pool, or labeled to red blood cells for subsequent equilibrium RNA evaluation. The new short-lived radionuclides ^{178}Ta, ^{191m}Ir, and ^{195m}Au are discussed in the section on new advances. For LR shunt studies, the gamma camera is positioned over the lungs so that primary and recirculation pulmonary flow is imaged (Fig. 50–9). Folse and Braunwald[102] devised a simple method for detecting, but not quantitating, LR shunt flow using a gamma probe over the lungs. They used a ratio of counts at peak activity (C_1) and counts at time twice of peak activity (C_2). A C_2/C_1 ratio over 0.34 was considered to represent a shunt. Two other methods of shunt detection are the area ratio techniques using extrapolation of the downslope[103] or gamma variate fit[104] (Fig. 50–10). The gamma variate method of Maltz and Treves[104] is the most accurate[105] and widely used technique. This technique requires manually drawing a region of interest encompassing one or both lung fields and generating a pulmonary time–activity histogram for analysis.

Validation of RNA-determined pulmonary-to-systemic flow ratio (Q_p/Q_s) is well documented. Alderson et al.[106] showed a correlation coefficient of 0.97 when Q_p/Q_s was determined from RNA and electromagnetic flow probes. Others have shown excellent correlation (0.71 to 0.94) when compared to calculated Q_p/Q_s using oximetry in children with LR shunts.[107–111] Deconvolution analysis will improve studies that have inferior bolus injection[57,58] and will help prevent the need for repeat studies due to injection technique. Careful analysis of time–activity curves in the right atrium and right ventricle can differentiate atrial level shunting from ventricular or ductal level shunting.

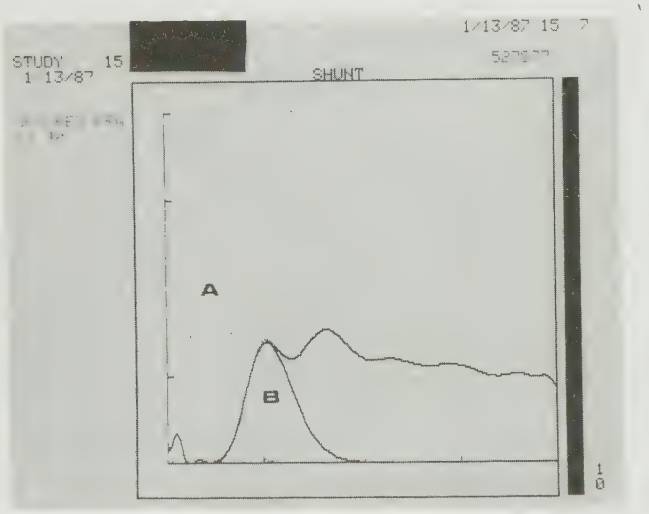

Fig. 50–9. A time–activity curve (x-axis and y-axis respectively) from a region of interest over the lungs in a patient with an atrial septal defect. The area under curve A represents the primary circulation of radionuclide through the lungs. The area under curve B represents early recirculation (left-to-right shunt) through the lungs. The pulmonary to systemic flow ratio (Q_p/Q_s) is equal to A/A − B. This patient had a Q_p/Q_s equal to 2.2/1.

A right-to-left (RL) intracardiac shunt can be detected by careful visual inspection of the tracer flow pattern. Peter et al.[112] devised a mathematical equation for quantitating RL shunts using time–activity curves over a carotid artery. Placing a region of interest over the LV and using an exponential extrapolation of the downslope of the curves can also calculate RL shunts.[9] Another method of detecting RL shunts uses radioactive particles (^{99m}Tc-macroaggregated albumin). This technique is described in the following section.

Clinical Indications

Left-to-Right Shunt

The detection and quantification of left-to-right shunt flow is the most useful aspect of tracer flow analysis[107,108,113,114,115] (Fig. 50–9). A patient with classic findings of an ASD may be sent for surgical closure without catheterization. The decision to send a patient with a suspected ASD to the operating room without catheterization depends on the confidence of the clinician in the diagnosis. The additional evidence of a calculated Q_p/Q_s by noninvasive means may be sufficient evidence to recommend surgery.

The size of shunt flow through a VSD may be followed serially by RNA. Repeat outpatient evaluations may prevent or promote early surgery depending on the calculated Q_p/Q_s. Decreasing shunt flow, however, must be carefully evaluated by physical examination. Increasing pulmonary resistance as well as a closing VSD will decrease the Q_p/Q_s. Pulmonary vascular reactivity can be evaluated in patients with pulmonary hypertension by calculating Q_p/Q_s in room air and in 100% inspired oxygen environment. Q_p/Q_s may also be measured during pharmacologic afterload reduction. The significance of a residual VSD after attempted surgical closure can be evaluated by RNA.[116] This information may help decide whether a repeat operation is necessary. Cyran et al.[117] identified a group of infants with increased risks after repair of a VSD. A $Q_p/Q_s > 3.0$ by RNA methods predicted ventricular dysfunction after operation.

Right-to-Left Shunt

The clinical utility of detecting a RL shunt by RNA is limited. Detection of a RL shunt can differentiate systemic hypoxemia caused by a pure intracardiac RL shunt versus an intrapulmonary RL shunt. A more frequent clinical question concerns the amount of pulmonary blood flow. Lung perfusion imaging is the best method for determining pulmonary blood flow (see below).

Systemic Venous Return

Peripheral venous injection will detect systemic venous abnormalities such as a persistent left superior vena cava, obstructed venous channels, hemiazygous continuation, and other venous anomalies. The resolution of these images requires that venous obstruction (e.g., after the Mustard procedure for d-TGA) be severe in order to be clearly seen.[116]

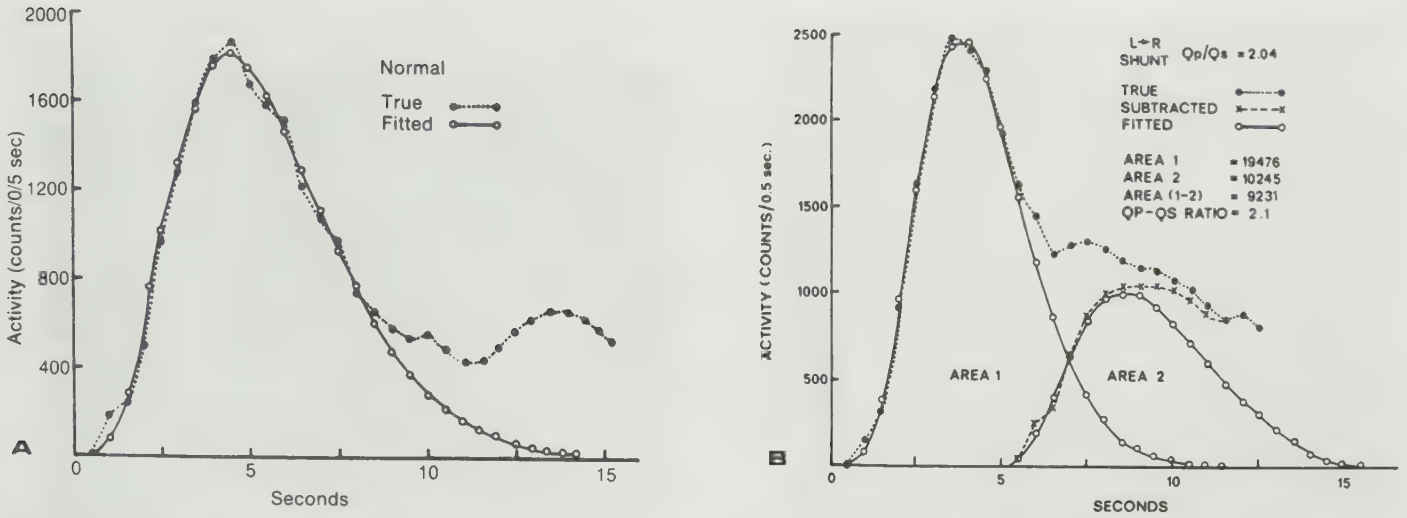

Fig. 50–10. (A) A normal time–activity lung curve showing no left-to-right shunt. The tail-end of the primary lung circulation is extrapolated using the gamma variate fit method. The "true" curve represents normal systemic venous recirculation. (B) Left-to-right shunt study. The primary circulation curve and the early recirculation curve are fitted with the gamma variate fit model. Pulmonary to systemic flow ratio (Q_p/Q_s) is determined by area 1/area 1 − area 2. (Maltz, D.L., and Treves, S.: Quantitative radionuclide angiocardiography: Determination of Q_p:Q_s in children. Circulation, *47*:1049, 1973. Reprinted with permission of the American Heart Association.)

VASCULAR PERFUSION IMAGING

Technique

The assumption in vascular perfusion imaging is that the radiotracer is stopped by the first capillary bed encountered. This assumption is generally realized if the tracer particle is 10 microns or larger in diameter. The radiotracer used for the performance of perfusion scanning is technetium-99m-macroaggregated albumin (^{99m}Tc-MAA). Dynamic tracer flow patterns can be imaged during injection of these particles. Subsequent static images outline the vascular perfusion pattern of the particles once they are trapped in a capillary bed. Qualitative blood flow volume is estimated from the relative count density in a defined region of interest. A standard gamma camera and general purpose collimator are adequate for image acquisition. A diverging collimator (see Fig. 36–11) will allow a larger field of view.

Clinical Indications

Lung Perfusion Imaging

Lung perfusion scans give qualitative images of pulmonary blood flow patterns. Perfusion abnormalities caused by absent or blocked pulmonary arteries are evident on these scans. The addition of a ventilation scan using inhaled xenon-133 gives information on ventilation/perfusion mismatch.

Right-to-Left Shunt

Detection and semiquantitation of a RL shunt is possible with ^{99m}Tc-MAA perfusion imaging (Fig. 50–11). The fraction of particles shunted right to left are trapped in systemic capillaries. The absolute ratio of pulmonary to systemic counts cannot be calculated because of geometry and attenuation of gamma rays, but an estimate of relative flows is possible. Total body counting is not necessary for the systemic blood flow fraction. A sum of brain, liver, kidney, and spleen is usually all that is necessary for systemic counts. Since microemboli of MAA are trapped in capillaries of the brain, kidney, and heart, the number of particles injected is kept at a minimum number of approximately 10,000.

Patency of Systemic-to-Pulmonary Artery Shunt

The patency and relative distribution of systemic-to-pulmonary artery shunts is possible with vascular perfusion imaging. We have often used this modality on postoperative patients to evaluate possible shunt failure due to thrombosis or mechanical obstruction and pulmonary overcirculation due to a large shunt (Fig. 50–11).[117]

INFLAMMATORY DISEASE IMAGING

Technique

Inflammatory processes are imaged with gallium-67 citrate or indium-111 oxine-labeled white blood cells (WBC). Gallium-67 localizes in areas of inflammation. Persistent body background requires delayed imaging at 24 to 48 hours after injection to visualize discrete areas of inflammation. The high-energy gamma rays from ^{67}Ga decay require that a high energy collimator be used on a standard gamma camera. Autologous WBCs labeled with ^{111}In also localize in areas in inflammation. This newer modality may be more sensitive than ^{67}Ga for inflammatory diseases and requires less time to complete.[118]

Clinical Indications

Myocarditis

Inflammatory cell infiltration of the myocardium can be detected by ^{67}Ga and ^{111}In-WBC scans. O'Connell et al.[119] found positive ^{67}Ga scans in 5 of 6 patients with biopsy-proven myocarditis. They also found nine equivocal ^{67}Ga scans in patients without myocarditis. This highlights the sensitivity but lack of specificity of ^{67}Ga scans for myocarditis. Jacobs et al.[120] used ^{67}Ga to diagnose my-

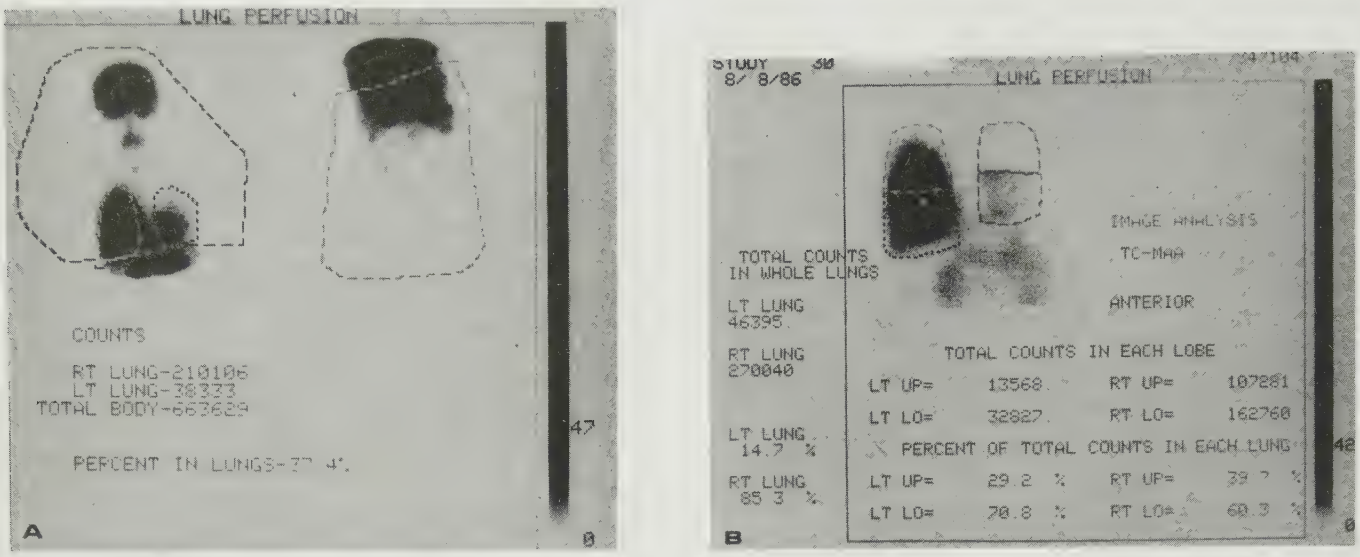

Fig. 50–11. A vascular perfusion study evaluating a surgical systemic to pulmonary shunt in a patient with pulmonary atresia and a ventricular septal defect. Technetium-99m macroaggregated albumin (Tc-MAA) injected in a systemic vein was used for this study. (A) Radioactivity is evident in the head, lungs and abdomen. Count density profiles show that 37.4% of systemic venous return flows to the lungs while 62.6% flows to the systemic circulation. (B) Anterior view of lung perfusion in the same patient. The left lung has significantly reduced perfusion (14.7%) compared to the right lung (85.3%). This patient had a thrombosed left pulmonary artery requiring surgical revision of the shunt. RT = right, LT = left, UP = upper lobes, LO = lower lobes.

ocarditis in a 15-year-old girl with Lyme disease. Williamson et al.[121] found positive ^{111}In-WBC scans in 4 of 4 patients with Kawasaki disease. They did not report the incidence of coronary aneurysms in this group. The use of ^{67}Ga or ^{111}In-WBC scintigraphy in the diagnosis and prognosis of Kawasaki disease requires further investigation.

Pericarditis

Leukocyte infiltration with inflammation of the pericardium is visible on ^{67}Ga and ^{111}In-WBC scans. Bufalino et al.[122] found positive ^{67}Ga scans in 7 of 7 patients with postpericardiotomy syndrome 14 days or longer after operation. Nine of nine patients less than 9 days after operation had negative scans. Purulent pericarditis can also produce a positive ^{111}In-WBC scan.[123]

RISKS AND BENEFITS

The risks of nuclear cardiology modalities are minimal. The largest risk is exposure to radiation. The radiation burden (see Table 36–5) to a patient is low, and this level of radiation exposure causes no known permanent effects. The risk of exercise stress is also minimal when performed under close observation in a properly equipped laboratory (see Chapter 49). The cost of an exercise ventricular performance study is considerably less than a cardiac catheterization.

The benefit of a nuclear cardiology evaluation is the availability of a safe, noninvasive, outpatient procedure that gives physiologic information on cardiac performance. Compared to echocardiography, first-pass and equilibrium RNA give more accurate information on right ventricular size and function, shunt flow, regurgitant fraction, and functional response to exercise stress. Echocardiography is far superior in delineating cardiac morphology. Myocardial perfusion imaging is not possible with any other imaging modality except positron emission tomography, the availability of which is currently limited.

FUTURE DIRECTIONS

Radiopharmaceuticals

The most promising future direction in blood pool radiopharmaceuticals is short-lived radionuclides. There are major advantages to using short-lived radionuclides: 1) the photon flux (counts/sec) is higher, giving greater statistical accuracy; 2) background activity is nearly eliminated, again giving improved accuracy; and 3) radiation dose to the patient is significantly reduced.

Tantalum-178

The half-life of ^{178}Ta (9.3 min) and the economy of the generator system make ^{178}Ta an ideal blood pool agent.[124,125] The half-life of 9.3 min makes repeat studies possible with low background activity but is long enough to allow equilibrium studies. The half-life also makes the radionuclide easy to work with in a clinical setting. The generator system is functional for at least 30 days. The radiation dose is $\frac{1}{20}$ the dose of ^{99m}Tc. The disadvantage of ^{178}Ta is the low-energy photons (55 to 65 keV) produced during decay. The low energy decreases resolution when using a conventional gamma camera. Full advantage of ^{178}Ta requires concomitant development of the multiwire proportional gamma camera.

Iridium-191m

The ultra-short half-life (5 sec) of ^{191m}Ir makes this radionuclide ideal for first-pass RNA.[109,126–128] It also delivers less radiation to the patient. The tabletop generator system is clinically useful for 1 to 2 weeks. Experimental and clinical validation of ventricular

function and shunt flow in children and adults is well established. The disadvantage of ^{191m}Ir is that the ultra-short half-life causes technical difficulties in a clinical setting. The generator is connected "in line" with the patient's intravenous line, and the generator is eluted directly into the patient.

Gold-195m

Another promising short-lived radionuclide is ^{195m}Au with a half-life of 30.5 sec.[129–132] Produced from a mercury-195m/gold-195m tabletop generator, the radiation dosimetry and clinical utility are favorable. Validation of ventricular function was established by Wackers et al.[129,130] and Dymond and colleagues.[131] The disadvantage of ^{195m}Au is the relatively short half-life of the parent ^{195m}Hg (half-life = 41.6 hours). The generator is useful for one week or less, which makes this system considerably more expensive.

Technetium-99m-Isonitrile Compounds

The new, promising radionuclides for myocardial perfusion imaging are the ^{99m}Tc-isonitriles.[133,134] These agents may replace ^{201}Tl as the radionuclide of choice for rest and stress perfusion scintigraphy. The advantages of the ^{99m}Tc-isonitriles are shorter half-life and better energy resolution. The ^{99m}Tc-isonitrile compound does not redistribute through the myocardium as does ^{201}Tl, which makes imaging technically easier.

Instrumentation

Multiwire Proportional Gamma Camera (MWPC)

The newest development in medical gamma ray detection instrumentation is the MWPC.[135,136] This gamma camera does not have a sodium iodide crystal. Detection and localization of radiation events are accomplished by a closely spaced wire grid positioned in a pressurized gas chamber. The major advantages of the MWPC are 1) high count rates (800,000 counts/sec) with little dead time, 2) high spatial resolution (2.5 mm FWHM), 3) small size, 4) low cost, and 5) ease of maintenance. (Count rate, dead time, and FWHM are discussed in Chapter 36). The MWPC is ideal for first-pass RNA with short-lived radionuclides. The major disadvantage of the MWPC is its low detection efficiency of gamma rays with energies over 80 to 100 keV. Since the gamma ray from ^{99m}Tc is 140 keV, it cannot be used with the MWPC. Consequently, new radionuclides (e.g., ^{178}Ta and ^{191m}Ir) with lower energy photons are required.

CHAPTER 51

Nuclear Magnetic Resonance and Positron Emission Tomography—Clinical Aspects

G Wesley Vick, III
Roxann Rokey
Donald L Johnston

NUCLEAR MAGNETIC RESONANCE

Acquisition of anatomic and functional information about the cardiovascular system is a central aspect of modern cardiology. Acquisition of data about the metabolic characteristics and tissue composition of the cardiovascular system will probably assume increasing importance. None of the presently available diagnostic methods are capable of giving the clinician all the information desired. The application of nuclear magnetic resonance (NMR) techniques to the clinical evaluation of the cardiovascular system, while still very new, has already shown considerable promise as an adjunct to other diagnostic methods in the clinical assessment of cardiovascular anatomy, function, metabolism, and tissue composition.[1-6]

NMR examinations have become relatively routine in the anatomic evaluation of disorders of the central nervous system. Cardiovascular NMR has developed more slowly because the motion of the cardiovascular structures substantially increases the technical difficulty of NMR studies. However, methods of reducing motion artifact in NMR studies are becoming more sophisticated and there is reason to anticipate continued progress in this field.

This chapter will consider the currently available clinical experience with cardiovascular NMR, then discuss the practical implementation of techniques for clinical NMR evaluation, and deal with recent developments in NMR, which are likely to have useful cardiovascular applications.

Clinical use of cardiovascular NMR has been limited to imaging, with the exception of a few experimental spectroscopic studies. Although clinical applications of NMR spectroscopy may develop in the future, it is likely that many of these applications will be performed in conjunction with imaging studies because of the need for spatial localization of spectra to regions of interest.

An Overview

First, it is important to recognize the elements that compose the NMR image. An NMR image is formed from a collection of small square or rectangular areas called pixels. Many of these pixels are required to form an image, usually between 256 × 256 (65,536) and 128 × 128 (16,384). The pixels usually are displayed in shades of gray. The shading of a particular pixel is determined by the NMR signal produced by the small volume element of the subject's anatomy that the pixel represents. Such volume elements are termed "voxels."

It follows that the key to understanding NMR imaging is an understanding of how an NMR signal can be obtained from a particular voxel of the subject. There are several possible approaches, but essentially all commercial imaging systems obtain localized NMR signals by the use of magnetic field gradients and appropriately designed radiofrequency pulses. With these magnetic field gradients and radiofrequency pulses, it is possible to give the NMR-sensitive nuclei (generally, hydrogen atoms) in each imaged voxel of the subject a unique combination of rotational frequency and phase, from which their unique NMR signal can be identified. This identification is usually made by a mathematical process known as Fourier transformation.

The NMR signal produced by a particular voxel is determined by a combination of the intrinsic NMR properties of the voxel and the methods used to obtain the localized signal. Modification of the characteristics of the magnetic field gradients and radiofrequency pulses employed in NMR imaging can emphasize the effect

of some NMR properties and deemphasize others. Because different voxels of the subject will often differ in their NMR properties, it is possible to increase or decrease the contrast of NMR images by manipulation of the magnetic field gradients and radiofrequency pulses.[7,8]

Cardiovascular examinations are facilitated because the intrinsic NMR properties of rapidly flowing blood differ substantially from the NMR properties of myocardium and vessel walls. There are also differences between the intrinsic NMR properties of infarcted and normal myocardium and between the intrinsic NMR properties of atheroma and normal arterial wall. Because of the inherent three-dimensional nature of NMR imaging, many different imaging orientations are possible (Fig. 51–1).

Anatomical Evaluation

Contrast between flowing blood and the myocardial and blood vessel walls provides the basis for NMR cardiovascular imaging.[9,10] With standard spin echo images, the blood vessels appear dark while the myocardium and vessel walls have a relatively high signal intensity (Fig. 51–2). This appearance may be reversed with types of imaging sequences other than spin echo. Slowly flowing or stationary blood will also appear relatively bright on spin echo images. The generally excellent spatial resolution of NMR greatly facilitates the measurement of chamber dimensions and wall thickness. Visceral and cardiac situs is readily apparent on NMR images, and atrioventricular and ventriculoarterial connections are easily recognized. Delineation of great vessel anatomy is an important strength of NMR imaging (Fig. 51–3). The ascending and descending aorta and the distal pulmonary arteries are well defined by NMR in many cases, as are the systemic and pulmonary veins. Particularly in older patients, these structures are difficult to characterize by echocardiography. The right ventricular cavity and right ventricular anterior wall are usually clearly displayed by NMR (Fig. 51–4). These areas are of particular importance in many varieties of congenital heart disease, and again, are often inadequately visualized by echocardiography in many older patients. The left ventricle is clearly depicted in most NMR studies, and multiple orthogonal views can be obtained at various points of interest in the cardiac cycle. The atrial and ventricular septa are usually well visualized by NMR. However, the presence of small defects in the fossa ovalis and atrioventricular septal areas is difficult to ascertain reliably because the normal septal thickness in these locations approaches the limits of resolution of presently available NMR equipment. The proximal coronary arteries are often visualized on NMR studies, and in many cases it is possible to visualize their origin from the sinuses of

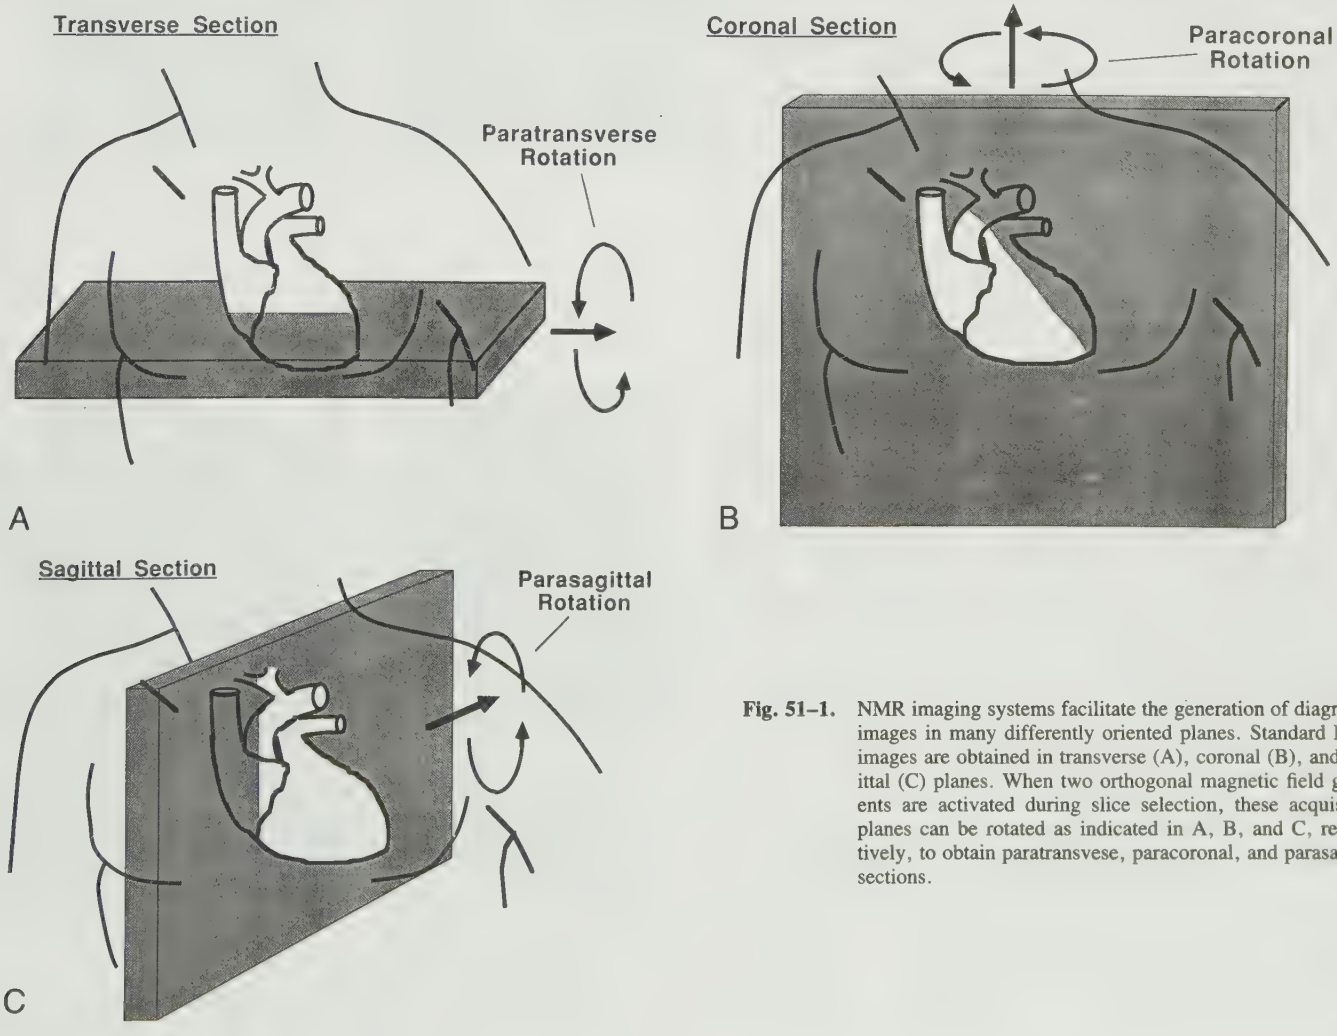

Fig. 51–1. NMR imaging systems facilitate the generation of diagnostic images in many differently oriented planes. Standard NMR images are obtained in transverse (A), coronal (B), and sagittal (C) planes. When two orthogonal magnetic field gradients are activated during slice selection, these acquisition planes can be rotated as indicated in A, B, and C, respectively, to obtain paratransvese, paracoronal, and parasagittal sections.

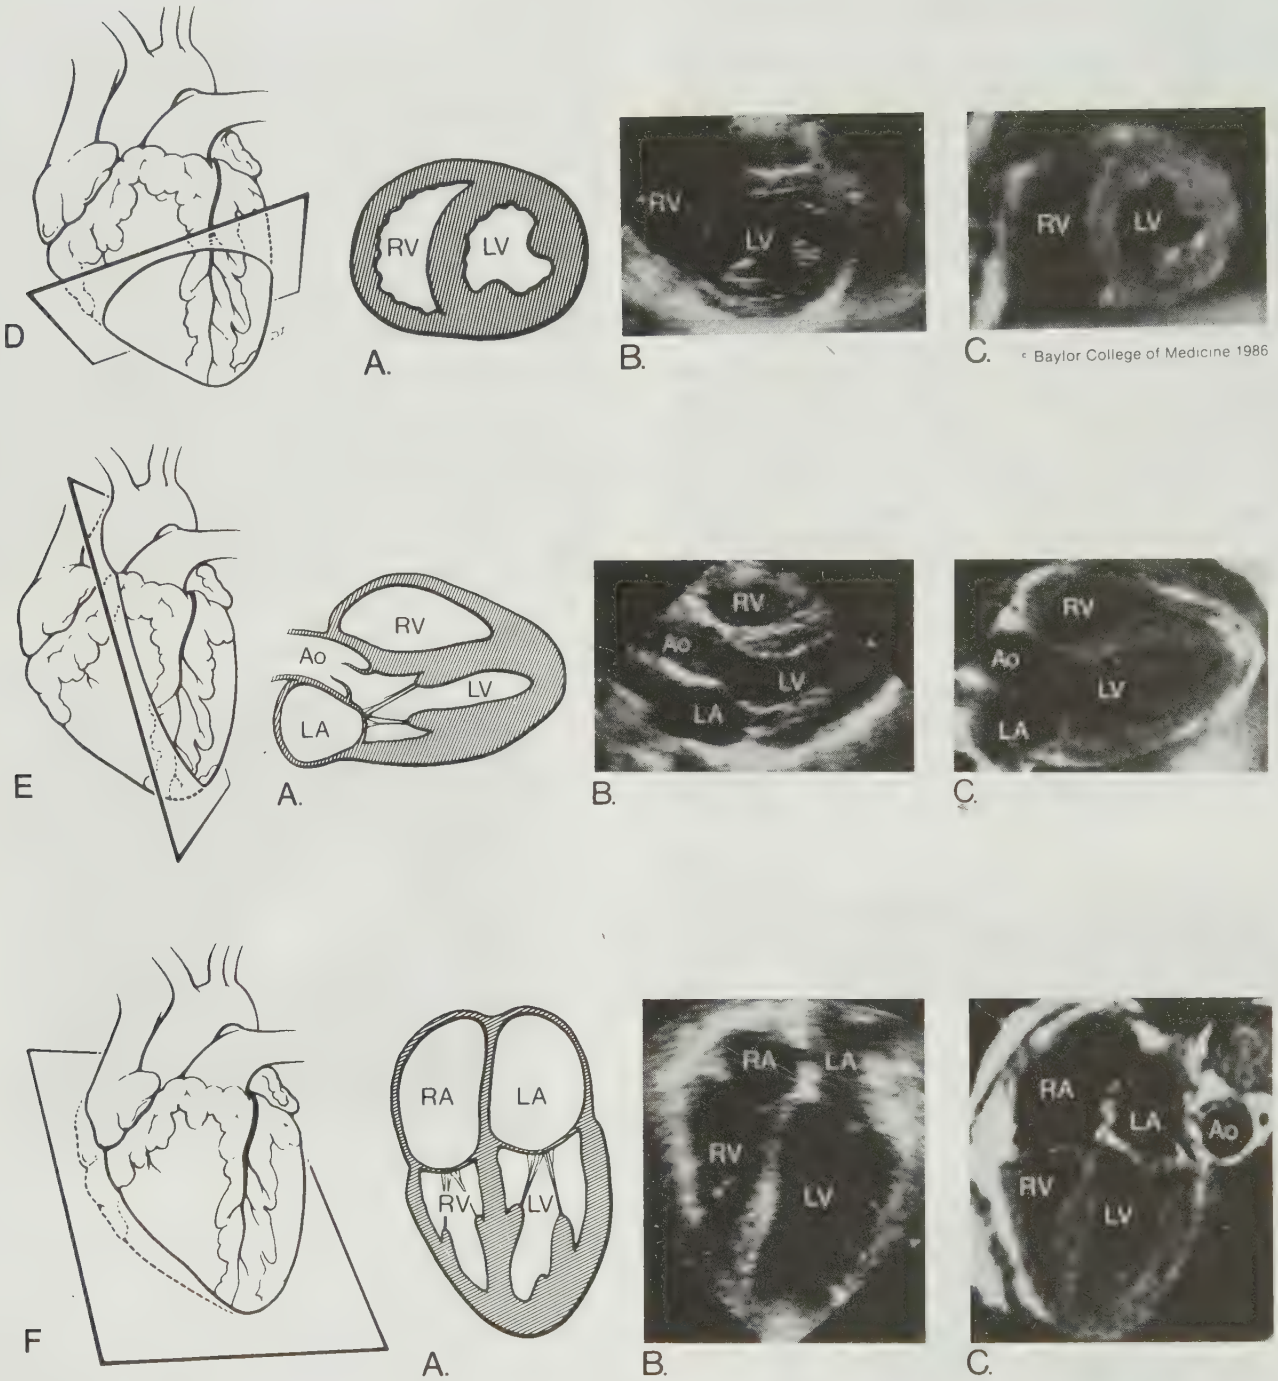

Fig. 51–1 ***continued.*** In many cases, however, planes perpendicular or parallel to cardiac structures of interest require either rotation of one of the orthogonal planes about more than one axis, or rotation of the patient. Such axial orientations can then be obtained with NMR imaging just as they can be with echocardiography or angiography. These panels illustrate NMR sections in the transverse (D), long-axis (E), and four chamber (F) orientation in comparison to illustrations and comparable echocardiographic sections. Illustrations are on the left, echocardiograms are in the center, and NMR sections are on the right. RV = right ventricle; LV = left ventricle; Ao = aorta; LA = left atrium; RA = right atrium.

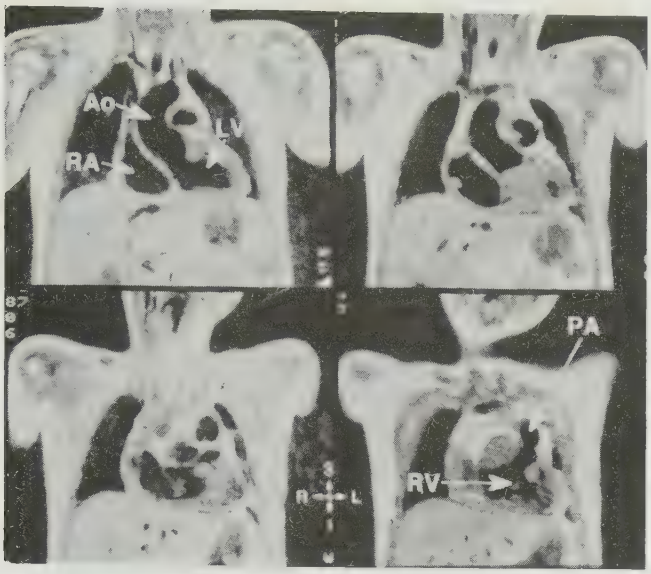

Fig. 51–2. Serial coronal sections with a progressively more anterior location clearly demonstrate cardiac structures in a postoperative patient who had undergone Rastelli repair of pulmonary atresia and ventricular septal defect and subsequent conduit replacement. The outflow tract is widely patent after the conduit revision, though the right ventricle remains hypertrophic. Ao = aorta; LV = left ventricle; RA = right atrium; RV = right ventricle; PA = pulmonary artery; S = superior; I = inferior; L = left; R = right.

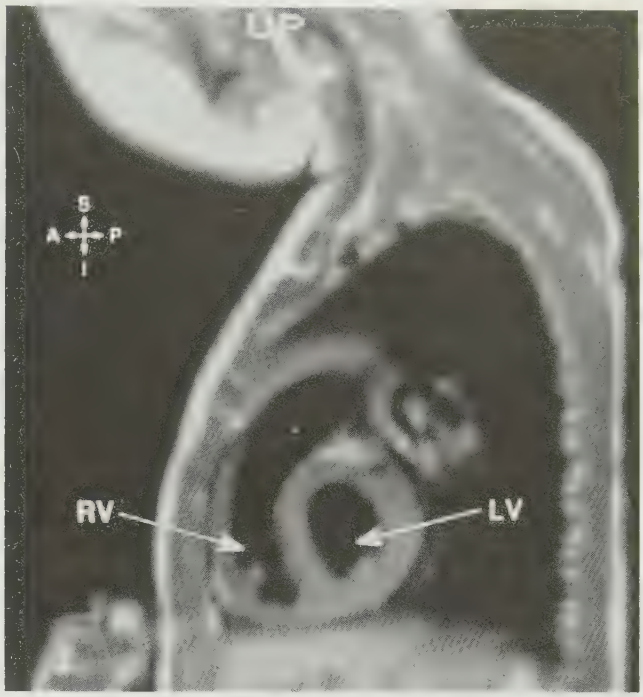

Fig. 51–4. Paracoronal spin echo image demonstrating right and left ventricles in patient with repaired coarctation of aorta. RV = right ventricle; LV = left ventricle; S = superior, I = inferior; P = posterior; A = anterior.

Valsalva. However, resolution is not yet adequate to define the presence or absence of coronary artery stenosis. Because of their rapid motion, and because they are normally very thin, the cardiac valves are inadequately defined by present NMR techniques.

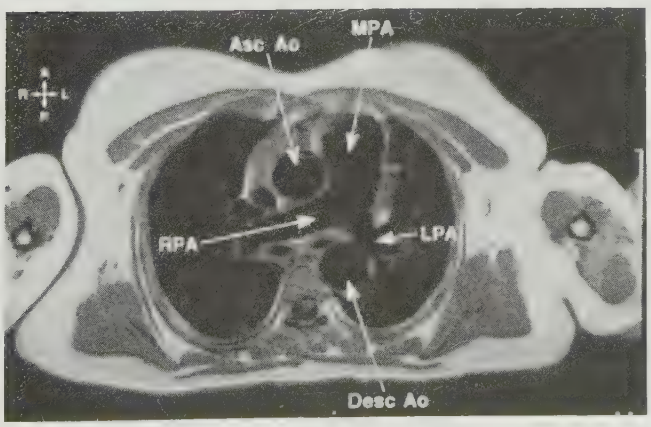

Fig. 51–3. Transverse spin echo image demonstrating the main pulmonary artery and its bifurcation into left and right branches. Asc Ao = ascending aorta; Desc Ao = descending aorta; MPA = main pulmonary artery; RPA = right pulmonary artery; LPA = left pulmonary artery; A = anterior; P = posterior; L = left; R = right.

Evaluation in Specific Cardiovascular Disorders

Coarctation of the Aorta

A considerable body of experience has demonstrated the utility of NMR imaging in evaluation of coarctation of the aorta, both before and after treatment[11–13] (Fig. 51–5). The presence of stenosis at the coarctation site can be detected and the length of the narrowed aortic segment or segments can be assessed as well as the presence of post-stenotic dilation (Figs. 51–6 and 51–7). NMR imaging can also detect the aneurysms that sometimes occur after coarctation surgery or balloon dilation (Fig. 51–8), though its sensitivity and specificity in this regard has not been determined. Although collateral vessels may be visualized on NMR studies of patients with coarctation and hemodynamically substantial obstruction to blood flow, the method for determining the adequacy of collateral formation by NMR has not been described.

Most reported studies of coarctation with NMR have used the standard spin echo technique. With this method, straight sagittal sections passing through the area of the coarctation will generally demonstrate it clearly. Paracoronal sections (which are analogous to angiographic left anterior oblique views) with appropriate angulation will usually demonstrate a larger portion of the aorta in the plane of the coarctation than will sagittal views. The sagittal views may display slightly better resolution than the angulated views, however.[14,15] Transverse sections, obtained through the de-

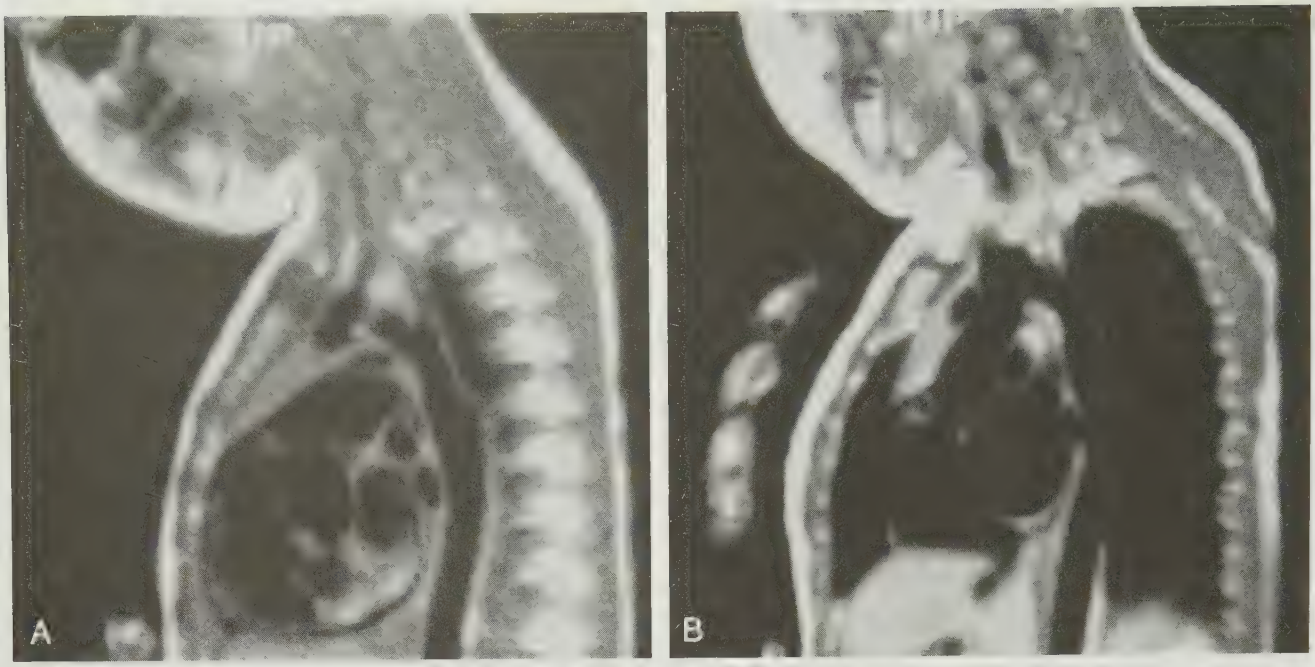

Fig. 51–5. Spin echo NMR study of aorta in a 7-year-old patient 1 yr after balloon coarctation angioplasty. Sagittal (A) and paracoronal (B) sections. Note that the ascending aorta does not lie in the sagittal plane passing through the upper descending aorta. (Orientation is as in Figure 51–4.)

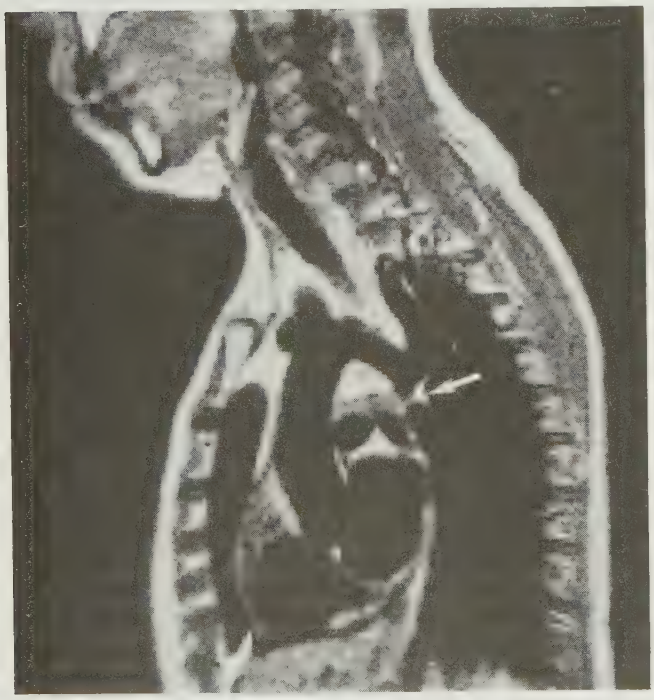

Fig. 51–6. Coarctation of the aorta demonstrated by spin echo NMR study (arrow marks site of coarctation). Paracoronal plane of acquisition. (Orientation is as in Figure 51–4.)

scending aorta at the level of the coarctation, are also useful, since they facilitate measurement of aortic diameter and provide an orthogonal imaging plane to the sagittal and paracoronal sections. Because the coarctation orifice may be extremely small and unusually oriented, it may be difficult to determine the precise diameter of the narrowest point in the coarctation with currently available NMR systems. In addition to assisting with the evaluation of the coarctation site, NMR is also a satisfactory method for evaluating the degree of ventricular hypertrophy present.

Cine NMR and NMR angiographic techniques are just now being applied to the study of coarctation. They should be particularly useful in evaluating obstruction to blood flow at the coarctation site and in assessing the adequacy of collateral formation.[16]

Marfan's Syndrome

Evaluation of Marfan's syndrome by NMR has been well described.[17] Again, NMR is an excellent tool for quantitating the aortic enlargement in this disorder. The aorta in Marfan's syndrome is characteristically enlarged in the region of the sinuses of Valsalva in relation to other portions of the aorta. Kersting-Sommerhoff and colleagues found that the ratio of aortic diameter at the sinuses of Valsalva to aortic diameter in the prearch region (upper ascending aorta) was 1.4 or greater in patients with Marfan's syndrome and 1.3 or less in patients with other causes of aortic enlargement and in normal controls.[18] NMR has shown promise as a method for detection and evaluation of aortic dissection in these and other patients with suspected aortic dissection (Fig. 51–9).[19]

The best projections for aortic evaluation in patients with Marfan's syndrome or suspected Marfan's syndrome are the transverse and paracoronal projections with the patient positioned straight supine, and the coronal projection with the patient in a 30-degree right anterior oblique position. Cine NMR and NMR angiographic

Fig. 51–7. Two paracoronal sections from a patient with coarctation of the aorta subsequent to balloon dilation. Because of the tortuous character of many vascular structures of interest, it is important to obtain multiple adjacent sections when using a tomographic imaging method. A vessel that appears to be obstructed or narrowed in one section may actually be widely patent, but with a course that carries it out of the imaging plane or slice. (Orientation is as in Figure 51–4.)

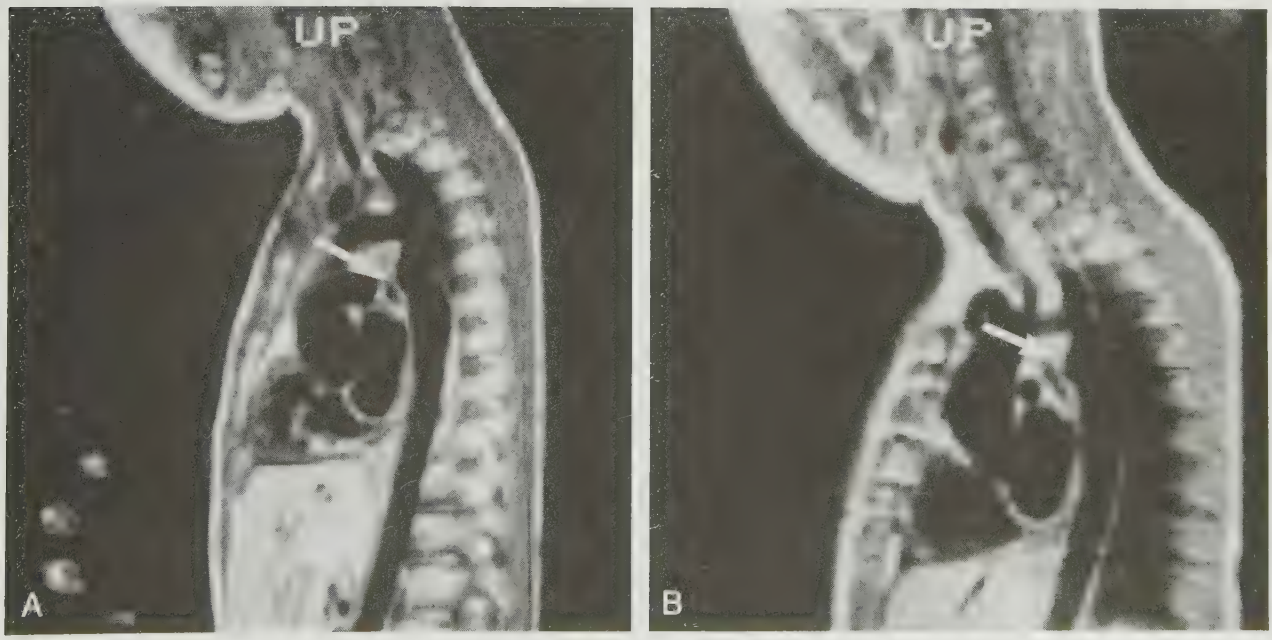

Fig. 51–8. Spin echo NMR study of aorta in an 8-yr-old patient 1 yr after balloon coarctation angioplasty. Sagittal (A) and parasagittal (B) sections are shown. A small aneurysm is present at the site of balloon dilation (arrow). (Orientation is as in Figure 51–4.)

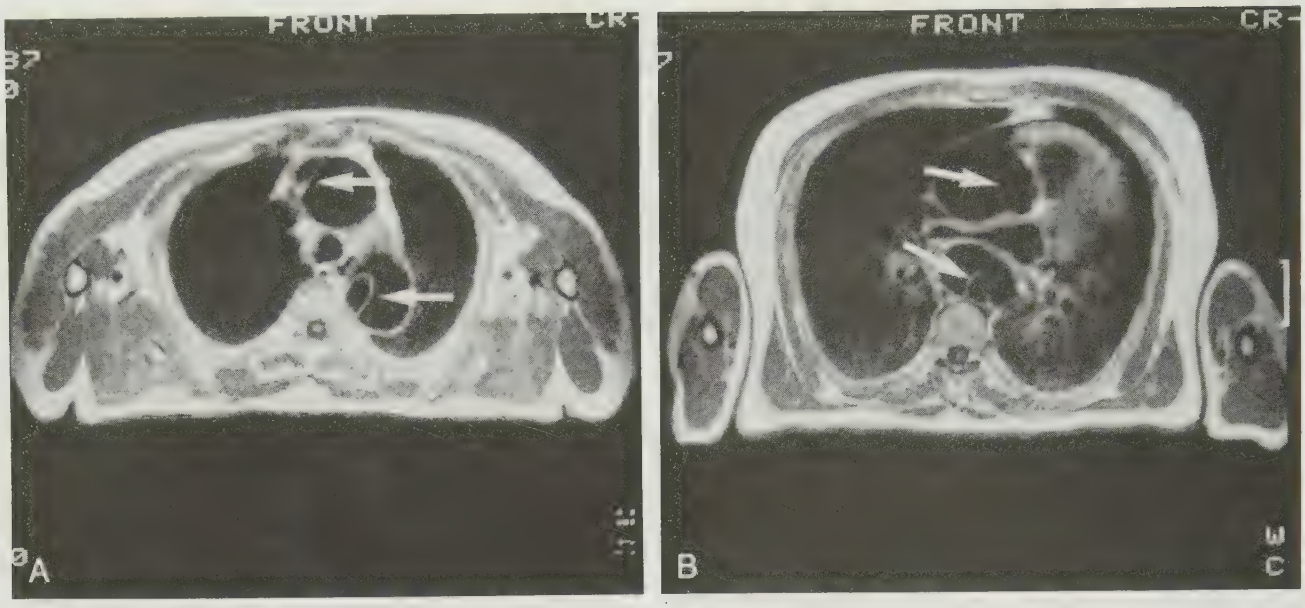

Fig. 51–9. Transverse spin echo sections demonstrating two lumens in ascending and descending aorta, findings consistent with dissection of the aorta (arrows point to location of intimal flap). Section A is obtained through the ascending and descending aorta well above the level of the aortic valve. Section B is obtained through the upper base of the heart. (Orientation is as in Figure 51–3.)

techniques promise to be very useful in Marfan's syndrome, since they should help with the evaluation of suspected aortic and mitral valvular regurgitation and may also assist in the assessment of suspected aortic dissection.[20–22]

Ventricular Septal Defects

Ventricular septal defects can be demonstrated by standard spin echo NMR imaging.[23] However, as noted above, the membranous ventricular septum is normally so thin as to be near the limit of resolution of many NMR machines.[24] Therefore one should be cautious when making the diagnosis of small perimembranous ventricular septal defect by NMR. However, large ventricular septal defects extending into the muscular septum are easily imaged with NMR (Fig. 51–10).

As is the case with angiography and echocardiography, ventricular septal defects are often displayed best if the viewing plane is either parallel or perpendicular to the plane of the ventricular septum.[25,26] In the limited number of studies so far performed, ventricular septal defect size as determined by NMR appears to correlate well with angiographic and echocardiographic results. With appropriate selection of viewing planes, it is usually possible to determine whether a ventricular septal defect is entirely muscular or whether it extends to the region of the membranous septum. It is also usually possible to classify it as being located primarily in the inlet, trabecular, or outlet ventricular septum.

The cine NMR flow studies so far performed in patients with ventricular septal defects suggest that the evaluation of velocity patterns of blood flow by NMR will be helpful in these patients.[27] NMR flow studies appear to be of particular use in localizing single ventricular septal defects and in ruling out small defects when the standard spin echo examination is equivocal. They may also prove useful for demonstrating the presence of multiple ventricular septal defects.

Fig. 51–10. Large muscular ventricular septal defect demonstrated by sagittal spin echo section. (Orientation is as in Figure 51–4.)

Atrial Septal Defects

The atrial septum is generally well visualized on standard spin echo NMR images.[28] Detection of sinus venosus, fossa ovalis, and ostium primum atrial septal defects by NMR has been described, and complete absence of the atrial septum, or common atrium, has been demonstrated as well.[29] As has been noted, the atrial septum in the area of the fossa ovalis is so thin that defects may be apparent when the septum is actually intact.

Hemodynamically significant atrial septal defects will usually be associated with right ventricular enlargement, which is easily seen on NMR images (Fig. 51–11). NMR flow studies should also demonstrate flow through the defect whenever the standard spin echo images are equivocal.[30]

Tetralogy of Fallot

NMR imaging is useful in patients with tetralogy of Fallot, both preoperatively and postoperatively.[31] In addition to the size and location of the ventricular septal defect, the right ventricular outflow tract and the pulmonary arteries can be clearly delineated. In older patients the quality of the pulmonary artery and right ventricular outflow tract images are often substantially superior to those obtainable by two-dimensional echocardiography.[32] With high-resolution systems it may be possible reliably to visualize the proximal coronary arteries and so identify the occasional patient with this disorder in whom the left anterior descending coronary artery originates from the right coronary artery and crosses the right ventricular outflow tract.

The high-quality definition of the distal pulmonary arteries obtainable by NMR in these patients can be a great help in deciding whether surgical correction is advisable in particular patients and in evaluating its results once performed. The ability of NMR to provide an accurate estimate of the extent of infundibular hypertrophy and of left and right ventricular size can be of assistance here. It does seem that patients with serious residual right ventricular hypertension after corrective surgery will have enlarged, hypertrophic right ventricles (Fig. 51–12). If they have no residual ventricular septal defect, their ventricular septum will appear flattened or will bulge toward the left ventricle. Sites of residual distal obstruction in the right ventricular outflow tract or pulmonary arteries can often be ascertained in such patients.

The pulmonary arteries are generally clearly visible on standard spin echo images performed in the transverse plane[33,34] (Fig. 51–13). It is usually advisable to obtain multiple overlapping sections to determine continuity, since the left pulmonary artery tends to lie slightly cephalad as compared with the right pulmonary artery. Properly angled sections will demonstrate the pulmonary artery bifurcation and right ventricular outflow tract, in a manner analogous to the angiographic sitting-up view, and obliquely angled sections can be useful in demonstrating the distal right and left pulmonary arteries. NMR imaging is usually not necessary to determine the mode of branching of the aortic arch, and whether it is left- or right-sided, but NMR appears to be very reliable in this regard.[35]

The limited experience currently available suggests that cine NMR and NMR angiography will substantially assist in the postoperative evaluation of patients with tetralogy of Fallot for the presence of residual ventricular septal defects, pulmonary insufficiency, and obstruction to right ventricular outflow.

Pulmonary Atresia

NMR appears to be a valuable tool in the evaluation of pulmonary atresia, particularly in older patients with this disorder,

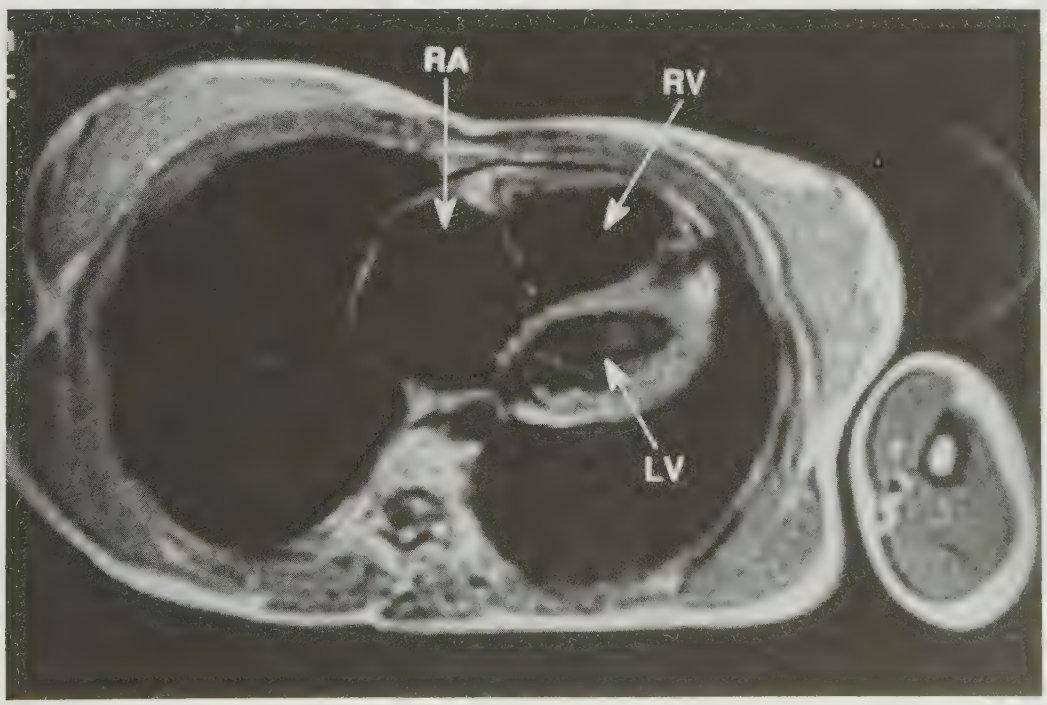

Fig. 51–11. Transverse spin echo NMR image at the midventricular level in a patient with a secundum atrial septal defect and a large left-to-right shunt. The right-sided cardiac structures are greatly enlarged. (Orientation is as in Figure 51–3.) RA = right atrium; RV = right ventricle; LV = left ventricle.

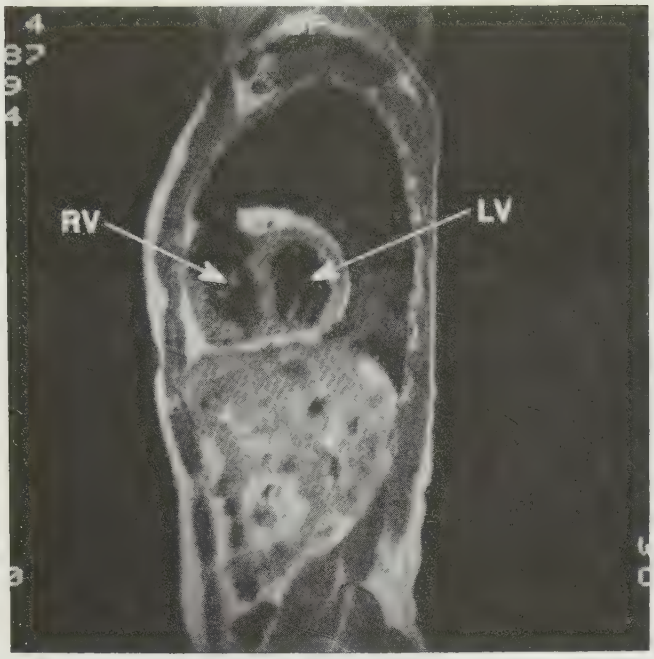

Fig. 51–12. Sagittal spin echo image of enlarged right ventricle and flattened interventricular septum in patient with right ventricular hypertension after corrective surgery for pulmonary atresia and ventricular septal defect. (Orientation is as in Figure 51–4.) RV = right ventricle; LV = left ventricle.

who have poor echocardiographic windows. Evaluation of pulmonary artery size and continuity is probably the most important part of the NMR examination in these patients, since the state of the pulmonary arteries is the most important factor in determining the suitability of these patients for corrective surgery.[36,37] The pulmonary arteries may be evaluated in the same manner as in patients with tetralogy of Fallot.

Relative ventricular sizes and degrees of hypertrophy are easily determined with NMR imaging and should be useful in the evaluation of these patients. NMR confirmation of the location and mode of branching of the aortic arch can be useful in selected cases. Many patients with pulmonary atresia have aorticopulmonary collateral vessels of substantial size, which originate from the descending aorta (Fig. 51–14). These are difficult to visualize echocardiographically and are difficult to follow on standard multislice spin echo images because of their tortuous nature. However, new methods of NMR angiography may substantially improve the noninvasive evaluation of these vessels, particularly if selective techniques can be developed.[38]

Aorticopulmonary Shunts

Surgical aorticopulmonary shunts can be clearly depicted by NMR techniques.[39] These shunts are often difficult to visualize in older patients with echocardiography. A distinction must be made between shunts with a tortuous anatomical nature, such as the Blalock-Taussig shunt and Gore-Tex shunts, and shunts that are created by side-to-side anastomoses between the aorta and pulmonary artery, such as the classic Waterston-Cooley and Potts shunts. Shunts with tortuous anatomy do not generally lie in one plane. Therefore, to follow the course of these shunts, multiple sections must be obtained in most cases when planar techniques are employed. Projective imaging with NMR angiography can be useful here, facilitating visualization of tortuous vessels along their length in one image.[40] Since direct anastomoses between the aorta and pulmonary artery are not lengthy, tortuous structures, they can usually be imaged in a single plane (Figs. 51–15 and 51–16).

Transposition of the Great Arteries

NMR imaging can clearly demonstrate the origin of the aorta and pulmonary artery and the relationship of these vessels to each other.[41,42] Although primary diagnosis of transposition complexes, both complete and corrected, can usually be made by echocardiography and other noninvasive means, NMR can have an important role in evaluating cardiovascular anomalies associated with transposition of the great arteries, both preoperatively and postoperatively, and in evaluating cardiovascular function in older patients with these disorders.[43]

In patients with transposition, NMR can demonstrate associated ventricular septal defects, atrial septal defects, and infundibular pulmonary stenosis. The relative sizes of the left and right ventricles, the extent of ventricular hypertrophy, and pulmonary artery anatomy can also be assessed. Systemic ventricular function in these patients has always been difficult to evaluate. Cine NMR could be useful here, and in assessing the systemic atrioventricular valve insufficiency often associated with transposition of the great arteries. Additionally, in patients with complete transposition who have undergone corrective surgery, NMR shows promise in detecting the obstruction to pulmonary and systemic venous return sometimes associated with intra-atrial baffle procedures,[44] and in detecting abnormalities of intracardiac and extracardiac conduits that may be associated with Rastelli repairs.

Tricuspid Atresia

While tricuspid atresia can usually be clearly demonstrated by NMR,[45] the principal role of NMR imaging in tricuspid atresia, as with transposition complexes, will probably be to evaluate these patients for associated anomalies rather than to make the primary diagnosis. NMR should be useful in evaluating the distal pulmonary arteries, pulmonary outflow tract, and aorta in these patients. In patients who have undergone the Fontan procedure or modifications of it, assessment of the atrial-to-pulmonary-artery conduit by NMR may prove helpful. Relatively poor echocardiographic windows often make anatomic evaluation of these structures incomplete.

Systemic Venous Anomalies

NMR often clearly shows systemic venous abnormalities.[46,47] Azygous continuation of the inferior vena cava is easily demonstrated with standard sagittal spin echo sections. Although azygous continuation of the inferior vena cava can usually be diagnosed by echocardiography in infants, it is more difficult to detect echocardiographically in older patients. Because the inferior vena cava does not enter directly into the heart in this disorder, cardiac catheterization from the femoral vein is complicated.

NMR readily depicts persistence of the left superior vena cava. This abnormality is usually best demonstrated in the coronal plane. With multiple coronal or sagittal sections, the course of the left superior vena cava can usually be followed to a junction with an enlarged coronary sinus, which is the usual mode of connection.

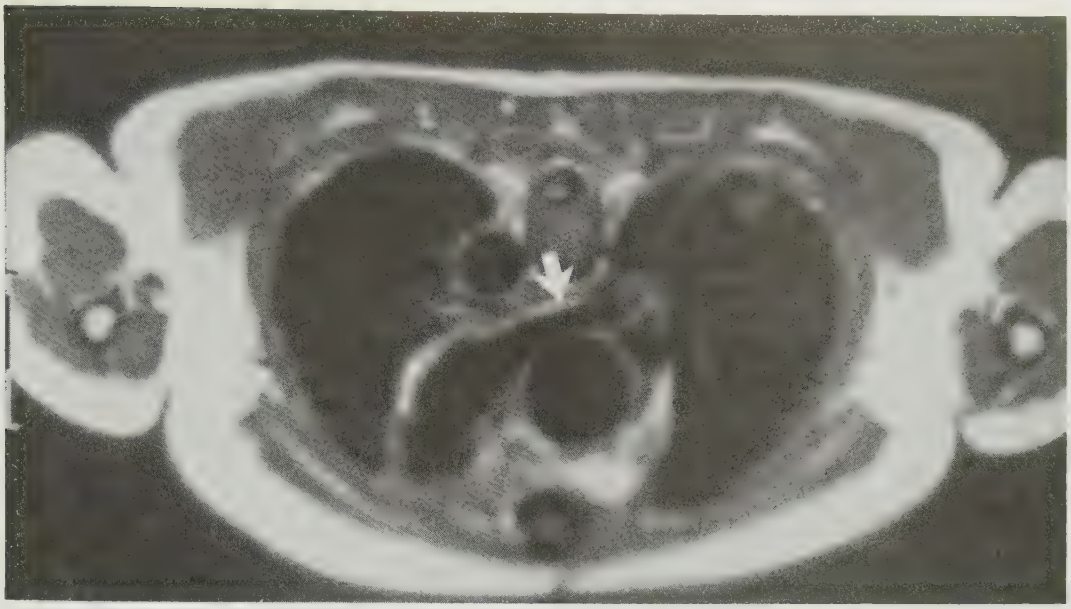

Fig. 51–13. Transverse spin echo image in postoperative patient with pulmonary atresia and ventricular septal defect, demonstrating narrowing of the right pulmonary artery (arrow).

Occasionally, a persistent left superior vena cava will connect directly to the left atrium. Diagnosis of a persistent left superior vena cava is important because its presence may complicate cannulation at the time of institution of cardiopulmonary bypass, and because in the unusual case in which its connection is to the left atrium, right-to-left shunting takes place.

Anomalous hepatic venous return is also demonstrable by NMR, and is best seen on sagittal or coronal images. Anomalous hepatic venous return to the atria, particularly the left atrium, can complicate intracardiac repair of complex congenital heart disease.

Pulmonary Venous Anomalies

The pulmonary veins can be visualized in many NMR studies, and the demonstration by NMR of several of the many abnormalities of pulmonary venous connection has been reported.[48,49] Because most patients with total anomalous pulmonary venous connection present with symptoms in early infancy, and because total anomalous pulmonary venous connection can be diagnosed in infants by echocardiography with a high degree of accuracy, NMR need not be widely employed to provide primary diagnosis

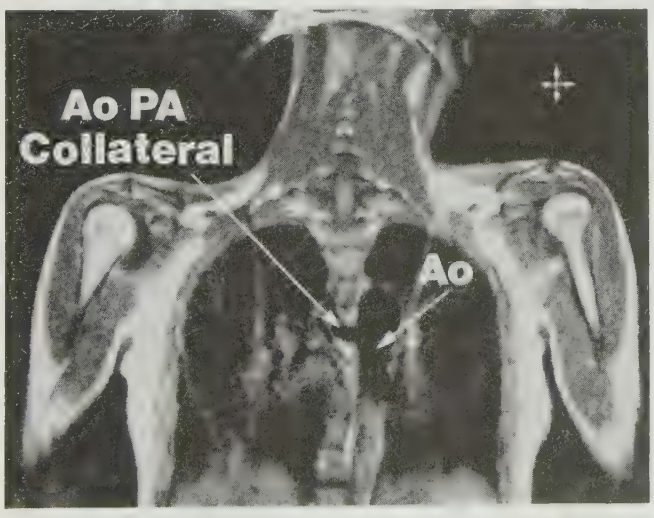

Fig. 51–14. Origin of large aorticopulmonary collateral vessel from the descending aorta in a 19-yr-old patient with pulmonary atresia and ventricular septal defect. Ao PA collateral = aorticopulmonary collateral vessel; Ao = aorta. (Orientation is as in Figure 51–2.)

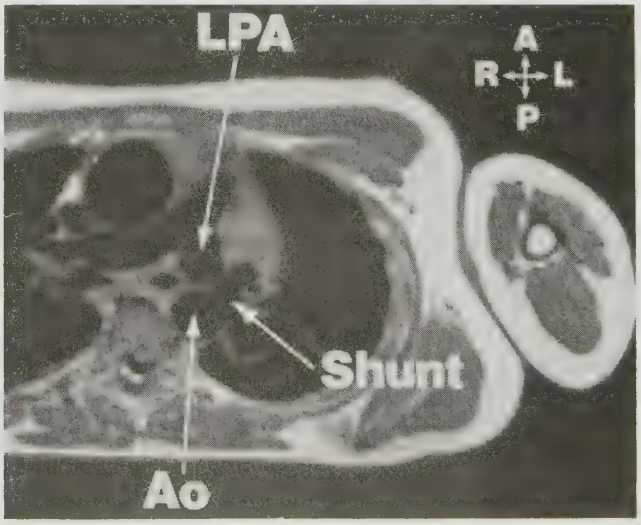

Fig. 51–15. Transverse spin echo image in a patient with severe pulmonary stenosis and a Potts' shunt, demonstrating the communication between the left pulmonary artery and the descending aorta at the site of the shunt. LPA = left pulmonary artery; Ao = aorta; shunt = Potts' shunt; A = anterior; P = posterior; L = left; R = right.

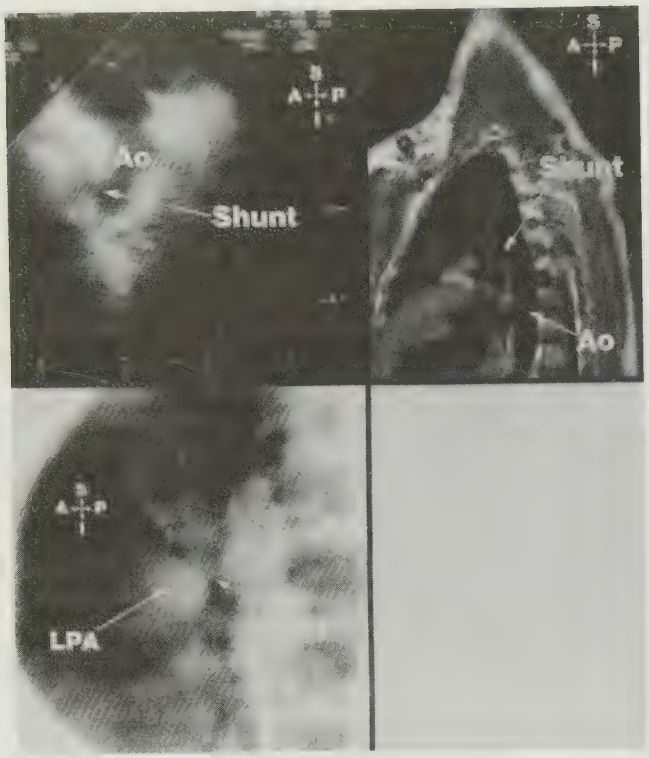

Fig. 51–16. A paracoronal spin echo NMR section, parallel to the axis of the aorta and parallel to the axis of the shunt, was obtained by using the transverse image shown in Figure 51–20 for guidance. This section is shown in the upper right-hand panel of the figure. Comparable echocardiographic (left upper panel) and angiographic (lower panel) studies of the shunt in this patient are also shown. The shunt lumen is more clearly depicted with NMR than with the other imaging methods. Ao = aorta; shunt = Potts' shunt; LPA = left pulmonary artery; S = superior, I = inferior; P = posterior; A = anterior.

in this disorder. However, NMR can be of considerable use in older postoperative patients with total anomalous pulmonary venous connection who have undergone corrective surgery. These patients may have residual stenosis at the site of the surgical anastomosis between the pulmonary venous confluence and the left atrium, and may also have stenosis of the individual pulmonary veins. In older patients, these residual defects may be difficult to visualize by echocardiography.

Partial anomalous pulmonary venous connection often presents in childhood and adolescence, and it is usually, but not always, associated with an atrial septal defect, often of the sinus venosus type. It can be corrected surgically in many instances, and if it is not detected preoperatively, patients may be left with a large residual left-to-right shunt after surgical repair of an atrial septal defect or other congenital cardiac anomaly. Partial anomalous pulmonary venous connection is relatively difficult to diagnose accurately by echocardiography in older patients, but is often demonstrable by NMR.[50] It is therefore likely that NMR will have an important role in both the primary and secondary evaluation of patients with this disorder.

The pulmonary veins and their connections are best depicted in the transverse and coronal planes.[51,52] Cine NMR techniques may facilitate quantitation of the velocity and amount of flow in individual pulmonary veins.

Atrioventricular Canal Defects

A major feature of atrioventricular canal defects—deficiency of the atrioventricular septum—is readily visualized with standard NMR imaging techniques.[53] The atrioventicular septum is best delineated by an imaging plane perpendicular to the axes of the lower atrial septum and the inlet ventricular septum. Such a plane demonstrates all four chambers of the heart, and is often termed the "four-chamber view."[54,55]

In addition to deficiency of the atrioventricular septum, abnormalities of the atrioventricular valves are present in patients with atrioventricular canal defects. These anomalies range from minor clefts to much more extensive defects, in which only a single common atrioventricular valve is present, rather than separate mitral and tricuspid valves. Because of their relatively thin structure and rapid motion, defects of the atrioventricular valves are difficult to visualize with currently available NMR techniques. However, cine NMR methods show promise for detection and quantitation of the atrioventricular valve insufficiency often associated with the structural atrioventricular valve defects. Furthermore, NMR can define many of the congenital cardiovascular abnormalities often associated with atrioventricular canal defects, such as coarctation of the aorta, pulmonary artery stenosis, pulmonary and systemic venous anomalies, and relative ventricular hypoplasia. Particularly in older patients, these associated anomalies may be difficult to define by other noninvasive techniques.

Hypertrophic Cardiomyopathy

The excellent definition of the cardiac wall provided by NMR imaging facilitates accurate characterization of ventricular hypertrophy in patients with hypertrophic cardiomyopathy[56,57] (Fig. 51–17). The highly varied spectrum of hypertrophic cardiomyopathy is well demonstrated by NMR. Some patients have hy-

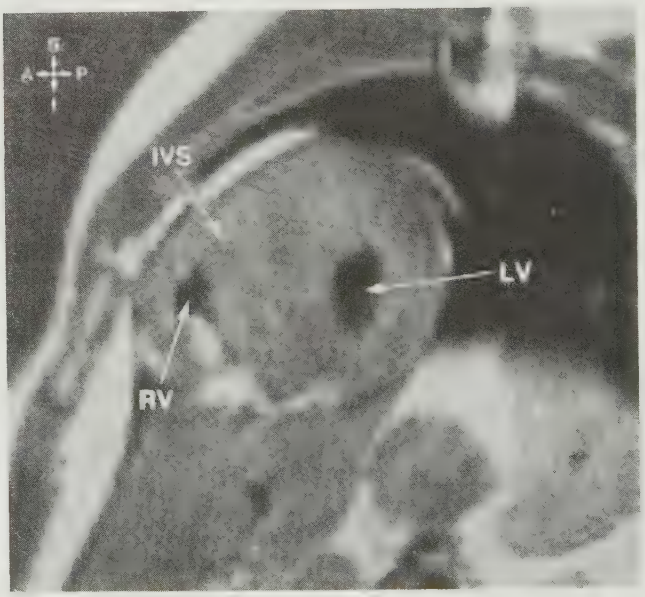

Fig. 51–17. Parasagittal spin echo NMR image in patient with severe hypertrophic cardiomyopathy. Note the prominent hypertrophy of the interventricular septum. IVS = interventricular septum; LV = left ventricle; RV = right ventricle; S = superior; I = inferior; P = posterior; A = anterior.

pertrophy of the entire ventricular septum; others have hypertrophy of the apex, the ventricular free wall, or the outlet septum. NMR and two-dimensional echocardiographic measurements of ventricular hypertrophy in these patients correlate well when adequate echocardiographic windows are available. However, a substantial number of older patients have such limited echocardiographic windows that complete ventricular evaluation is not possible by echocardiography.[58] In these patients, NMR appears to be the imaging method of choice. Echocardiography has the advantage of allowing for relatively easy estimation of pressure gradients across sites of possible obstruction through Doppler measurements of intracardiac blood flow velocity. This information is not currently available by NMR.

Cardiac Tumors

There have been several reports of identification of intracardiac and extracardiac mediastinal tumors by NMR imaging[59–61] (Fig. 51–18). When two-dimensional echocardiography and NMR have been compared, NMR has generally provided better resolution of these tumors. Many tumors have substantially different T1 and T2 relaxation parameters from surrounding tissue, making possible high contrast between normal and abnormal tissue with appropriate adjustment of pulse sequences.

Pericardial Disease

The pericardium is normally a membranous structure that usually is not resolved by standard NMR imaging techniques. On standard spin echo images, a thin line of low signal intensity separates the myocardium from the epicardial and pericardial fat.[62] This line may be produced by the small amount of fluid normally present in the pericardial cavity. Pericardial thickening, such as that present in chronic constrictive pericarditis, is readily visualized by NMR.[63,64] When constrictive pericarditis is present, the vena cava is dilated while the ventricles are relatively small. Pericardial effusions can also be clearly demonstrated with NMR,[65] and preliminary studies[66] suggest that it may be possible to obtain information about the content of the pericardial effusion (i.e., transudate, exudate, chylous nature, and presence of hemoglobin) by appropriate NMR pulse sequences (Fig. 51–19).

Cardiac Valve Stenosis and Insufficiency

Although the semilunar and atrioventricular valves are often visible on NMR images, their rapid motion generally precludes reliable structural evaluation with current techniques. However, valvular stenosis and insufficiency create flow disturbances that are readily visualized by cine NMR techniques. Quantitation of the degree of cardiac valvular stenosis and insufficiency with cine NMR is just beginning, but it shows promise.[20,67] NMR imaging also provides useful information about the extent of cardiac hypertrophy and chamber enlargement in these patients.

Congenital Coronary Artery Anomalies

Vandenbossche and colleagues demonstrated a left coronary arteriovenous fistula by NMR imaging and confirmed its presence with angiography.[68] Because the proximal coronary arteries and their origins are often visualized by NMR, it would seem that NMR diagnosis of other types of coronary artery fistulas and such anomalies as origin of the left anterior descending coronary artery from the right coronary artery, and aberrant left anterior descending artery coursing between the aorta and pulmonary artery should be feasible.

Cardiac Hypertrophy

NMR can provide detailed evaluation of cardiac hypertrophy.[69,70] NMR measurement of left ventricular hypertrophy correlates well with echocardiographic and angiographic determinations. NMR may prove to have particular importance in evaluating right ventricular hypertrophy, since the right ventricle is well defined by

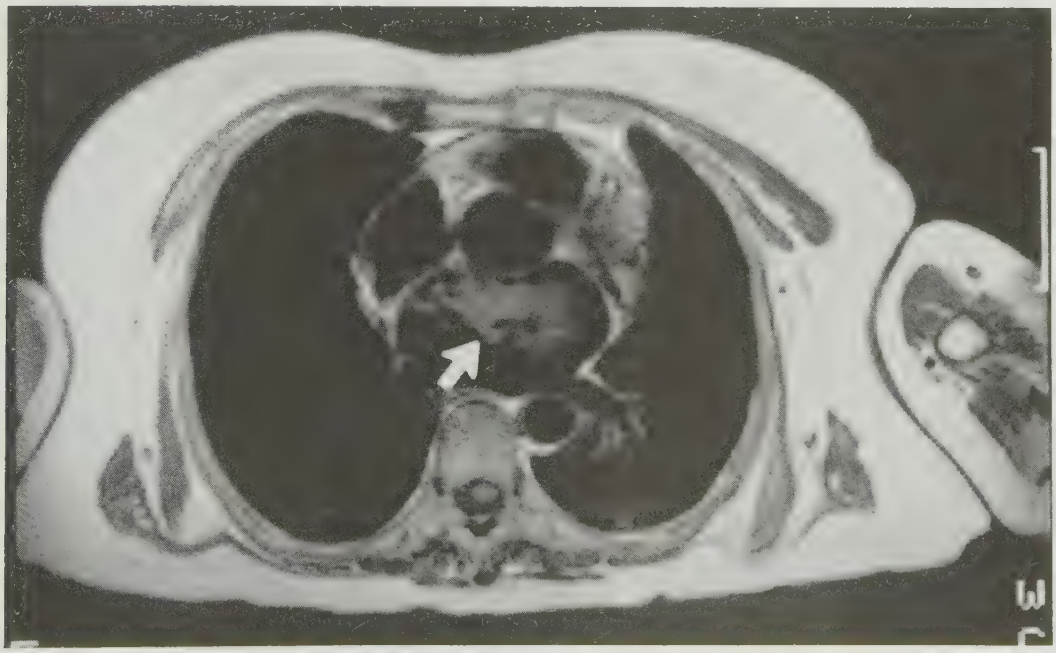

Fig. 51–18. Transverse spin echo NMR image demonstrating large left atrial myxoma (arrow). (Orientation is as in Figure 51–3.)

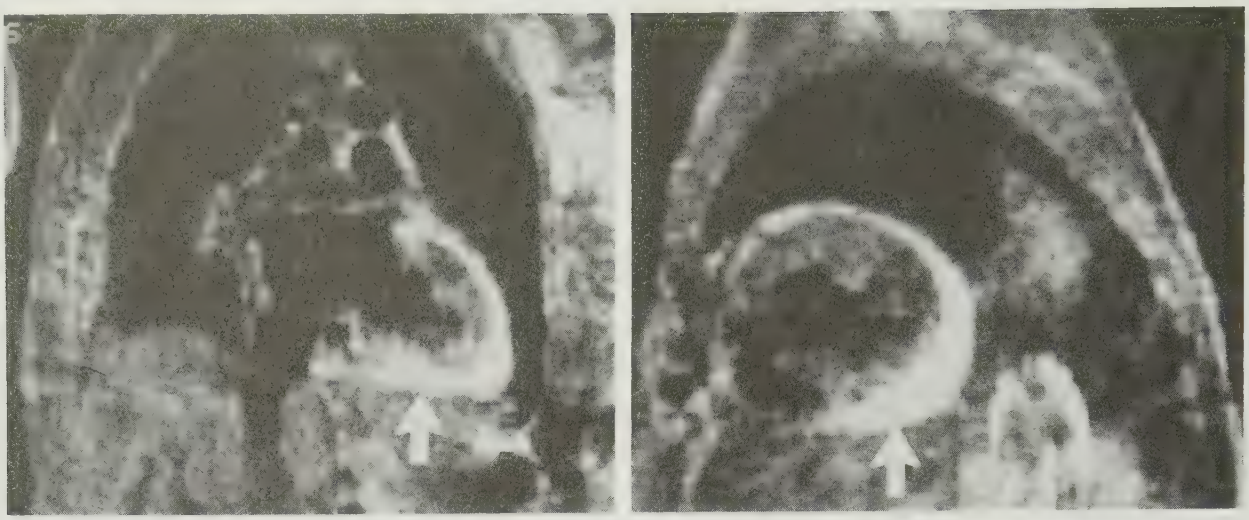

Fig. 51–19. Paracoronal (left) and parasagittal (right) spin echo NMR images demonstrating pericardial effusion (arrows) with high signal intensity. The effusion was determined to have an elevated cholesterol content. Tissues containing lipid have a low T1 and, as a consequence, tend to have a high signal intensity when imaged with the spin echo technique. (Orientations are as in Figures 51–2 and 51–4, respectively.)

NMR imaging but is often difficult to evaluate by echocardiography.[71,72] Common lesions in which ventricular hypertrophy is well defined by NMR include valvular heart disease and pulmonary and systemic hypertension.

Dilated Cardiomyopathy

The presence of a dilated cardiomyopathy is readily detected by NMR (Fig. 51–20). Cardiac chamber sizes are easily evaluated by standard NMR imaging methods. Volume determinations by magnetic resonance imaging correlate well with other methods.[73,74] Cardiac function can also be evaluated, as discussed below, by either the multislice imaging method or with one of the newer cine NMR techniques.[75] However, NMR contrast between cardiac walls and intracavitary blood is often diminished in dilated cardiomyopathy because of relatively slow intracardiac blood flow. Since echocardiography can also evaluate cardiac chamber size and function, the role of NMR imaging in patients with dilated cardiomyopathy remains to be determined. Possible areas in which NMR imaging may provide information not available by echocardiography in these patients include evaluation for segmental cardiac dysfunction, evaluation of possible intracardiac thrombus in locations not well visualized echocardiographically, and assessment of patients with poor echocardiographic windows. As discussed below, NMR spectroscopy may be of use in evaluating the cause of dilated cardiomyopathy.

Cardiac Transplantation

Initial results of NMR imaging in experimental animals and in patients that have undergone cardiac transplantation suggest that transplanted hearts being rejected have elevated T1 and T2 relaxation values in comparison with hearts not being rejected.[76,77] NMR imaging could potentially facilitate noninvasive monitoring of these patients for rejection and thus reduce the need for cardiac biopsies. NMR spectroscopy could also prove to be useful in evaluating patients with a heart transplant, since experimental results suggest that transplant rejection is associated with a substantial decrease in myocardial creatine levels.[78] This area needs further study.

Ischemic Cardiac Disease

NMR imaging can assist in the evaluation of many aspects of ischemic cardiac disease. Since ischemic atherosclerotic vascular disease affects different segments of the myocardium in different manners depending on the blood supply to these segments, the ability of NMR imaging to assess segmental cardiac function is particularly useful.[79] Segmental cardiac function can also be assessed by echocardiography, but the relatively unsatisfactory echocardiographic windows in adult patients sometimes make evaluation of all cardiac segments infeasible.

Ischemic periods too short to cause necrosis do not alter the measured T1 and T2 relaxation times of the myocardium. Thus routine imaging with spin echo pulse sequences alone is unable to detect the presence of myocardial ischemia. Myocardial wall thinning and altered motion in areas of ischemia may be visualized, however, and ischemia may be inferred when such changes are detected. However, new NMR imaging techniques sensitive to flow may eventually allow evaluation of myocardial perfusion as a means of predicting ischemia,[80] and spatially resolved NMR spectroscopy may become a useful tool for detection of myocardial ischemia.[81]

Acute Myocardial Infarction

Acute myocardial infarction causes an increase in both the T1 and T2 relaxation times of the infarcted myocardium.[82–85] The relaxation time changes associated with acute infarction are caused by a combination of factors, including myocardial edema, lipid accumulation in the myocardium, and as yet undefined biochemical changes. Spin density of the myocardium also increases, probably as a result of increased water content. The changes generally are not clearly apparent until 3 to 4 hr after coronary occlusion. Coronary reperfusion tends to accentuate the increase in relaxation times and spin density. With appropriately designed pulse sequences, NMR images will reflect the relaxation time changes

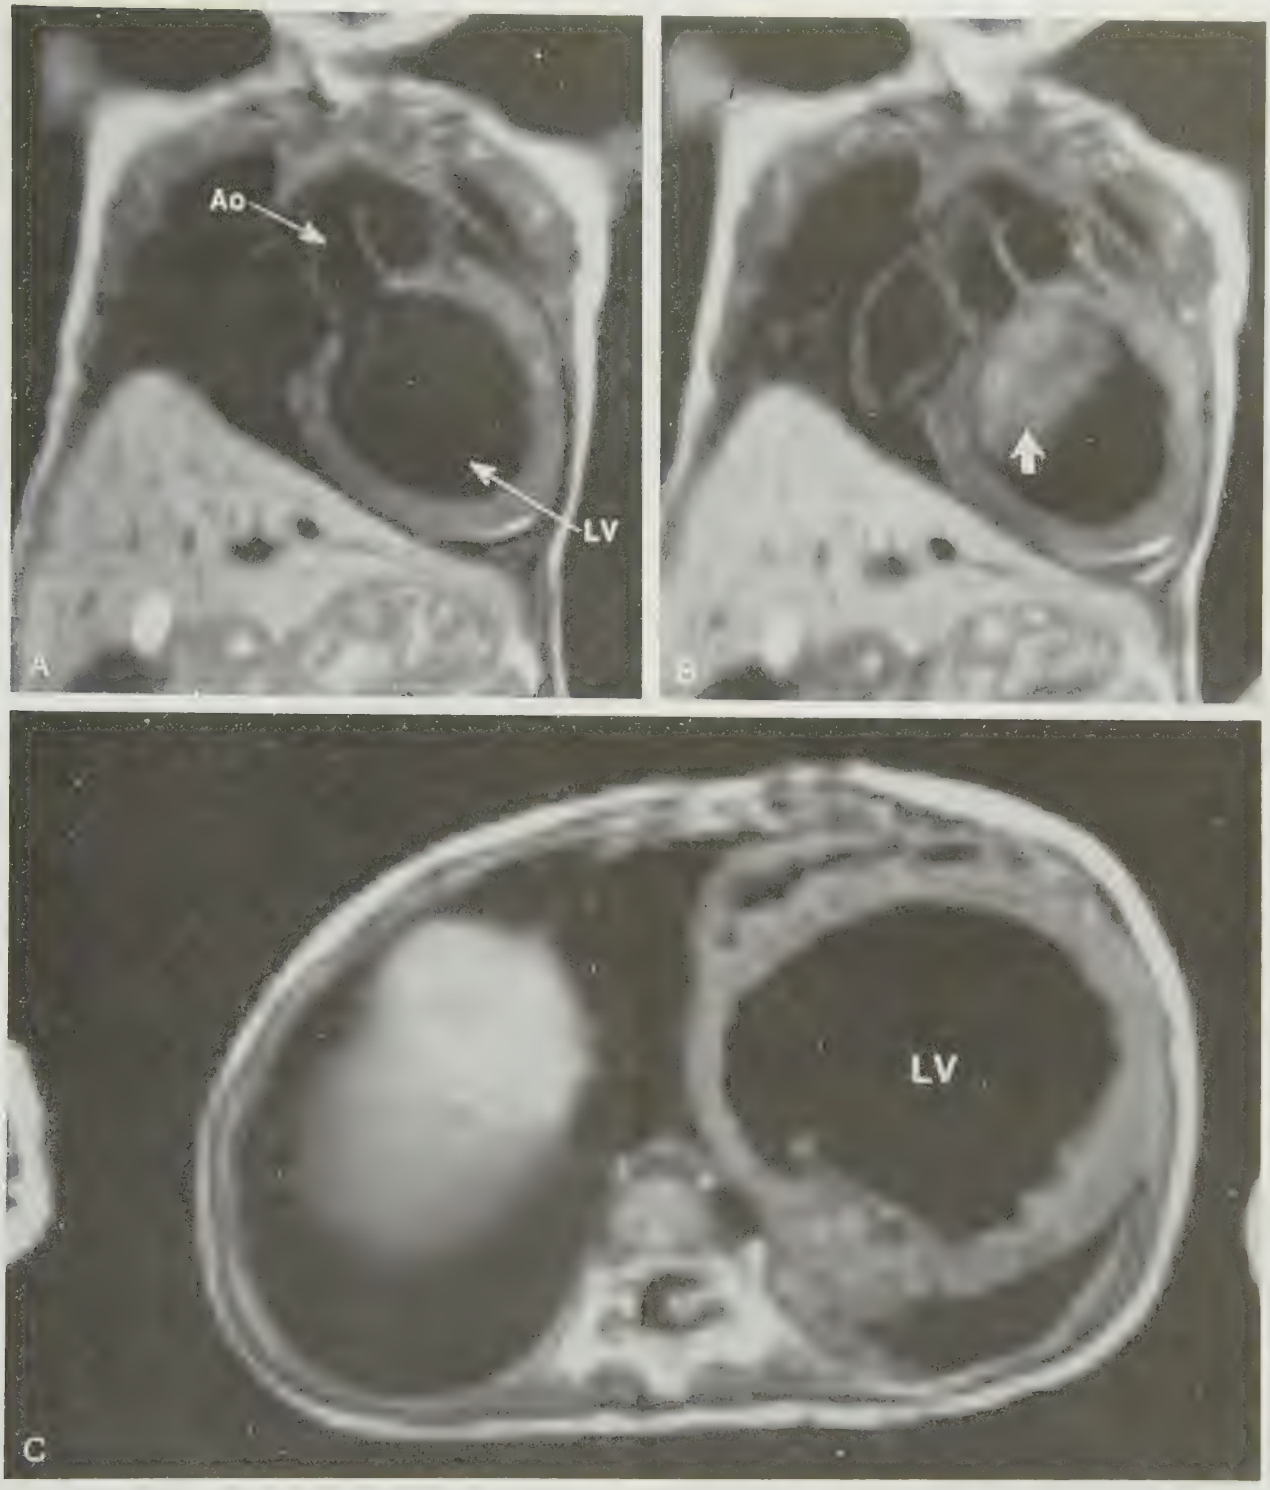

Fig. 51–20. Spin echo images obtained in a 7-yr-old patient with severe dilated cardiomyopathy. A. This paracoronal image was obtained with an echo time of 22 msec. The left ventricular cavity is severely dilated. B. This image was obtained in a paracoronal plane identical to the image in panel A but with an echo time of 15 msec. Note the increased signal intensity of the blood in the left ventricular outflow tract. Presumably, the shorter echo period results in reduced dephasing of spins across imaged voxels, and results in increased NMR signal intensity from theses voxels. Transverse spin echo image demonstrating the severe dilation of the left ventricular cavity in this patient in another plane. Ao = aorta; LV = left ventricle. (Orientation of panels A and B is as in Figure 51–2. Orientation of panel C is as in Figure 51–3.)

induced by acute infarction by showing contrast between normal and infarcted myocardium[86–88] (Fig. 51–21). The location and size of the infarct can then be assessed. Contrast agents, such as gadolinium diethylene triamine pentaacetic acid (DTPA) may facilitate the detection of injured and infarcted myocardium in the initial hours after coronary artery occlusion.[89–91]

Peripheral Atherosclerotic Vascular Disease

Because substantial contrast is generally demonstrated between the lumen and vessel walls by NMR imaging, peripheral arteries are often well visualized by NMR. Stenotic and aneurysmal areas can be clearly demonstrated in the larger vessels. Several experimental and clinical studies of NMR have demonstrated atherosclerotic plaques projecting into the lumen of larger peripheral arteries.[92–94] NMR has the potential for use in the evaluation of atherosclerotic vascular disease and its response to medical and surgical treatment. Current research, which is focused on the tissue-characterization ability of NMR, may make it possible to evaluate noninvasively the composition of the arteries and putative atherosclerotic plaques, and to determine such features as lipid and fibrous tissue content.[95]

Coronary Atherosclerosis

Although the coronary arteries are often visualized on NMR scans,[96,97] direct demonstration of the lesions of coronary atherosclerotic lesions is not possible with currently available NMR systems. Because they are small and move rapidly, coronary arteries are difficult to image. To demonstrate atherosclerotic plaques in these small vessels reliably, it will be necessary to achieve extremely high resolution and prevent motion artifact.

It is possible to determine the patency of aortocoronary bypass grafts with NMR imaging.[98,99] The use of surface coils can increase resolution and facilitate this determination.

Cardiac Functional Assessment by NMR

NMR shows much promise as a tool for cardiac functional assessment. Qualitative evaluation of overall ventricular function is easily made from systolic and diastolic short-axis, long-axis, or four-chamber images (Figs. 51–22 and 51–23). Left and right ventricular ejection fractions can be calculated from sets of systolic and diastolic images, using either Simson's rule or simplified modifications of it.[100,101] Ventricular ejection fractions determined by NMR have correlated well with ventricular ejection fractions determined by other techniques. Regional cardiac wall motion abnormalities can be evaluated either with a multislice rotation method employing spin echo sequences, or with the new cine NMR techniques.[102,103] The spin echo technique generally gives superior myocardial definition; however, the cine studies yield much better time resolution for an equivalent imaging period, and usually have adequate spatial resolution (particularly when implemented with velocity-compensation gradients).

Techniques of Clinical NMR

Optimization of Cardiovascular NMR Images

The quality of cardiovascular NMR images is determined by multiple parameters, some intrinsic to the subject studied and some determined by the NMR imaging system or its operator. A major factor in determining image quality is the signal-to-noise ratio, which is generally increased by increasing field strength. The relation between signal-to-noise ratio and field strength is complex, but seems to be linear at high field strength, where noise from the subject is the predominant form of noise, a situation that is gen-

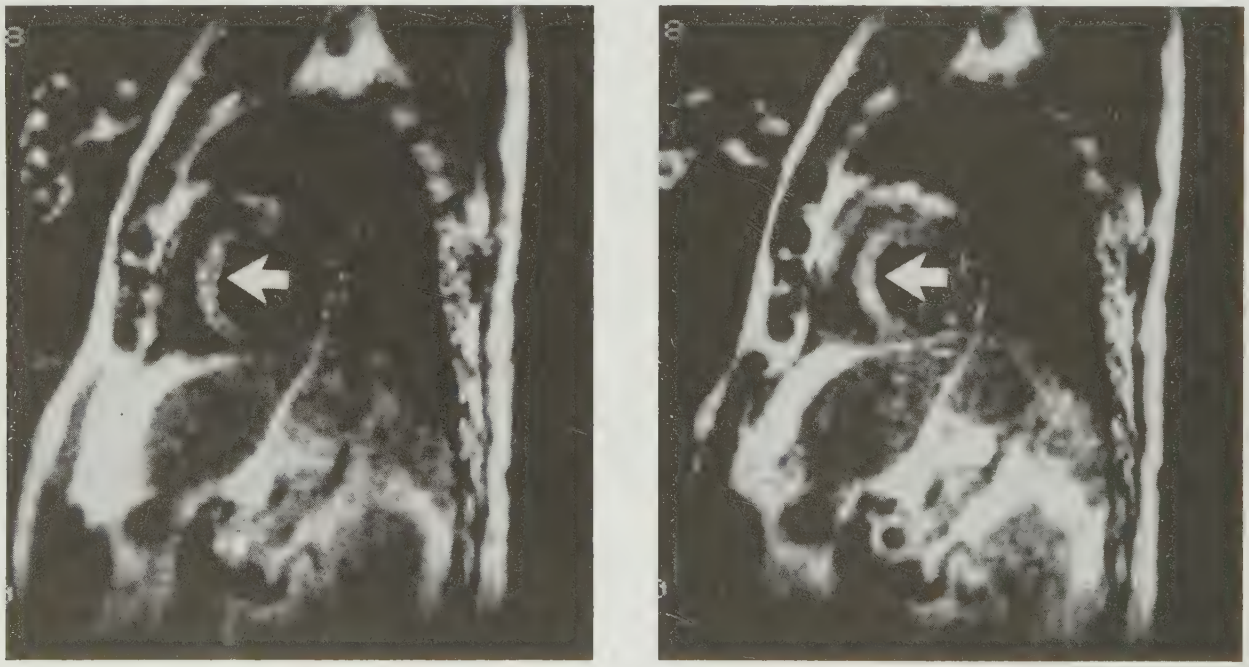

Fig. 51–21. Diastolic (left) and systolic (right) spin echo NMR images in patient with anteroseptal myocardial infarction. Note the increased signal intensity in the anteroseptal region of the left ventricle in comparison with other locations in the left ventricle (arrows). Note also that the contrast between the anteroseptal region and other regions of the ventricle is greater in systole than in diastole. (Orientation is as in Figure 51–4.)

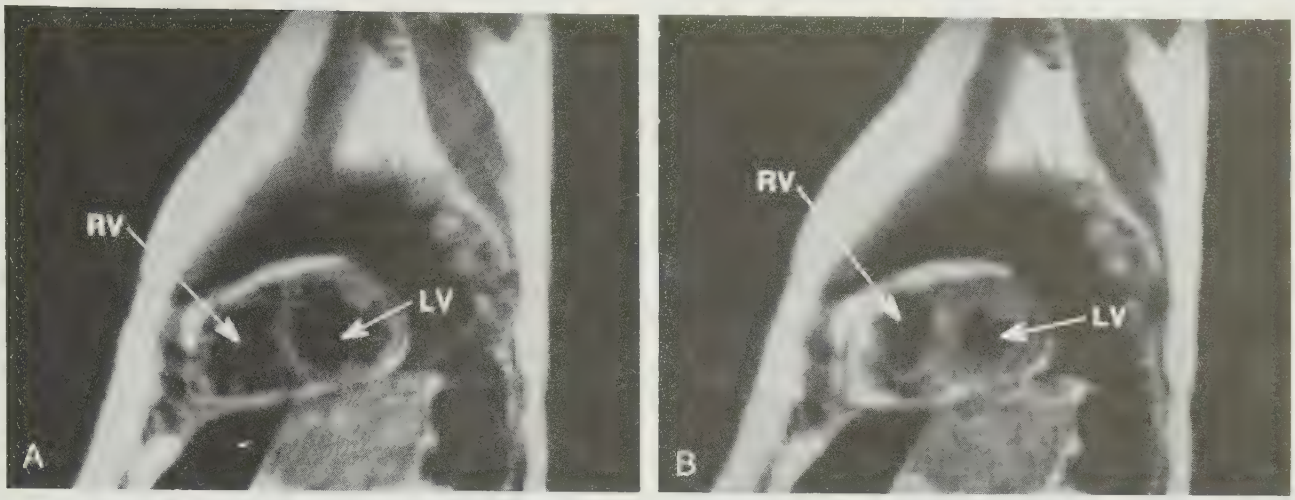

Fig. 51–22. Spin echo parasagittal images obtained in diastole (A) and systole (B) in short-axis sections at the midventricular level. RV = right ventricle; LV = left ventricle. (Orientation is as in Figure 51–4.)

erally prevalent in clinical imaging.[104] The signal-to-noise ratio may be increased by averaging, since signal increases linearly with the number of averages, while noise increases as the square root of the number of averages. Averaging, of course, will extend the time of NMR studies.

Image artifact due to subject motion can substantially degrade NMR images. Motion artifacts can be reduced with the techniques described in Chapter 7. Artifacts due to the presence of metals or other ferromagnetic substances may degrade NMR images. Careful screening of patients before examination is essential in order to prevent such objects from being inadvertently carried into the imager.

The diagnostic utility of NMR images is dependent in large part on the contrast-to-noise ratio between structures of interest. This contrast-to-noise ratio (C/N) is defined as the absolute value of the signal-intensity difference between two structures divided by the square root of the sum of the squared standard deviations of the signal intensities of the two structures[105]:

$$C/N = |SI_A - SI_B|/\sqrt{(\sigma^2{}_A + \sigma^2{}_B)}$$

where SI_A and SI_B indicate the signal intensity in region A and region B, respectively (this formula assumes no cross-correlation in noise between the regions of interest), and where $\sigma^2{}_A$ and $\sigma^2{}_B$ indicate the squares of the standard deviation of signal intensity in regions A and B, respectively.

Contrast can be maximized or minimized by appropriate manipulation of NMR imaging parameters. It is imperative that individuals interpreting NMR studies understand the underlying principles responsible for NMR image contrast. It is particularly important that interpreters of these studies realize that changes in the types of imaging sequences or in their parameters can result in major changes in the appearance of the resultant images without

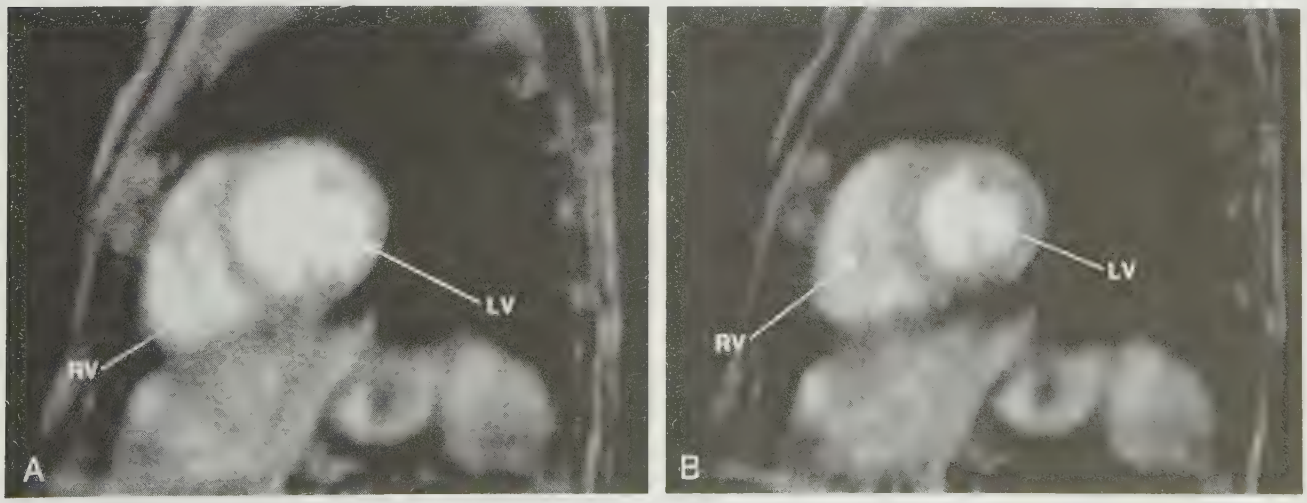

Fig. 51–23. Velocity-compensated FISP (fast imaging with steady precession) parasagittal images obtained in diastole (A) and systole (B) in short-axis sections at the midventricular level. RV = right ventricle; LV = left ventricle. (Orientation is as in Figure 51–4.)

any concomitant change in the imaged subject. Otherwise, the potential for misinterpretation is high.

The contrast between two regions of interest is, in general, a complex function of T1, T2, spin density, and blood flow with any given imaging sequence. Because of these multiple factors, we will consider the effect of these parameters on two commonly used imaging sequences, spin echo and FISP (fast imaging with steady precession).

The standard spin echo sequence, which employs a 90-degree initial excitation radiofrequency pulse, is versatile and can be used to emphasize T1, T2, spin density, or blood flow differences between regions of interest. Although images reflecting only the T1, T2, or spin density parameters can be produced by mathematical combination of sets of spin echo images, it is generally impractical to generate such images for routine clinical use. Furthermore, the quality of these images is degraded by the combination process. Rather, it is more effective in most clinical imaging to generate images that are "weighted" to reflect primarily T1, T2, spin density, or flow differences.[106]

T1 differences may be accentuated by appropriate choice of repetition time (TR) (see Chapter 37) (Fig. 51–24). To provide good delineation of T1 differences, it is necessary to use echo time (TE) (see Chapter 37) values substantially shorter than the T2 values of the tissues of interest. Until recently, most scanners were incapable of employing spin echo sequences with an echo time short enough to adequately detect T1 differences in the myocardium.[107,108]

T2 differences can be emphasized by proper selection of TE (Fig. 51–25). Because of T2 and T2* (effective transverse relaxation time) decay, the signal obtained from sequences with a long TE is often low. Thus the signal-to-noise ratio on images obtained with relatively long TE values is often reduced and image quality suffers.

Spin density differences are accentuated by a long TR and a short TE. Because of the requirement for a long TR, spin-density weighted images usually require a lengthy imaging time.

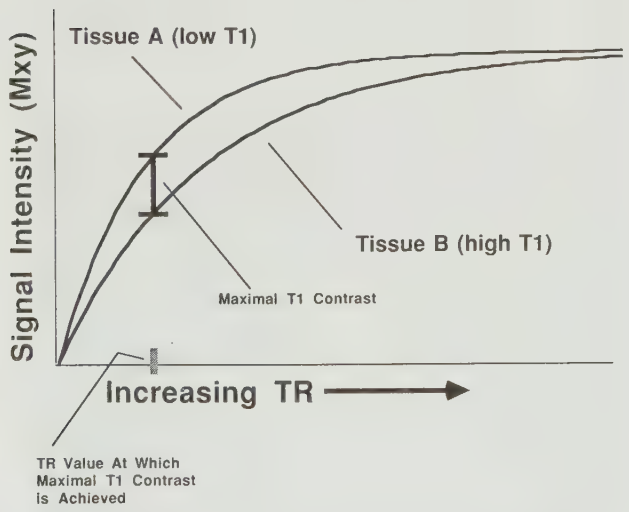

Fig. 51–24. If the T1 values of tissues of interest are known (even approximately), repetition time can be adjusted to emphasize T1 contrast differences between the tissues of interest. Unfortunately, cardiac synchronization of data acquisition interferes with this optimization, since repetition time is limited to multiples of the cardiac cycle with standard spin echo sequences.

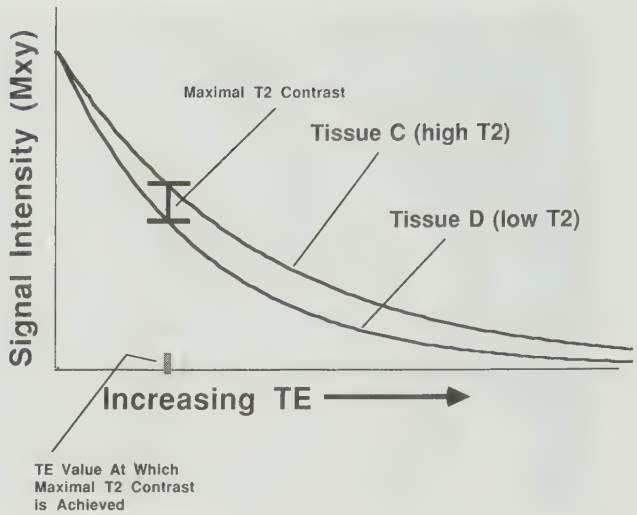

Fig. 51–25. The T2 contrast between two tissues of interest can be maximized by varying echo time. It should be noted, however, that the NMR signal obtained from any given tissue progressively decreases with increasing echo time.

In general, regions with relatively short T1 values in relation to TR tend to appear bright on spin echo images, and regions with relatively long T1 values in relation to TR will appear dark. Regions with relatively short T2 values in relation to TE appear dark and regions with relatively long T2 values in relation to TE will appear bright. Regions with a high spin density appear bright and regions with a low spin density will appear dark.[109]

Rapidly flowing blood has a very low signal intensity on spin echo images because substantial dephasing of nuclei occurs during the TE period. Therefore contrast between vessel walls and rapidly flowing blood or between myocardium and rapidly flowing blood is generally readily apparent. Stagnant or slowly flowing blood will appear brighter than myocardium or vessel wall in many cases because of the relatively long T2 of blood in relation to myocardium, and because of the slice entry phenomenon created by slowly flowing blood. Blood flowing at moderate velocities may appear bright if TE is made very short.

Weighting of imaging parameters to emphasize T1, T2, spin density, or blood flow differences can also be accomplished with FISP and other rapid imaging sequences. These techniques allow manipulation of the pulse flip angle α in addition to TR and TE. Since these sequences are primarily used for obtaining cine NMR studies, it is generally better to keep TR as short as possible so that more images can be obtained in a given interval and time resolution can be maximized.

T1 weighting with FISP is accomplished by increasing α to the 45- to 90-degree range. An increase in TR will accomplish additional T1 weighting. T2 or T2* weighting is produced with short TR values and with α in the 30- to 60-degree range. Spin-density weighting is best produced with a short TE and a low value of α. The signal intensity of flowing blood will be bright in relation to myocardium and vessel walls on most FISP images, because the NMR-sensitive nuclei in stationary structures become relatively saturated during the imaging sequence. Exceptions occur in the

case of extremely rapid blood flow, such as that produced by a stenotic cardiac valve. Blood in these regions of extremely rapid flow may appear dark. The signal intensity of flowing blood can be increased by shortening TE.[110,111]

Dynamic Cardiac NMR Imaging

Functional cardiac evaluation requires excellent time resolution. Rapid acquisition of cardiac NMR images can "freeze" the cardiovascular structures and facilitate such evaluation. Until recently, technical difficulties precluded application of these "real-time" techniques to patients of adult size. Furthermore, image quality was often unsatisfactory with early methods of this type. Newly introduced techniques make it possible to acquire complete NMR images of adequate quality in periods as short as 40 msec. Wider application of these techniques promises to facilitate cardiovascular NMR evaluation greatly.[112]

Another approach, which has achieved considerable success, is to acquire cardiac images from multiple time periods during the cardiac cycle with a standard multislice spin echo imaging sequence, with the acquisition time of each section synchronized to a different point in the cardiac cycle.[113,114] Once acquired, these images can be displayed in a video loop. With standard multislice spin echo imaging sequences, the order of anatomic slice selection can be changed in a rotational manner over several acquisitions. This process is known as multislice rotation and will yield images at different parts of the cardiac cycle in several tomographic sections. This method generally produces superior image quality and is a good technique for evaluation of overall ventricular function. However, its time resolution is limited in practical clinical settings, since only one image per tomographic section is created for each acquisition. Five acquisitions, each requiring 128 or 256 heart beats, would thus produce images at only five different points in the cardiac cycle—an inadequate number for wall motion studies. To produce images at 12 points in the cardiac cycle—probably the minimum acceptable number for wall motion studies—would require 12 acquisitions, which would be impractical clinically from a time standpoint. Modifications of this technique show promise for increasing time resolution. If two spin echo images per slice are obtained with each acquisition, time resolution can be doubled. Time resolution can be doubled again if half-Fourier acquisition is employed.

The new rapid imaging gradient echo sequences such as "FISP" (fast imaging with steady precession), "GRASS" (gradient recalled acquisition in the steady state), and "FLASH" (fast low-angle shot) have greatly facilitated dynamic cardiac imaging. With these techniques, TR can be made as short as 20 msec.[115–119] With such short TR periods, NMR data can be acquired at multiple points during each cardiac cycle. Of course, many NMR data acquisitions are necessary to produce an image. If the process is continued over many (usually 128 or 256) cardiac cycles, separate images can be built up from data obtained at each point of acquisition during the cardiac cycle. These images can be obtained in several tomographic sections orthogonal to the intrinsic cardiac axes. They can be displayed in cine loop format so that cardiac wall motion and blood flow patterns are more easily appreciated. With these methods a complete functional evaluation of the heart can be obtained in only a few minutes (Fig. 51–26).

Flowing blood usually has a higher signal intensity than myocardium on images produced by short TR gradient echo sequences. This effect occurs because the myocardium in a given slice becomes relatively saturated by the repetitive radiofrequency pulses of the short TR sequences, whereas the flowing blood in the slice is constantly being replaced by fresh, unexcited nuclei. Hence, the blood produces a stronger NMR signal than the myocardium in most cases (Figs. 51–27 to 51–29). However, when blood flow is turbulent, there will be a relatively large distribution of velocities across voxels of blood. Under the influence of magnetic field gradients the nuclei within these voxels will accumulate substantial phase differences. These phase differences will diminish the NMR signal produced from the voxel. It follows that the signal intensity of regions of turbulently flowing blood will be low.

Since moving blood usually has a high signal intensity on gradient echo sequences, spatially misregistered signal caused by motion of this blood along magnetic field gradients will also have high signal intensity. The high intensity of this spatially misregistered signal can substantially degrade images. By contrast, spatially misregistered signal from flowing blood imaged with a spin echo technique will have a low signal intensity and is less noticeable. Gradient moment nulling rephases moving spins at the echo and thus reduces the effect of spatial misregistration in gradient echo sequences. Image quality is often substantially enhanced by this process.

NMR Angiography

Since flowing blood has NMR characteristics that differ from stationary tissues, it is possible to produce NMR images that demonstrate regions containing flowing blood as areas of high signal intensity against a dark background, in a manner similar to angiography.[38] There are several techniques for producing these "NMR angiograms." The method that has achieved the most widespread application is that of subtraction arteriography.[120] Two electrocardiographically synchronized images are produced with a different delay, and the resulting images are subtracted. The delay is chosen so that one image will be obtained in diastole and another near peak systole. The diastolic image will show increased signal intensity in the lumen of arterial vessels, as the blood will be essentially stationary. The systolic image will show decreased signal intensity in the lumens of these vessels, as the NMR signal will be dephased by the rapidly flowing blood. The image obtained by subtracting the systolic from the diastolic image will depict the functional arterial tree. If the selection slice is made thick, a projective image will be produced with a striking resemblance to an arteriogram.

The original subtraction arteriography method is susceptible to misregistration artifacts when motion occurs between the time the systolic image is acquired and the time the diastolic image is acquired. Data acquisition during multiple phases of the cardiac cycle with a rapid imaging gradient technique can eliminate a substantial amount of misregistration artifact since systolic and diastolic images are then acquired over the same set of cardiac cycles.

A further modification of the subtraction arteriographic method employs a phenomenon known as gradient refocusing.[121–123] In the standard spin echo pulse sequence, the gradient in the frequency-encoding direction is turned on during the time of data acquisition from the spin echo and prior to the 180-degree pulse. Stationary NMR-sensitive nuclei are rephased by this gradient, but moving NMR-sensitive nuclei exhibit velocity-sensitive dephasing. If ad-

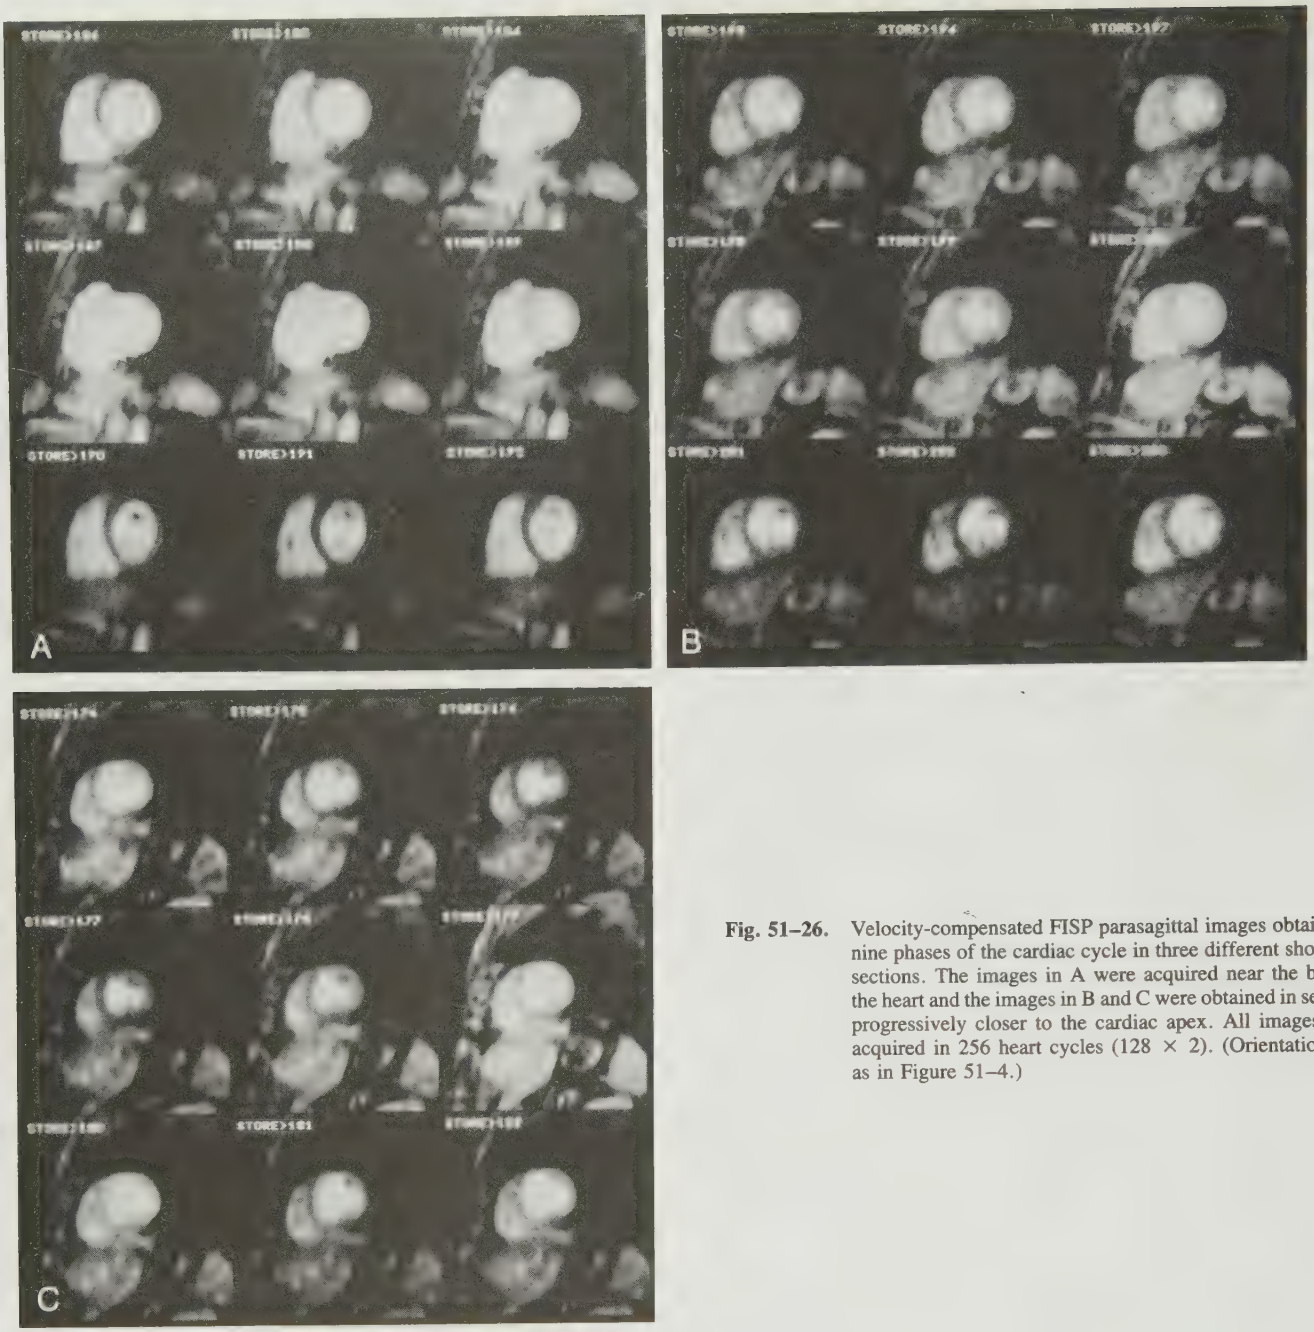

Fig. 51–26. Velocity-compensated FISP parasagittal images obtained in nine phases of the cardiac cycle in three different short-axis sections. The images in A were acquired near the base of the heart and the images in B and C were obtained in sections progressively closer to the cardiac apex. All images were acquired in 256 heart cycles (128 × 2). (Orientations are as in Figure 51–4.)

ditional magnetic field gradients are applied in the frequency-encoding direction in a bipolar (having equal amplitude and opposite direction) fashion, nuclei with constant velocity can be refocused so that they are in phase at the time of the echo, and give substantial NMR signal. Magnetic field gradients can also be added to an imaging sequence in such a manner that dephasing of moving nuclei is strongly accentuated. Subtraction of images generated with dephasing gradients from images generated with rephasing gradients yields an image of the flowing blood. Dephasing and rephasing of gradients can be incorporated into the gradient echo rapid-imaging pulse sequences to decrease acquisition time or to increase the number of phases in the cardiac cycle obtained when the acquisition is synchronized to the electrocardiogram. Acceleration rephasing and defocusing gradients can be added to these sequences. Arterial flow can be distinguished from venous flow with these acceleration-sensitive sequences.

Another method for generating a representation of flow with NMR imaging is the phase display. The NMR imaging process yields a quantitative estimate of the value of the transverse component of the net magnetization vector of the imaged voxels of the subject. This quantity is a complex number with both magnitude and phase. Most NMR images are constructed strictly from magnitude information. However, a separate image derived from the phases of the imaged voxels can also be constructed. This is done by establishing a correspondence between the gray scale of the image and the phase change of the voxels. The zero-degree

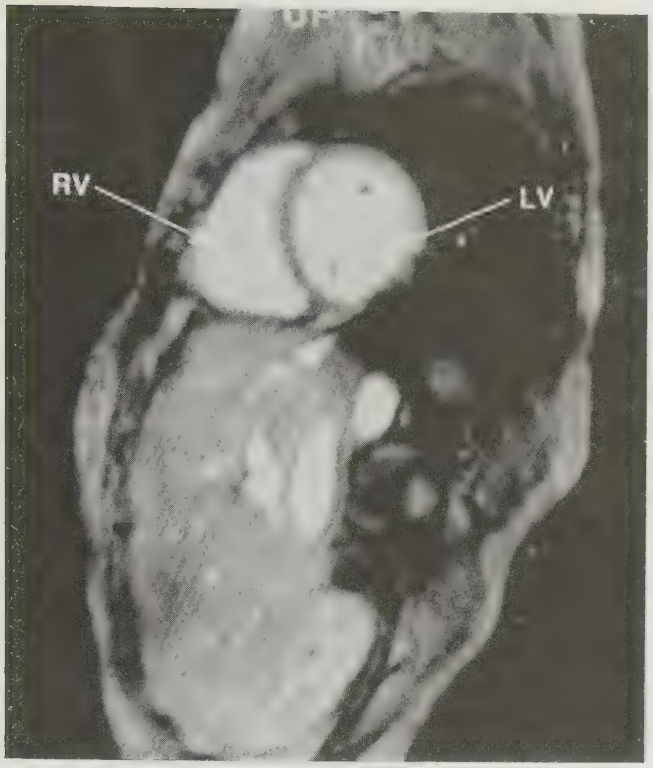

Fig. 51–27. Parasagittal image obtained in a short-axis section near the base of the heart with a velocity-compensated FISP sequence. Note that the blood in the ventricular chambers and blood vessels has a high signal intensity relative to the myocardium and the blood vessel walls, a feature characteristic of these short TR sequences. RV = right ventricle; LV = left ventricle. (Orientation is as in Figure 51–4.)

phase change of the stationary protons is generally set to the midrange of the gray scale, with phase changes of +180 degrees and −180 degrees at the highest and lowest intensities, respectively. Gray scale reversal will occur if the phase change exceeds 180 degrees from the reference phase. Flow and motion manifest themselves as abrupt changes in the signal intensity of the phase images. Phase images are obtainable with many NMR systems in a straightforward manner, and are particularly useful in facilitating the distinction of slow flow from thrombus.[124,125]

Van Wedeen has devised a method for NMR flow densitometry with projective angiography. With this technique, which requires radiofrequency pulses of sufficient bandwidth to affect all protons within the field of view, the phase of the magnetization vector of a moving proton is proportional to its velocity of flow, and the resultant signal intensity of the projective image of the vessel is proportional to the volume of flow through it.[126]

A great advantage of contrast angiography is that selective injections can be made. Selective injection facilitates demonstration of vessels that overlie other vessels or the cardiac chambers. Dixon and colleagues described a method of NMR angiography that is a step toward selective NMR angiography.[127] They employed the principle of adiabatic fast passage, which reverses the magnetization of moving spins, to label blood passing through the field of a surface coil placed on the necks of human subjects. The technique enabled them to visualize the common, internal, and carotid arteries in a projective format.

Chemical Shift Imaging

Two major types of protons contribute to the NMR signal generated by biologic subjects. These are water protons and protons linked to aliphatic carbons. The two types of protons resonate at slightly different frequencies. Dixon developed a novel method to generate images principally from water protons and images derived principally from water protons.[128] This chemical shift imaging method is based on the principle that the centerpoint of a refocused gradient echo can be moved so that the net magnetization vectors of aliphatic and water protons point in opposite directions at the time of data acquisition and therefore tend to cancel.[129] An out-of-phase proton image is formed with this centerpoint shift, and another, in-phase, image is formed. When the images are added, a water image is formed. When the out-of-phase image is substracted from the in-phase image, a fat image is formed. The advantage of this form of imaging is that fat content, rather than T1 or T2 relaxation times, becomes the major source of imaging contrast. The Dixon technique has shown promise as a method for detecting fatty infiltration of the liver.[130] It also may be useful for evaluation of lipomatous tumors of the heart and distinguishing epicardial fat from infiltrative disorders in the paracardiac region. Modifications of this method may prove useful for evaluating arterial vessels for signs of atherosclerosis.

Since the original Dixon method depends on subtraction or addition of images from two different acquisitions, the technique is subject to the effect of misregistration artifacts that may occur because of patient movement during the two acquisitions. Recently developed methods have made it possible to reduce such artifacts by acquiring multiple lines or even entire images subsequent to a single excitation.[131]

Electrocardiographic Synchronization

Synchronization of NMR data acquisition to the cardiac cycle is usually necessary to reduce motion artifact and obtain useful images of cardiovascular structures.[132] The most convenient way to accomplish synchronization with the cardiac cycle is to initiate data acquisition in conjunction with the electrocardiogram[133,134]—a process that is not truly "gating," but rather, synchronization of data acquisition to the cardiac cycle.[135]

Several important technical considerations must be addressed if technically adequate synchronization of the NMR data acquisition is to be achieved. First, the rapidly changing magnetic field gradients will induce electrical currents in the electrocardiographic leads, thereby creating artifacts. These artifacts may confuse the electronic triggering mechanism, causing it to initiate data acquisition at undesirable times. These artifacts also may obscure the electrocardiographic signal, so that the ST segment and other portions cannot be seen. The effectiveness of the electrocardiogram as a tool for monitoring acutely ill patients is thus reduced.

In order to avoid imaging artifacts, electrocardiographic electrodes and leads should be made from nonparamagnetic materials. The artifacts in the electrocardiographic signal may be further reduced by wrapping the leads and placing the electrodes near each other, to reduce the size of the current loops created by the monitoring system.[136,137] In addition, an electrocardiographic monitoring and synchronization device with improved capabilities has

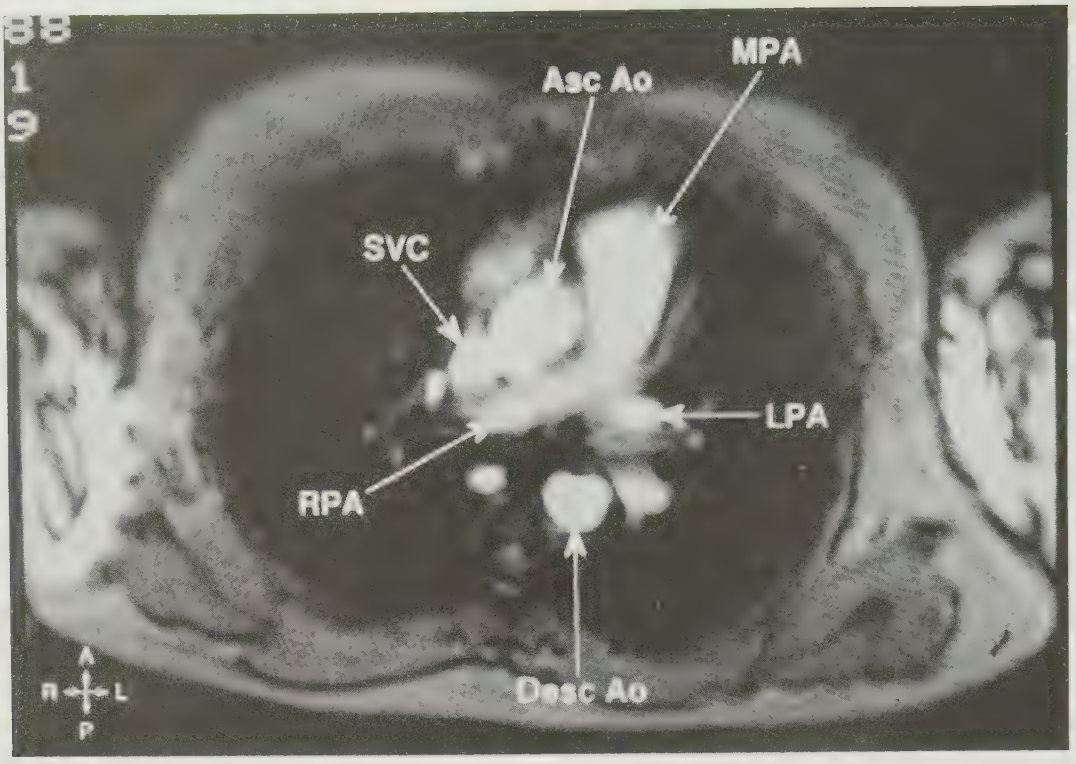

Fig. 51–28. Velocity-compensated FISP paratransverse image obtained in a plane lying along the right ventricular outflow tract to simulate a view analogous to the angiographic "sitting-up view." Asc Ao = ascending aorta; Desc Ao = descending aorta; MPA = main pulmonary artery; LPA = left pulmonary artery; RPA = right pulmonary artery; SVC = superior vena cava; A = anterior; P = posterior; L = left; R = right.

Fig. 51–29. Velocity-compensated FISP transverse images obtained in different phases of the cardiac cycle at 25-msec intervals at the level of the pulmonary artery bifurcation. Sixteen images are shown. Twenty images were acquired in 256 heart cycles (128 × 2). (Orientations are as in Figure 51–3.)

recently been introduced to facilitate active reduction of these artifacts.[138] This device also facilitates identification of abnormalities of cardiac rhythm during NMR studies, and thus improves patient monitoring capabilities. The device employs a time-varying low-pass filter. It takes advantage of the time-varying nature of frequency content of the electrocardiographic signal. The high-frequency components of the electrocardiographic signal are generally contained in the QRS complex. The remainder of the electrocardiogram contains primarily low-frequency components. The gradient artifacts in the electrocardiographic signal are essentially entirely of high frequency. Since the magnetic field gradients are triggered by the QRS complex, and in general are not activated until after the completion of the QRS complex, it is possible to activate the low-pass filter after the QRS complex, and before the effect of the gradients appears in the electrocardiographic signal. An electrocardiographic signal of good quality is thus obtained during NMR data acquisition. Cardiac synchronization of NMR data acquisition may be hindered by arrhythmias. When the irregularities are only occasional it is possible to avoid data acquisition during the time of the irregular beats with proper setting of the filter durations.

Enhancement of NMR Contrast with Paramagnetic Agents

Contrast between different tissues can be accentuated by appropriate choice of NMR imaging pulse sequence parameters, as noted above. Sometimes, however, the spin density, T1 and T2 relaxation times, and motional characteristics of two different types of tissue are so similar that they cannot be clearly distinguished by pulse sequence manipulation. Examples of two such

tissues are normal and injured cardiac muscle in the first hours after coronary occlusion. Several investigators have demonstrated that a paramagnetic ionic form of gadolinium, a rare earth element, can accentuate the contrast between normal and injured myocardium after intravenous injection.[139–142] Because gadolinium is toxic in its free ionic form, it is complexed with diethylene triamine pentaacetic acid (DTPA), a chelating agent. Like most paramagnetic agents, gadolinium-DTPA shortens both T1 and T2, with the more substantial shortening occurring in T1.[143–145] When given after complete coronary occlusion, it modifies the NMR relaxation characteristics of the normally perfused myocardium. When T2-weighted pulse sequences are employed, the normal myocardium will appear dark in relation to the injured myocardium. Greater degrees of T2 weighting are associated with greater contrast between normal and injured myocardium. Conversely, heavily T1-weighted sequences will cause images of normal myocardium to have increased signal intensity in comparison with images of injured myocardial tissue. Recent evidence suggests that when gadolinium-DTPA is given after complete coronary occlusion, the area of infarction is defined, as opposed to the entire region at risk for infarction.[146]

Clinical Cardiac NMR Spectroscopy

Studies of the human myocardium with NMR spectroscopy are just beginning. A great deal of technical development will be necessary before NMR spectroscopy can be routinely applied in a clinical setting. Whitman and colleagues[147] performed ^{31}P NMR spectroscopy with a surface coil placed directly over the sternum in an 8-mo-old female infant with a congenital cardiomyopathy of uncertain cause. No attempt at spatial localization of signal was made, but it was noted that the patient had massive cardiomegaly with minimal skeletal muscle development, so that the contribution of skeletal muscle to the cardiac nuclear magnetic resonance signal was presumably minimal. The infant's myocardial creatine-to-inorganic-phosphate ratio was determined and was found to be half that found in a normal control infant. Intravenous and oral glucose were administered. This treatment raised the myocardial creatine-to-inorganic-phosphate ratio from 1.0 to 1.8 without affecting this ratio in skeletal muscle. Medium-chain triglycerides had no noticeable effect on myocardial metabolism.

Rajagopalan and colleagues[148] studied six normal subjects and six patients with hypertrophic cardiomyopathy with ^{31}P NMR spectroscopy. Rotating frame zeumatography (see Chapter 37) was employed for spatial localization. Because of technical limitations on the depth of sampling, spectra were apparently obtained primarily from the right ventricular free wall. The normal subjects were determined to have a creatine-to-ATP ratio of 1.53 ± 0.12. One patient with severe right ventricular hypertrophy and a history of cardiac decompensation had a creatine-to-ATP ratio of 0.9 ± 0.2 as determined on three separate occasions. The remaining patients, who did not have right ventricular hypertrophy (though all had substantial interventricular septal and/or left ventricular free wall hypertrophy) had myocardial creatine-to-ATP ratios within the normal range.

Bottomley and Andrew[149] employed ^{31}P NMR spectroscopy to evaluate seven normal control subjects and four patients with confirmed acute anterior myocardial infarction 5 to 9 days after the onset of symptoms. Spatial localization of signal was performed with a surface coil in conjunction with the DRESS (depth-resolved surface-coil spectroscopy) technique. Proton spectroscopic imaging was employed to localize endocardial, epicardial, or transmural regions of interest. Substantial reductions in the endocardial creatine-to-inorganic-phosphate ratio were noted in the patients in comparison with controls.

Hazards of and Contraindications to NMR

Standard clinical imaging magnets present no known hazards to biologic materials. Three different magnetic fields are employed by such magnets. These are 1) the relatively large static mangetic field, 2) smaller, but rapidly varying magnetic fields secondary to the magnetic field gradients, and 3) radiofrequency pulses. Guidelines set by the Food and Drug Administration keep the strength of these fields well below levels that could cause significant biologic effects.[150–153] Animal studies evaluating the influence of static magnetic fields have not demonstrated significant bioeffects for fields of up to 2 Tesla. Chinese hamster cells and human lymphocytes incurred no cytogenetic damage in a study exposing them to moderate and high static magnetic field strengths and to prolonged stimulation with time-varying magnetic field gradients and radiofrequency pulses. The amount of radiofrequency power deposition that these cells were subjected to was far in excess of that given during clinical imaging studies.[153] Thousands of patients have undergone NMR studies without any noticeable immediate or longterm sequelae. Because these magnets do attract ferromagnetic objects, extreme caution should be employed in approaching magnets with objects containing iron or other ferromagnetic materials. It is best to keep an NMR magnet in a room from which such objects are barred. A number of unfortunate accidents have occurred because ferromagnetic objects (such as iron oxygen cylinders or wrenches) came too close to a magnet.

Implanted metallic objects are a subject of particular concern, since they could potentially undergo undesirable torquing movements if the magnetic field is sufficiently strong and if they contain sufficient ferromagnetic material. Fortunately, surgical clips and sternotomy wires (usually stainless steel) implanted in the chest and abdomen are often only weakly ferromagnetic. Furthermore, these devices quickly become immobilized by surrounding fibrous tissue. Patients with these implants can be routinely studied; however, the wires and clips may cause image artifact.

Intracranial aneurysm clips do not become immobilized by fibrous tissue, however, and can undergo torque in a magnetic field. Although nonferromagnetic aneurysm clips are now available, NMR studies of patients with these intracranial clips are contraindicated unless the clip is specifically known to be nonferromagnetic. Other types of intracranial ferromagnetic objects or materials may also contraindicate NMR studies. Welders are prone to accidents that may result in the intracranial implantation of ferromagnetic chips. One case has been reported in which a patient who had suffered such accidents sustained damage to his optic nerve.[154]

Prosthetic heart valves manufactured after 1964 contain little ferromagnetic material. Hence, patients with these valves in place can be routinely studied.[155] Heart valves manufactured before 1964 may contain substantial ferromagnetic material. Patients with these valves in place should be studied only if their valve type has been evaluated and found to exhibit acceptable torquing in a magnetic field of similar strength to the contemplated imaging field.

The presence of a cardiac pacemaker is a contraindication to

NMR studies, mainly because of concern that the pacemaker electronics might be damaged.[156] It is also possible that magnetic field gradients could induce currents in the pacemaker leads and that these currents could be recognized as cardiac activity by the electronic sensing mechanisms of the pacemaker. The pacemaker might then be improperly inhibited. Another possibility is that the reed switch of the pacemaker could be activated, causing it to pace in the asynchronous mode. There is a theoretical concern that current induced in pacing wires by the magnetic field gradients could actually cause electrical stimulation of the heart. Many patients have now been studied in whom temporary pacing wires were left in place after surgery, and amputated at the point of passage through the patient's skin. No abnormal effects have been observed in these studies, except for some image artifact.

Pregnancy is presently a relative contraindication to NMR studies, though the magnetic field levels used in clinical imagers have no known effects on the embryo, and though patients have undergone NMR imaging during all trimesters of pregnancy without reported ill effect on the mother, fetus, or infant. When maternal health considerations require diagnostic studies, NMR may be preferable to methods that employ roentgen rays, such as computed x-ray tomography or angiography.

Summary

Clinical NMR is a complex diagnostic tool that demands much of the examining physician. However, NMR promises to facilitate the diagnostic evaluation of congenital and acquired cardiovascular disease in many ways. Current NMR techniques can provide excellent anatomical and functional definition of many aspects of cardiovascular disease. NMR techniques being developed may greatly increase the clinician's ability to evaluate the cardiovascular system metabolically.

POSITRON EMISSION TOMOGRAPHY

Considerable experimental work has demonstrated that positron emission tomography (PET) has important potential applications in the evaluation of cardiovascular disease.[157,158] Clinical studies of this imaging method have primarily evaluated its efficacy in adult ischemic heart disease, but there are now several reports of the use of PET to assess patients with cardiomyopathy of various causes. PET can provide considerable information about regional myocardial perfusion and metabolism, within its inherent limitations of spatial and temporal resolution. Because of these limits, which particularly serve to reduce the quality of studies in patients with small hearts and rapid heart rates, cardiac PET scanning has not been widely applied in pediatric populations. As patients with congenital heart disease age, however, myocardial dysfunction becomes progressively more common. PET scanning may have an important role to play in the clinical evaluation of these older patients.

An Overview

PET scanning employs positron-emitting radionuclides. Positrons travel a short distance in tissue before colliding with an electron. The collision results in annihilation of both electron and positron, with the release of two 511-keV photons at approximately 180-degree angles. Since the photons are produced at the same instant, they will strike a surrounding detector ring simultaneously, except for a slight difference in time of flight dependent on the relative distance of the positron-electron collision from the center of the detector ring. With computer methods, it is possible to use the virtual coincidence of detection of the photon pair to assign the location of the positron-electron collision spatially in a relatively exact manner. The location of the original radionuclide producing the positron can then be inferred with a modest amount of ambiguity determined by the average distance that the positron travels prior to collision. The number of radionuclide particles present in each small region (voxel) of a tomographic plane defined by the detector ring is then estimated from the number of photons arising from the voxel, and a tomographic image is subsequently reconstructed from this estimate.[159] Carbon, oxygen, and nitrogen all have positron-emitting isotopes. Thus many biologic compounds of interest can be labeled and used as tracers.[160] Unfortunately, these isotopes have very short half-lives. Hence, an on-site cyclotron and organic synthesis laboratory is necessary to exploit such physiologic tracers. Rubidium-82, which can be produced with an on-site radionuclide generator, may be a more practical tracer for myocardial perfusion studies.

Clinical Studies in Ischemic Heart Disease

Identification of myocardial ischemia is a problem of major importance in diagnostic cardiology, and one that has become of particular concern in the past few years, with the introduction of methods for salvage of endangered myocardium. Ischemic tissue is at risk for damage, but potentially could resume its role as normally functioning myocardium if the hemodynamic cause for the ischemia were eliminated. When myocardium has suffered irreversible injury, however, aggressive intervention to relieve the causative coronary obstruction only exposes the patient to needless risk. It follows that the appropriateness of therapeutic decisions in patients with suspected ischemic heart disease depends, in many cases, directly upon the accuracy with which normal, ischemic, and irreversibly injured myocardial tissue can be identified and anatomically distinguished.

Quantitative blood-flow measurements are not feasible with single photon radionuclide methods because the variable attenuation of the photons produced by these radionuclides cannot be easily corrected for.[161] By contrast, the coincidence-detection method used by PET scanners facilitates determination of absolute tracer concentration, and makes quantitative blood-flow determination at least theoretically possible. The short half-life of the positron-emitting radionuclides employed facilitates sequential examination, which might be performed to follow the evolution of an episode of ischemia or infarction. Because resting coronary blood flow is decreased only when coronary artery narrowing is in excess of 85%, resting cardiac perfusion studies are insensitive for detection of coronary artery disease.[162] The presence and location of coronary disease can be inferred when characteristic regional perfusion abnormalities become apparent with exercise or after pharmacologic vasodilation with such agents as dipyridamole.

Radionuclide compounds that have been successfully employed for perfusion scanning with PET include ^{13}N ammonia, rubidium-82, and ^{15}O water. Each of these compounds has advantages and disadvantages as a perfusion tracer. ^{13}N ammonia, which must be produced by a cyclotron, has a physical half-life of 10 min, a first-pass retention or extraction factor in the myocardium of 80%, and a biologic half-life of over 1 hr.[163] ^{13}N ammonia exists in the blood

in equilibrium with the ammonium ion ($^{13}NH_4^+$). At physiologic pH, 95% of the tracer is in the ionic form. This ion is trapped within myocardial cells by the glutamine synthetase reaction. This reaction is energy dependent and operates at lower rates during acute myocardial ischemia and pH levels below 7.0. Thus decreased uptake of ^{13}N ammonia (and consequent underestimation of flow) is apparent under these conditions. Decreased uptake is also apparent at high flow rates (>2.5 ml/min/g). However, for most physiologic conditions, estimates of regional myocardial blood flow with ^{13}N ammonia appear to be reasonably accurate when properly corrected for tracer decay.

The myocardium extracts almost 100% of ^{15}O water on the first pass, and its uptake is not affected by metabolic factors. However, the short half-life (2 min) of this tracer, which must be produced in a cyclotron, creates technical difficulties, and the high concentration of ^{15}O water in the lungs and blood may necessitate subtraction of blood pool activity.[164] Blood-pool activity may be evaluated separately by PET imaging after administration of small quantities of ^{15}O carbon monoxide. Rubidium-82 also has a short half-life (76 sec) but can be produced by generator.[165] The extraction fraction of rubidium is only about 50%, and varies with metabolism and blood flow. This relatively low and variable extraction fraction complicates quantitative evaluation of myocardial blood flow with rubidium. However, promising results have been obtained in experimental animals with a tracer kinetic model, which enables correction for this variable extraction.

Qualitative analysis of PET perfusion scans has demonstrated good correlation of exercise-induced perfusion defects with regions of myocardium supplied by obstructed coronary arteries. Schelbert and colleagues examined 13 normal volunteers and 32 patients with angiographically documented coronary artery disease at rest and after dipyridamole treatment.[166] PET scans were performed with ^{13}N ammonia. The normal volunteers showed no perfusion deficits. In the patients, 52 of 58 coronary stenoses were correctly identified. All patients with double- and triple-vessel disease were correctly identified and 15 of 16 patients with single-vessel disease were correctly identified. In a subgroup of 19 patients, exercise planar thallium-201 perfusion studies were also performed. Planar thallium evaluation correctly identified the area of coronary artery stenosis in 11 of 19 cases. PET correctly identified the stenosis in 17 of 19 cases. The presence of coronary stenosis has also been identified with rubidium-82, and ^{15}O water.

Assessment of regional myocardial metabolism with PET has also been found helpful in patients with ischemic heart disease. When myocardial cellular glucose uptake mechanisms are functioning, ^{18}F deoxyglucose will be phosphorylated and trapped inside myocardial cells. Experimental evidence suggests that glucose uptake is preserved even in the presence of severe ischemia causing loss of regional contractility, provided cell damage is not irreversible.[167] Myocardial uptake of ^{13}N ammonia is decreased by such ischemia, as has been noted. Thus when both ^{13}N ammonia and ^{18}F deoxyglucose are administered, regions in which uptake of both tracers is depressed can be identified as irreversibly injured, and regions in which only ^{13}N ammonia uptake is decreased can be identified as ischemic but potentially salvageable myocardium. Using this method of evaluation, Tillisch and colleagues studied 17 patients who had preoperative abnormalities of left ventricular wall motion.[168] They predicted that wall-motion abnormalities in regions of preserved ^{18}F deoxyglucose uptake but depressed ^{13}N ammonia uptake would be reversible by coronary bypass surgery and that wall-motion abnormalities in regions where both isotopes was depressed would not be reversible. Wall motion was evaluated by radionuclide or contrast angiography or both. Reversibility was correctly predicted in 35 of 41 myocardial segments and irreversibility in 24 of 26 segments. By contrast, electrocardiographic evidence of irreversibility (presence of a pathologic Q wave attributable to a hypokinetic myocardial segment) was relatively inaccurate in predicting the return of contractile function. Studies performed with this double-tracer technique in patients with acute and chronic myocardial infarction suggested the presence of persistently hypoperfused but viable regions of myocardium that were not apparent by electrocardiography or gated-wall-motion radionuclide studies.

Myocardial free fatty acid and uptake and metabolism is depressed by ischemia. Thus ^{11}C palmitate can be used as a tracer for evaluation of the extent of myocardial ischemia and its response to treatment. Sobel and colleagues performed PET studies with ^{11}C palmitate in 19 patients with the diagnosis of transmural myocardial infarction upon hospital admission and again 48 to 72 hr after intracoronary administration of tissue-type plasminogen activator or streptokinase.[169] Thrombolysis occurred in 11 of the patients. The regions of coronary occlusion were apparent as perfusion defects on the initial PET scans. In each instance angiographic evidence of coronary reperfusion was accompanied by improvement in the uptake of ^{11}C palmitate in the jeopardized region. Interestingly, myocardial wall-motion abnormalities often did not immediately improve in the reperfused areas. Thrombolysis did not occur in 8 patients, and there was no improvement in the PET studies of these patients.

Normal subjects exhibit a homogeneous uptake of ^{11}C palmitate. The clearance of ^{11}C palmitate from the myocardium occurs in a biexponential fashion. The rapid first phase of clearance is determined by the rate and amount of ^{11}C-labeled carbon dioxide release caused by the oxidation of the palmitate. The second, and slower, phase is thought to be determined by incorporation of ^{11}C into the endogenous lipid pool. Grover-McKay and colleagues studied 10 patients at rest and during atrial pacing with ^{11}C palmitate PET.[170] During the pacing, it was noted that ^{11}C clearance half-times were 17% longer and residual fractions 14% higher in normal myocardium than in myocardium at risk. The findings were interpreted as suggesting that metabolic reserve for free fatty acid oxidation is impaired in myocardium supplied by stenotic coronary arteries.

Clinical Studies in Cardiomyopathy

Several reports have documented abnormalities in cardiac PET studies of patients with cardiomyopathy. Geltman and colleagues studied 13 normal subjects, 17 patients with congestive cardiomyopathy, and 6 patients with transmural myocardial infarction with ^{11}C palmitate PET scans.[171] Studies obtained from the normal subjects demonstrated homogeneous accumulation of ^{11}C palmitate within the myocardium. Studies of patients with transmural myocardial infarction were characterized by discrete regions of depressed accumulation of the tracer, corresponding to the region of infarction, surrounded by regions of homogeneous tracer uptake in the residual normal myocardium. The studies obtained from patients with cardiomyopathy, however, demonstrated substantial spatial heterogeneity of tracer distribution throughout the entire myocardium. This spatial heterogeneity correlates with patholog-

ical findings in patients with congestive cardiomyopathy demonstrating the presence of patchy and variable fibrosis and with histochemical evaluations suggesting patchy metabolic derangements, including depression of oxidative phosphorylation. It was suggested that spatial heterogeneity of ^{11}C palmitate uptake might prove to be a useful tool for early detection and characterization of cardiomyopathy.

Schelbert and colleagues investigated the metabolism of ^{11}C palmitate with PET in 5 normal volunteers and 16 patients with ventricular dysfunction, including idiopathic dilated cardiomyopathy, and cardiomyopathies secondary to doxorubicin (Adriamycin) cardiotoxicity, sickle cell anemia, myocarditis, hypertension, and ischemia.[172] Subjects were studied after an overnight fast and after an oral glucose load. In the normal subjects, myocardial ^{11}C palmitate in the early rapid phase of redistribution fell by 43% and the tracer clearance half-time increased by 46%. In 9 patients, the response was similar to that in normal controls. In 7 patients, however, there was a "paradoxic" response characterized by a 30% increase in the myocardial tracer content in the early rapid phase of clearance and a 36% decline in clearance half-time. The reason for the paradoxic response, which was independent of the cause of disease, but which was most apparent in the patients with the most depressed ventricular function, was unclear to these investigators. They suggested that the response might be related to a depression of citric acid cycle activity in severe cardiomyopathy.

Perloff and colleagues studied patients with Duchenne's muscular dystrophy with PET, employing ^{18}F deoxyglucose and ^{13}N ammonia.[173] They found that ^{13}N ammonia activity was selectively decreased in the posterobasal and posterolateral walls of the left ventricle in 13 of 15 patients, and that ^{18}F deoxyglucose activity was increased in the same regions in 11 of 12 patients. They concluded that the patients in whom the abnormalities were demonstrated had either a reduction in regional blood flow or regional metabolic alterations in uptake and trapping, or both. These findings are of considerable interest, in view of autopsy findings in patients with Duchenne's dystrophy, which consistently demonstrate a predilection for myopathic involvement of the posterobasal and lateral left ventricular walls, with relative sparing of the ventricular septum, right ventricle, and atrial myocardium.

Studies of PET-Labeled Drugs

Recently, labeling of drugs with positron-emitting radionuclides has become possible.[174] Calcium antagonists, beta-blockers, and positive inotropic compounds can be so labeled, and their myocardial distribution can be studied with PET. Although these studies are just beginning in humans, the possibilities for regional myocardial evaluation of drug affinity or receptor concentration are exciting.

Summary

Positron emission tomography is a complex diagnostic method that is still in its infancy. Major technical problems remain to be solved. Improved spatial and temporal resolution will be required before PET can be applied effectively to the evaluation of a number of disorders of particular concern to pediatric cardiologists, such as subendocardial ischemia in aortic stenosis or the regional myocardial metabolism of congenital heart disease in infants. However, much progress has been made with the development of PET and there is good reason to expect that this progress will continue.

CHAPTER 52

Computed Tomography

Barry D Toombs

One of the most important advances in medicine of the recent past has been the development and refinement of computed tomography (CT) scanning. When first introduced in 1973, CT promised to revolutionize noninvasive diagnosis of diseases occurring inside the body. Pioneering work in back-projection mathematics by Godfrey Hounsfield made this new technique possible.[1] For the first time, roentgen rays were coupled with a computer for the purposes of both generation and processing, thereby creating a digital image. CT was the first of a new group of digital imaging devices that now includes computerized sonography, magnetic resonance imaging, positron emission tomography (PET scanning), digital radiography, and digital subtraction angiography.

In current CT scanners, a moving roentgen ray tube mounted in a circular housing called a gantry sends a thin fan-shaped roentgen ray beam through the centrally positioned patient. After passing through the patient, the roentgen ray beam impinges on an array of receptors (detectors) in the gantry on the opposite side of the roentgen ray tube (Fig. 52–1). Electronic signals produced by the detectors are then sent to the computer for processing. An image or "slice" created on a digital matrix is then displayed on a television monitor. Because the image data are stored in a computer, one can interact with the data to alter the image display and to perform a variety of anatomic and physiologic calculations.

CT provides unique three-dimensional anatomic information that is not available from other sources. CT is useful in imaging virtually all the structures in the body, especially those with little spontaneous motion. Cardiac imaging requirements are far more demanding than those for other parts of the body because of the rapid, complex movements that take place during each cardiac cycle. This is one reason why other imaging techniques with high sampling rates including cineangiography and two-dimensional echocardiography are better suited for cardiac diagnoses. Current conventional CT scanners take 0.6 to 5 s to obtain only one scan, and there is generally an interscan delay of at least 1 s before the next scan can begin. These factors have limited CT's utility in the evaluation of intracardiac disorders such as intracardiac shunts, valvular abnormalities, and some myocardial diseases. However, CT can provide useful information about many other diseases affecting the heart, great vessels, and mediastinum.

One advantage of CT over some of the other imaging techniques is its three-dimensional capability. A series of sequential images can be "stacked" on one another, creating a cubic matrix or volume. Once the volume has been created, one can manipulate data to display images in virtually any plane.

Another advantage that CT possesses is its superior contrast resolution, that is, its ability to separate tissues that are only slightly different in their roentgen ray absorption characteristics. Also, CT uses a tomographic technique that eliminates undesirable overlap from adjacent structures.

PERFORMING CT SCANNING

CT scanning is well tolerated by most patients, but the patient should answer several preliminary questions before commencement of the CT examination. A brief history and pertinent physical examination are useful in tailoring the CT examination to the patient. Questions about prior intravascular iodinated contrast tolerance should be answered, and a recent serum BUN and/or cre-

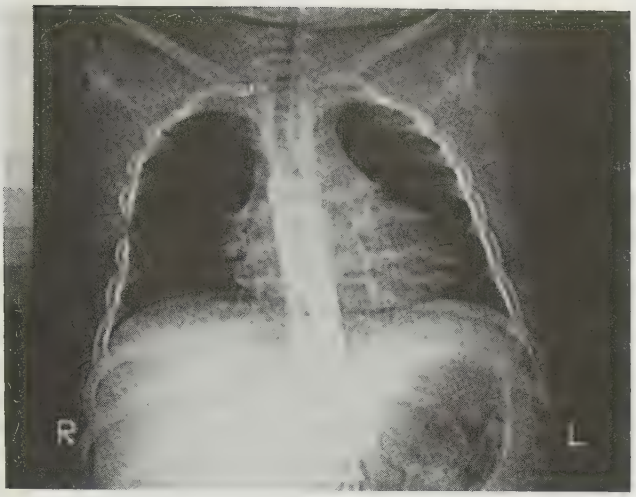

Fig. 52–1. A digital radiograph of the chest. This image is produced as the patient is moved through the scanning gantry while the roentgen ray fan beam is turned on. The image is displayed on the monitor. The vertical scale on the right of the image is a reference scale in centimeters.

atinine should be available. If the patient has had a prior contrast reaction, the nature of the reaction should be elucidated. If the reaction was mild—for example, hives, vomiting, or mild facial swelling—we generally give intravenous diphenhydramine hydrochloride (Benadryl) (1.5 mg/kg) and 25 to 100 mg of hydrocortisone sodium succinate (Solu-Cortef) before injection of contrast. For patients with histories of severe contrast reactions (hypotension, laryngospasm, and/or pulmonary edema), careful reassessment of the necessity of the examination is made; CT of the heart and mediastinal structures is very limited without the use of IV contrast. If the examination is still deemed necessary despite the increased chance of significant allergic reaction, the patient should be treated with diphenhydramine hydrochloride (Benadryl) (1.5 mg/kg, maximum 50 mg) and dexamethasone (Decadron) (0.1 mg/kg, maximum 4 mg) given orally four times a day for 48 hours prior to CT scanning.

Sedation

Patients must be as still as possible during the scanning sequence, since motion dramatically degrades the quality of the images. Generally, this means that patients under 5 years of age and others who cannot cooperate must be sedated to ensure the quality of the scan. Sedation can be obtained by using oral chloral hydrate or an intramuscular injection of meperidine hydrochloride (Demerol), promethazine hydrochloride (Phenergan), and chlorpromazine hydrochloride (Thorazine) (DPT).[2] In patients with seizure disorders, Phenergan and Thorazine are omitted, and hydroxyzine is substituted at a dose of 0.1 mg/kg. If the patient remains uncooperative after the initial chloral hydrate or DPT dose, droperidol (Inapsine) can be given parenterally, usually in 0.25-mL increments up to 0.11 mg/kg. Occasionally, other tranquilizers are required.

Opaque devices including monitor leads, snaps, and nasogastric tubes should be positioned away from the area of interest prior to scanning.

Intravenous Contrast

Intravenous contrast is an extremely important part of the CT study, since it provides a means for distinguishing flowing blood from other structures such as myocardium, vascular walls, thrombus, thymus, and mediastinal soft tissues. Without IV contrast, intravascular lesions including thrombi, neoplasms, and dissections cannot be fully evaluated, and other conditions such as pericardial and mediastinal masses cannot be seen optimally.

When possible, a relatively large-bore IV cannula is preferable because the contrast medium to be injected is rather viscous, and larger IVs allow greater flow rates. For many cardiac and mediastinal studies, a modified dynamic infusion of 0.5 to 1.0 mL/s of meglumine iothalamate is given up to a total of 2 mL/kg. When the modified dynamic scanning sequence is to be used, scanning is commenced after 50% of the total amount to be infused has been injected. Scanning then proceeds in a dynamic fashion with the shortest scan times and interscan delays possible until the total area of interest is scanned.

For certain conditions such as suspected aortic dissection, intracardiac tumors, and in some cases a congenital heart disease, a bolus injection of a higher-density contrast (at least 75%) is used. One third of the total amount of contrast to be given is injected rapidly at rates up to 4 to 5 mL/s, and serial scans are obtained at one level of interest. This method is called dynamic CT scanning.[3]

Digital Radiography

After the patient is placed on the table in the CT scanner and prior to IV contrast administration, a preliminary image is taken using the roentgen ray beam and detectors while the table is moved through the gantry. The resultant digital radiograph displayed on the CT monitor looks similar to a conventional roentgenogram. This digital image is annotated in 1-cm markings (Fig. 52–1). Digital images of the chest can be obtained in either the anteroposterior or lateral projection and serve as references for locations to be scanned. The anatomic limits for scanning are chosen from the digital radiograph, and scanning begins after the venous contrast infusion is initiated. The computer registers each image slice with a longitudinal scale on the digital radiograph. Scan slices that are 5- or 10-mm thick are obtained consecutively at contiguous levels.

GATED CT

Conventional CT scan times are long in relation to the beating of the heart. Attempts have been made by several groups to overcome this deficiency by gating the cardiac image.[4–8] Each of the methods is similar in that data are collected from the same phase of several cardiac cycles during several continuous revolutions of the CT scanner. Typically, the CT scanning system is modified so that the roentgen ray tube rotates continuously for three to five revolutions, during which time data are collected. Data collected during a certain phase or "window" of the cardiac cycle are added together to form an image. Late diastole is usually chosen as the window because it is a relatively large segment of the cardiac cycle during which relatively little motion is occurring. The angular projections obtained during the chosen phase of the cardiac

cycle are summed together along with corrective algorithms for missing projections, producing an image.

Some reports have suggested that gated CT offers advantages over conventional CT.[6-8] Oyama and colleagues[7] have found that gated CT was superior to conventional CT in a variety of cardiovascular disorders in 39% of positive cases and in 33% of negative cases. However, the time for each scanning level is rather lengthy, since the roentgen ray tube is heated often to its limit and therefore must be given several minutes to cool prior to additional scanning.

Other problems include increased exposure of the patient to radiation over that required for conventional scanning by a factor of at least three. Also, reconstruction time for each image is rather long and cumbersome. The images obtained appear to be only slightly better than standard CT. However, in some cases, only slight improvement of the image quality may be enough to make a scan diagnostically useful, particularly in cases of intracardiac masses and in some cases of myocardial infarction.

Interest in gated CT has waned considerably since the advent of Cine-CT scanning and magnetic resonance imaging (MRI).

FAST CT SCANNING

Interest in the development of a rapid CT scanning device began soon after the development of the CT scanner and reached a milestone in the development of the dynamic spatial reconstructor (DSR) at the Mayo Clinic in the mid- to late 1970s.[9,10] This research device uses an array of roentgen ray tubes in a gantry that rotates at 15 revolutions per second around the object scanned. The roentgen ray tubes are operated in rapid succession to obtain fast scanning. The roentgen ray signal detected is recorded by 14 imaging chains such that a three-dimensional composite image of the heart is produced every 60 ms. The DSR can obtain images at even shorter intervals, as little as 16 ms. Images are created in a 128 matrix format taken from the 128 × 128 × 128 cubic volume of the area scanned. Work with the DSR has proven that it is extremely accurate in the evaluation of left ventricular mass, chamber volumes, and congenital and acquired heart disease, and in coronary artery size and flow assessment.[9-13]

Recently, a new design in rapid CT was developed by Douglas Boyd, which became commercially available as Cine-CT.[14] The details of this device are given in Chapter 38. Briefly, an electron gun produces an electron beam that is magnetically deflected and swept across one of four semicircular tungsten plates (Fig. 52–2). Two 8-mm roentgen ray fan beams are produced that are transmitted through the patient and collected by two arrays of solid-state detectors positioned in the gantry above the patient. Two continuous 8-mm-thick scans can be obtained in 50 ms, and additional scans can be performed after only an 8 ms interscan delay.

Cine-CT can operate in one of several modes because the scans can be synchronized with the EKG.

In the *flow mode,* one to four levels of the heart are chosen for scanning, and two scans are obtained at each of these levels each time the EKG reaches a certain phase (usually end-diastole). In this way, when scans are obtained at the same cardiac phase over 8 to 20 heart beats, sequential flow of the injected IV contrast is demonstrated through the cardiac chambers. This mode is useful for displaying anatomic and physiologic diseases in which data analysis programs are employed. Region-of-interest cursors placed over the anatomic site to be studied in the sequential flow mode provide time–density curves with precise gamma-variate fit for quantitative and qualitative information on blood flow. Cardiac output,[15-17] patency of arterial grafts,[18-22] myocardial perfusion,[17,19,20] intracardiac shunts, and shunt calculations[21,23-26] can be measured.

Cardiac output is calculated by using the time–density curve evaluation given by the Stewart-Hamilton equation $CO = KQ/A$, where CO = cardiac output; K = calibration factor; Q = amount of contrast injected; and A = area under the curve.[15-17] These calculations are performed automatically by the software in the computer as a region-of-interest cursor is placed over either the left ventricle or the aorta. In an experimental study, this method was highly correlated ($r = 0.92$) with simultaneous thermodilution measurements.[15]

Quantitation of intracardiac shunts can also be performed by time–density curves with gamma-variate fitting. In a laboratory using surgically created right-to-left shunts in canines, there was

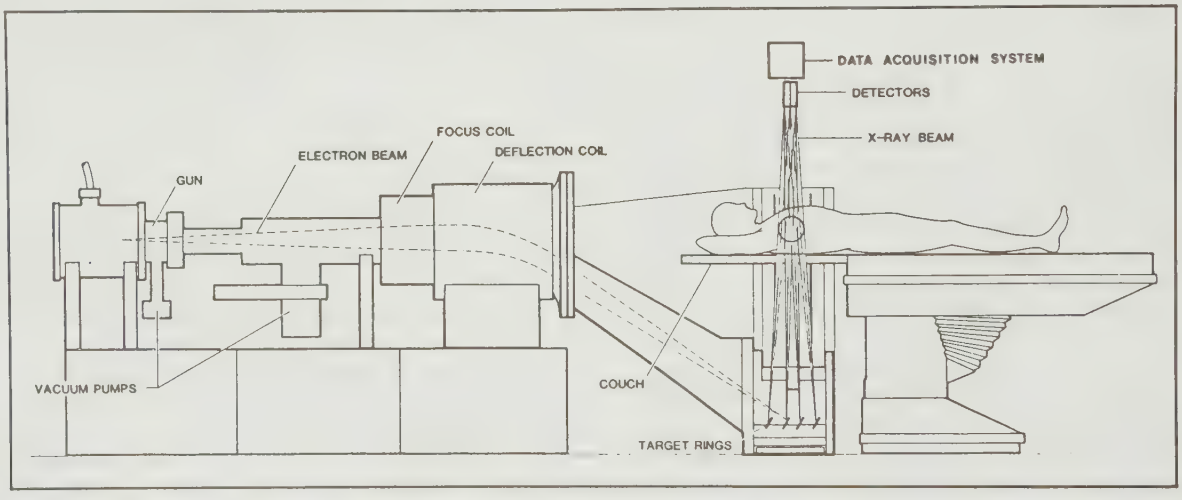

Fig. 52–2. Diagram of the Imatron Cine-CT scanner. An electron gun produces an electron beam that is focused and then deflected onto the target rings beneath the patient. Roentgen rays are produced as the electron beam is swept across the rings and, after passing through the patient, is collected by the detectors. (Courtesy of the Imatron Inc., South San Francisco, CA.)

excellent agreement ($r = 0.91$) with oximetric values over a wide range (0 to 50%).[26]

In the continuous or *cine mode,* multiple scans are obtained at two, four, six, or eight levels at a rate of up to 17 per second. Following reconstruction, the scans can be played back sequentially in a movie loop displaying dynamic cardiac function. Left and right ventricular function,[17–19] cardiac output, valvular regurgitation measurements, volume determinations, and some valvular motion abnormalities can be displayed by this mode. In contrast to the flow mode, in which cardiac output is determined by the Stewart-Hamilton equation, cardiac output in the cine mode is calculated by the heart rate times stroke volume. The entire volume of the ventricle is scanned, and cavity measurements are made at each level at both end-systole and end-diastole. Stroke volume is then calculated on the basis of Simpson's rule.[17,19] Cardiac output determinations using both the flow and cine modes are limited, however, in the presence of valvular regurgitation and intracardiac shunting.

Ejection fractions are also determined in the cine-mode by tracing the volumes calculated from scans performed through the left ventricle or right ventricle using the conventional formula

$$\frac{\text{end-diastolic volume minus end systolic volume}}{\text{end-diastolic volume}}$$

The calculated ejection fraction using Cine-CT is highly correlated with biplane angiography and exceeds equilibrium radionuclide ventriculography by a factor of approximately 8% because of the left atrial overlap on radionuclide studies.[27]

In the *volume mode,* the table is moved rapidly through the gantry while one target ring is rapidly scanned. This permits the acquisition of up to 80 slices covering 64 centimeters of anatomy. From these data, images can be reformatted in any operator-selected plane. Relationships of the cardiac chambers and great vessels, masses, and abnormal fluid collections can be determined as well as patency of surgical shunts.[3,17,21]

CLINICAL CASES

Conventional CT scanning is often used to provide additional anatomic information about diseases of the chest. Intrinsic subject contrast of the various mediastinal structures is quite low because attentuation values of the heart and normal mediastinal structures are similar and contrasting mediastinal fat is usually sparse in children. To compensate for this low-contrast state, IV contrast is used to opacify the great vessels and cardiac chambers. This allows separation of the great vessels from pathologic and normal mediastinal structures. When IV contrast cannot be given in large quantities, there are significant limitations in detecting and defining pathological processes in the mediastinum (Figs. 52–3 and 52–4).

In conventional CT, motion artifacts from physiologic motion and from moving radiopaque catheters degrade the image, decreasing the definition of the heart and, to a lesser extent, the great vessels (Fig. 52–5). Conventional CT is best applied to a number of mediastinal and pulmonary masses such as pericardial lesions, tumors of the mediastinum and heart, and great vessel abnormalities.

Pericardial Lesions

Echocardiography has proven extremely useful in the diagnosis of pericardial disease, especially in pericardial effusions. However, CT is even more sensitive to a wide variety of diseases affecting the pericardium, including pericardial thickening, calcification, and other pericardial masses.[28–33] In one study of eight patients, CT demonstrated pericardial masses in all patients, whereas echocardiography was abnormal in only one of the seven patients studied. In restrictive pericardial disease, calcifications of the pericardium may be seen with CT that cannot be observed with echocardiography (Fig. 52–6).

Pericardial effusions are often better seen with CT. Adipose tissue may produce anterior and/or posterior echo-free spaces on echocardiography, resulting in a false-positive reading for pericardial effusion. These areas, however, are properly displayed as fat containing on CT.[32] Effusions from a variety of conditions including trauma (Fig. 52–7),[34] thickening from infection (Fig. 52–8),[35] and solid and cystic neoplasms (Fig. 52–9) are easily seen. Partial or complete absence of the pericardium can also be suggested on CT.[36,37]

Great Vessels

Assessment of the position and patency of the great vessels is usually easily displayed with CT. While echocardiography provides examination of the proximal great vessels, changes affecting the more distal portions of the great vessels can often be better displayed on conventional CT and Cine-CT. Acquired conditions such as superior vena cava thrombosis (Fig. 52–10), congenital variations such as right aortic arch (Fig. 52–11), aberrant subclavian vessels (Fig. 52–12), persistent left superior vena cava (Fig. 52–13), and some anomalous veins can be often visualized with conventional CT[3,23,37–42] and Cine-CT.[21–23] Also, coarctations can be seen on conventional dynamic CT scanning[43] (Fig. 52–14) and with Cine-CT (Fig. 52–15) performed in the volume mode. In coarctations, reformatted off-axis images formed in the plane of the thoracic aorta are useful to demonstrate the proximally dilated brachicephalic vessels, the coarctation, and the diminutive descending aorta. Sagittal MRI may prove even better than CT for detecting coarctations.

The diagnosis of aortic aneurysms and aortic dissections is more precisely made with dynamic CT scanning than with any other technique.[43–45] For suspected thoracic aortic dissections, a dynamic scanning sequence performed with a conventional CT scanner at three different levels in the aorta following contrast injection can provide exquisite detail (Fig. 52–16). The information derived from the dynamic scanning sequence provides morphologic as well as physiologic information.[3,44–46] CT offers advantages over conventional aortography in dissections in that it is noninvasive, takes only 10 to 15 minutes to complete, and demonstrates hematomas and thrombosed false lumen that may be quite difficult to see by angiography. In one study done on an older CT instrument, CT was more sensitive in detecting dissections than aortography (83% versus 75%).[44]

Some centers have advocated the use of CT in the evaluation of suspected aortic injuries in blunt trauma.[47] CT has certainly markedly improved noninvasive accuracy in the assessment of neurological and abdominal/pelvic system injuries. While the diagnosis of aortic injuries by CT remains controversial, CT can certainly document the presence of periaortic hematomas that should suggest aortic injuries (Fig. 52–17). In our experience, demonstration of the aortic pseudoaneurysm has been difficult; our

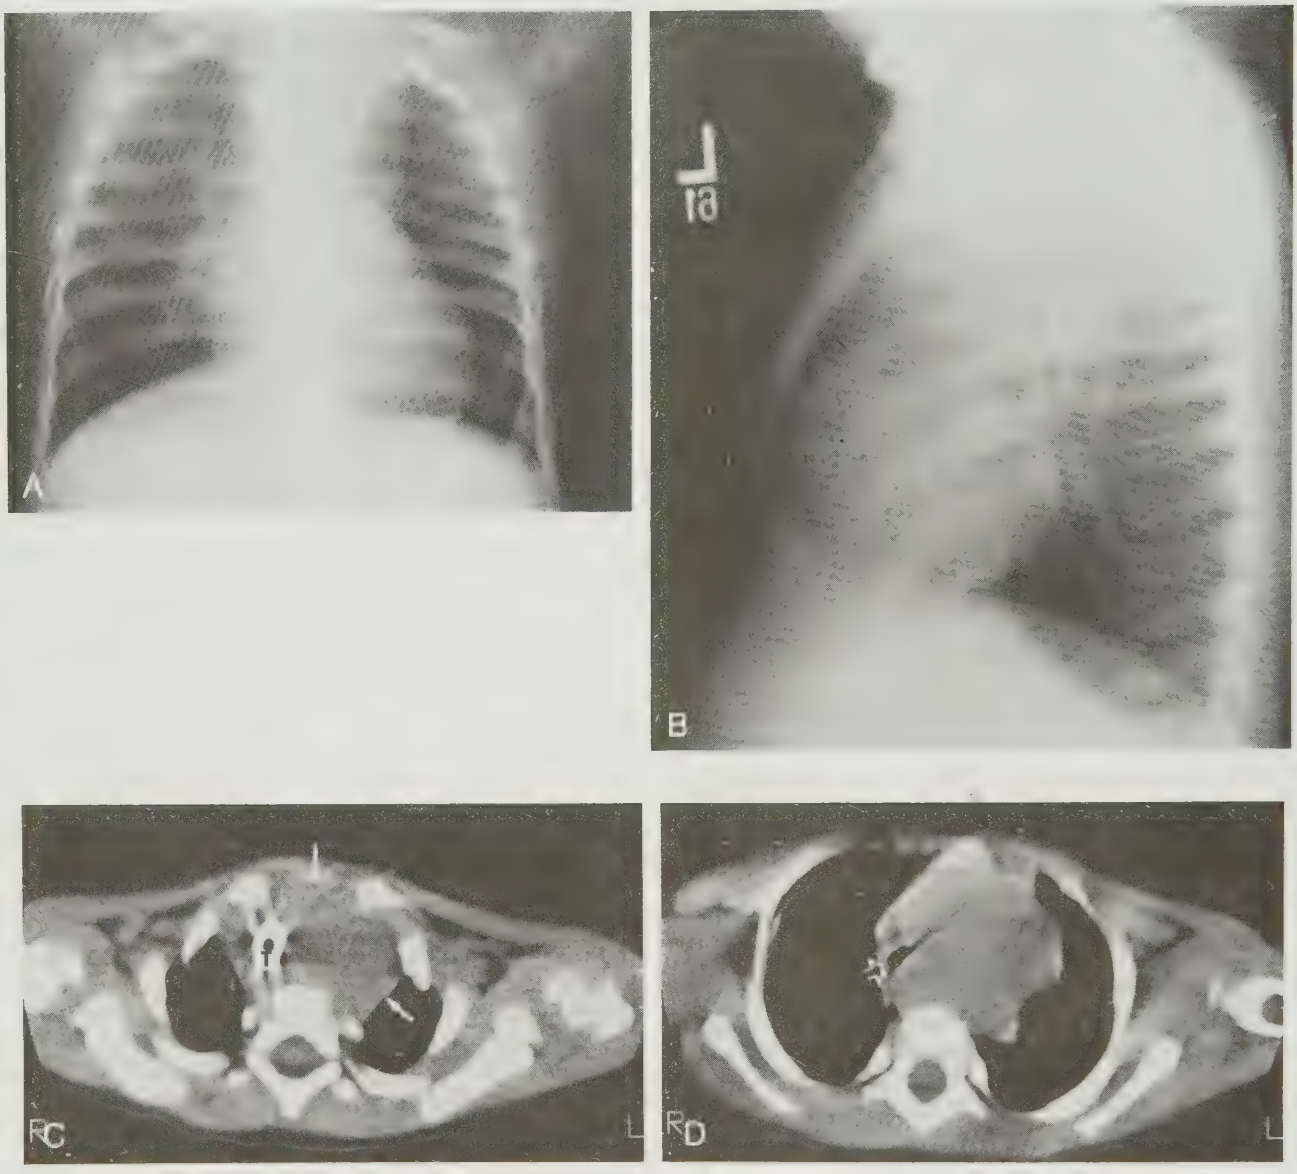

Fig. 52–3. Large neck and mediastinal hemangioma. It is poorly separated from adjacent structures because of lack of intravenous contrast. (A and B) Chest films disclose a large mediastinal mass primarily in the left paratracheal area extending down to the aortopulmonary window level. (C) A CT scan through the upper chest discloses a homogeneous left paratracheal soft tissue mass (arrows). The mass has the same density as the thoracic musculature and thoracic great vessels. The vasculature can be separated from masses when dynamic or modified dynamic scanning is used with high doses of intravenous contrast. Also notice the tracheostomy tube (T) in the trachea. R = right; L = left. (D) A CT scan 2 cm below that shown in part C discloses displacement of the trachea (arrow) to the right of midline by the homogeneous mass.

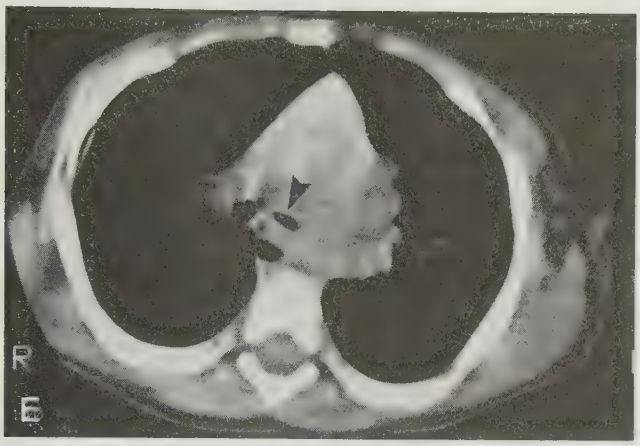

Fig. 52–3. continued. (E) A CT scan 2 cm below that shown in part (D) demonstrates a narrowed left main bronchus (arrowhead) by the hemangioma mass. (F, G, and H) Subtraction films from arch aortography in early arterial, midarterial, and capillary phases disclose the vascular mass (arrowheads) extending from the upper portion of the neck to a point below the aortic arch, compressing the left main bronchus.

Fig. 52–3. continued.

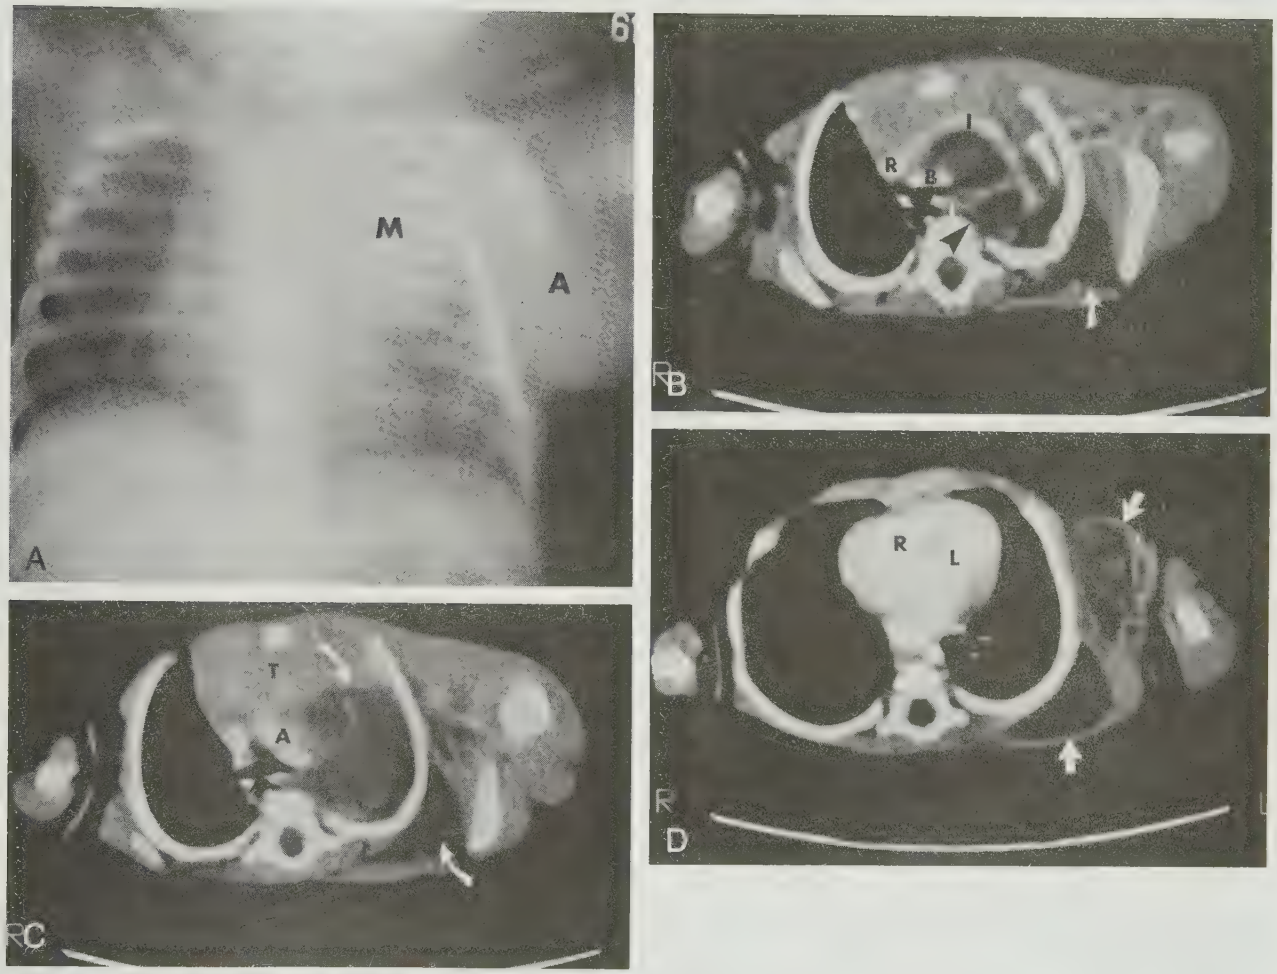

Fig. 52–4. A cystic hygroma extending into lateral axilla and mediastinum. There is excellent separation of the mass from contrast-filled great vessels. (A) Chest film discloses a left paratracheal mass (M) and a lateral axillary mass (A). (B) A CT scan of the upper chest demonstrates contrast-filled left innominate vein (I) with thymus anterior and cystic hygroma posterior extending into the left posterior axillary recess (arrows). The right innominate vein (R) and brachycephaliac artery (B) are also seen. (C) A CT scan 1 cm below that shown in part (B) using the modified dynamic technique in a 4-year-old, discloses the thymus (T), contrast-filled aortic arch (A), and low-density left superior and axillary low-density cystic hygroma (arrows) in the mediastinum and axilla. (D) A CT scan through the ventricular level shows a left axillary cystic hygroma (arrows) with mediastinal involvement at this level. Contrast right (R) and left (L) ventricles are separated by the interventricular system.

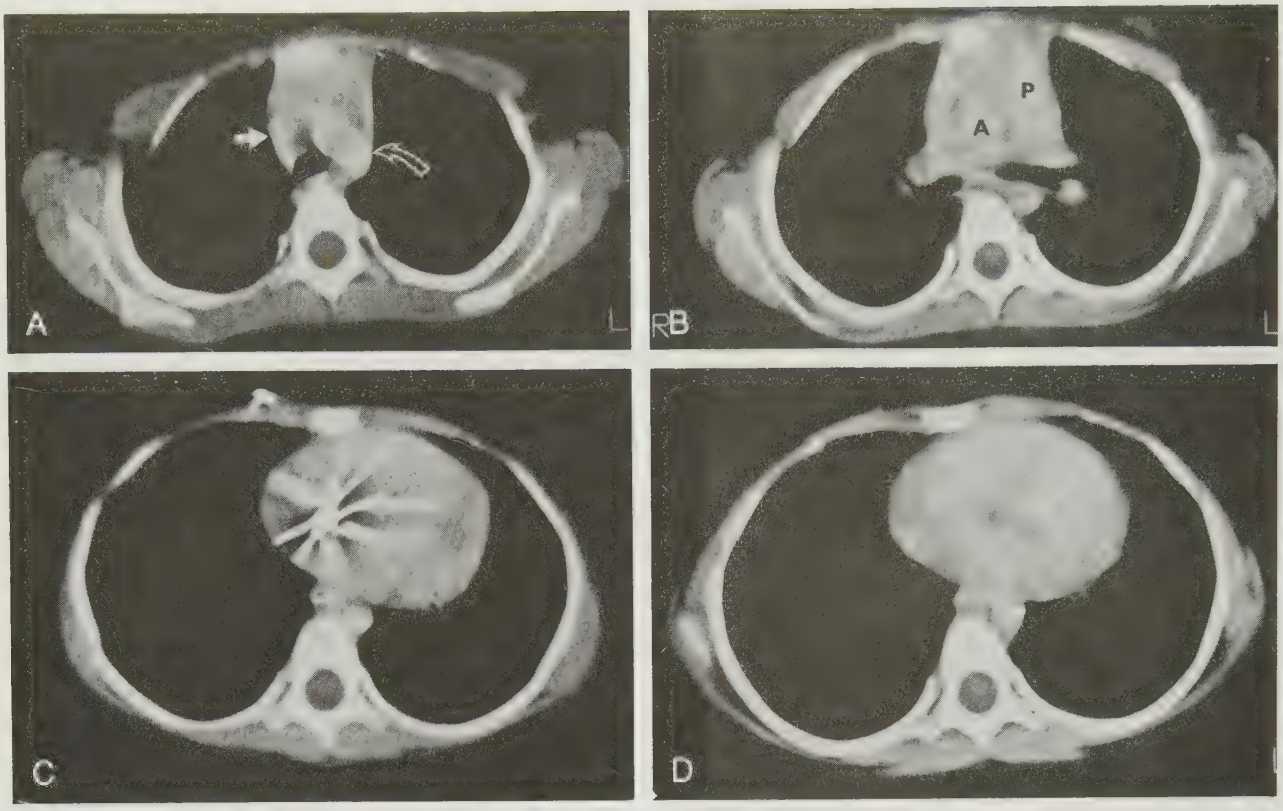

Fig. 52–5. A normal CT scan of the chest, using a modified dynamic technique. (A) A CT of the upper chest discloses aortic arch (curved arrow) and superior vena cava (straight arrow). The thymus is just anterior to the aortic arch. (B) A CT scan through the midchest just below the carina demonstrates motion and some contrast in the proximal ascending aorta (A) and main pulmonary artery (P). (C) A CT scan through the heart demonstrates a "star" artifact from a high-density moving central venous catheter in right atrium. Intracardiac morphology is poorly seen. (D) A CT scan through the heart 1 cm below that shown in part C discloses artifacts and partial visualization of the interventricular septum (arrow).

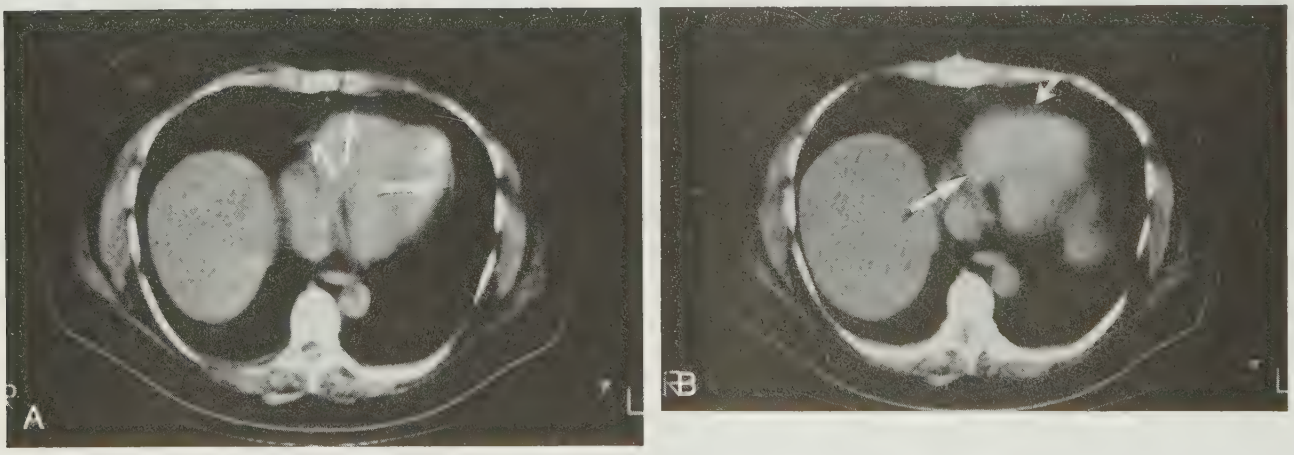

Fig. 52–6. Calcific constrictive pericarditis in a 40-year-old woman with normal echocardiography. (A) A CT scan through the level of ventricles discloses slight thickening at the pericardium medial and laterally with normal thickness anteriorly. (B) A CT scan 1 cm below that shown in part A demonstrates calcification (arrows) in the pericardium adjacent to the right atrium and ventricle.

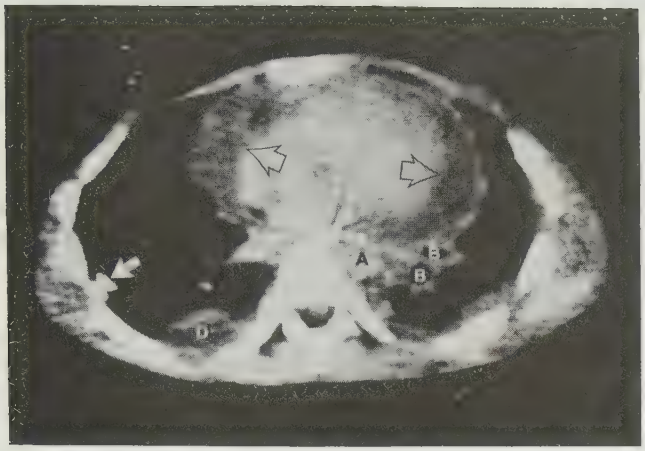

Fig. 52–7. Traumatic pericardial effusion in a 5-year-old 10 days after an auto-pedestrian accident. A low-density pericardial effusion (dark arrows) surrounds the heart. Bronchi (B), descending aorta (A), posttraumatic peripheral pulmonary density (B), and chest tube (white arrow) are also seen. (Reprinted with permission from Toombs, B.D., Sandler, C.M., and Lester, R.G.: Computed tomography of acute chest trauma. Radiol. Clin. N. Am., *140*:733–738, 1981.)

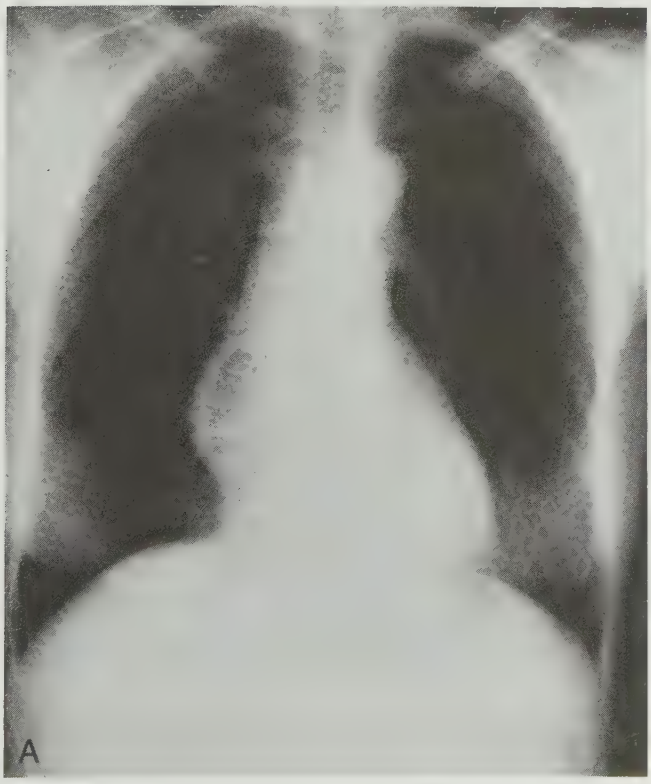
Fig. 52–8. Pericardial abscess. This patient received a gunshot wound three weeks prior to this study. Low-density abscess fluid (dark arrowheads) is seen in the pericardial space. The pericardium is thickened (white arrow). Left empyema is also present (E). (Reprinted with permission from Toombs, B.D.: Complications of chest trauma. *In* Computed Tomography in Trauma. Edited by B.D. Toombs and C.M. Sandler. Philadelphia, W.B. Saunders, 1987, pp. 84–111.)



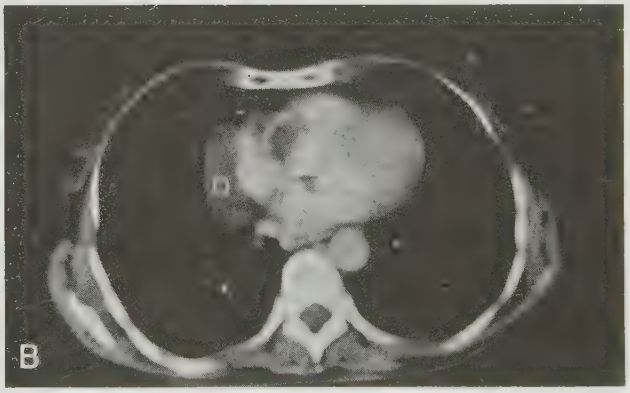


Fig. 52–9. Pericardial cyst. (A) A chest roentgenogram discloses a nonspecific bulge along the right heart border. (B) A CT scan displays low-density (0 Hounsfield units) mass (O) just lateral to the right atrium, diagnostic of a cyst.

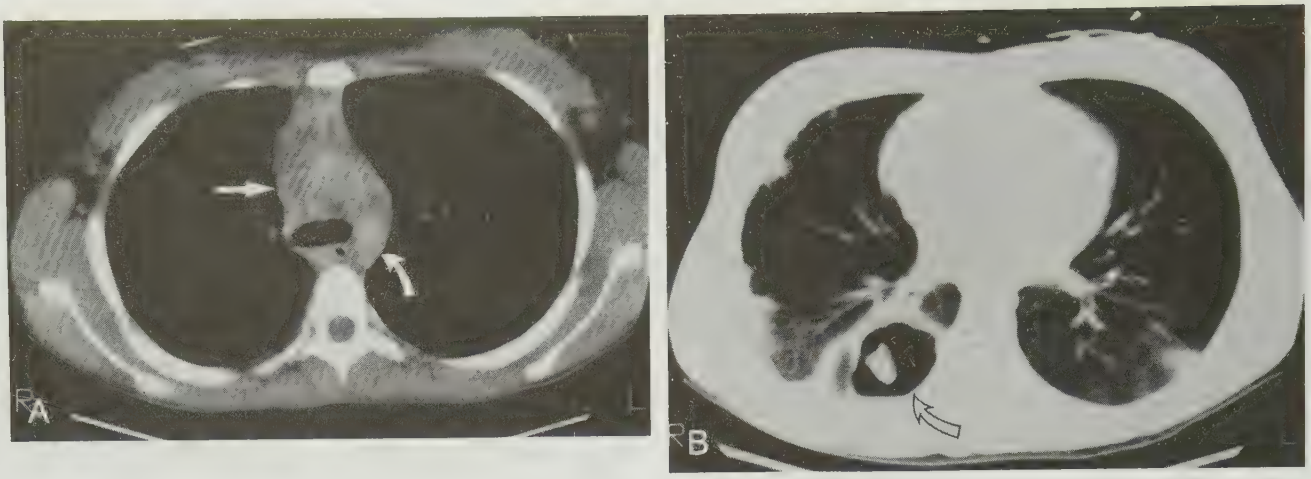

Fig. 52–10. Superior vena cava thrombosis in a 13-year-old with right lower lobe abscess. (A) A CT scan just below the level of the aortic arch demonstrates "ring-like" density (arrow) with a low-density center (thrombus) representing the superior vena cava. The descending aorta (curved arrow) is higher in density. (B) A CT scan through the level of the right lower lobe abscess (arrow), exhibiting a thick wall and internal debris.

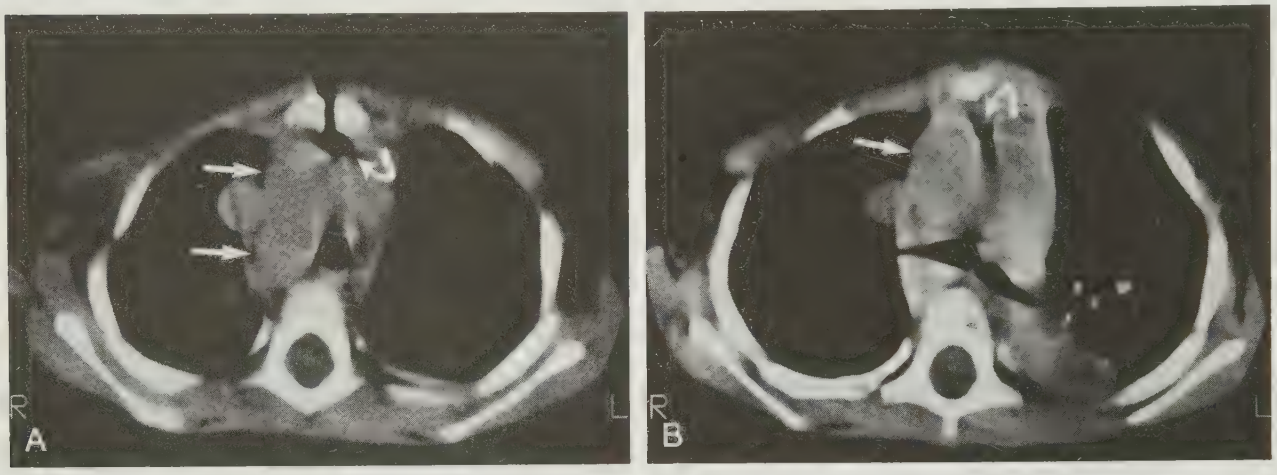

Fig. 52–11. Right aortic arch in a 2-year-old patient with tetralogy of Fallot with postoperative mediastinal abscess. No intravenous contrast was used. (A and B) CT discloses a right aortic arch (arrows) and abnormal gas in the mediastinum (curved arrows).

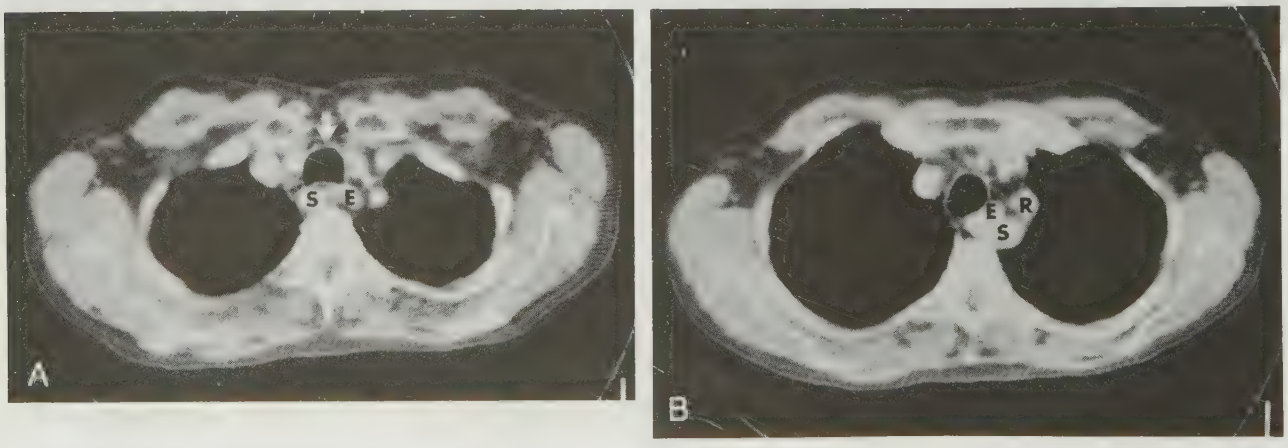

Fig. 52–12. Aberrant right subclavian artery. (A) A CT scan through the upper chest discloses the right subclavian artery (S) behind the trachea (arrow) and to the right of the esophagus (E). (B) A CT scan obtained 1 cm cardial to that shown in part (A) demonstrates the right subclavian artery (S) behind the esophagus (E) and left subclavian artery (R).

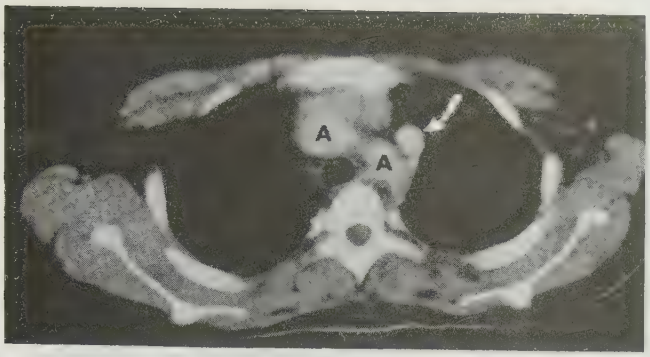

Fig. 52–13. Left superior vena cava in a 16-year-old patient. A CT image shows a left superior vena cava (arrow) adjacent to the aortic arch (A).

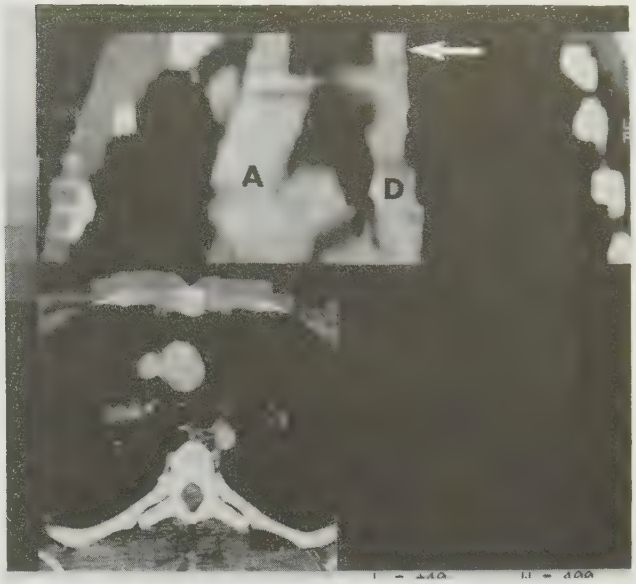

Fig. 52–14. Coarctation of the aorta, a postoperative study. CT images were obtained at 1-cm intervals, and an oblique sagittal reformatted image (upper part of image) was created through the plane outlined in the lower standard axial image. Ascending aorta (A), descending aorta (D), and persistently dilated left subclavian artery (arrow) are seen.

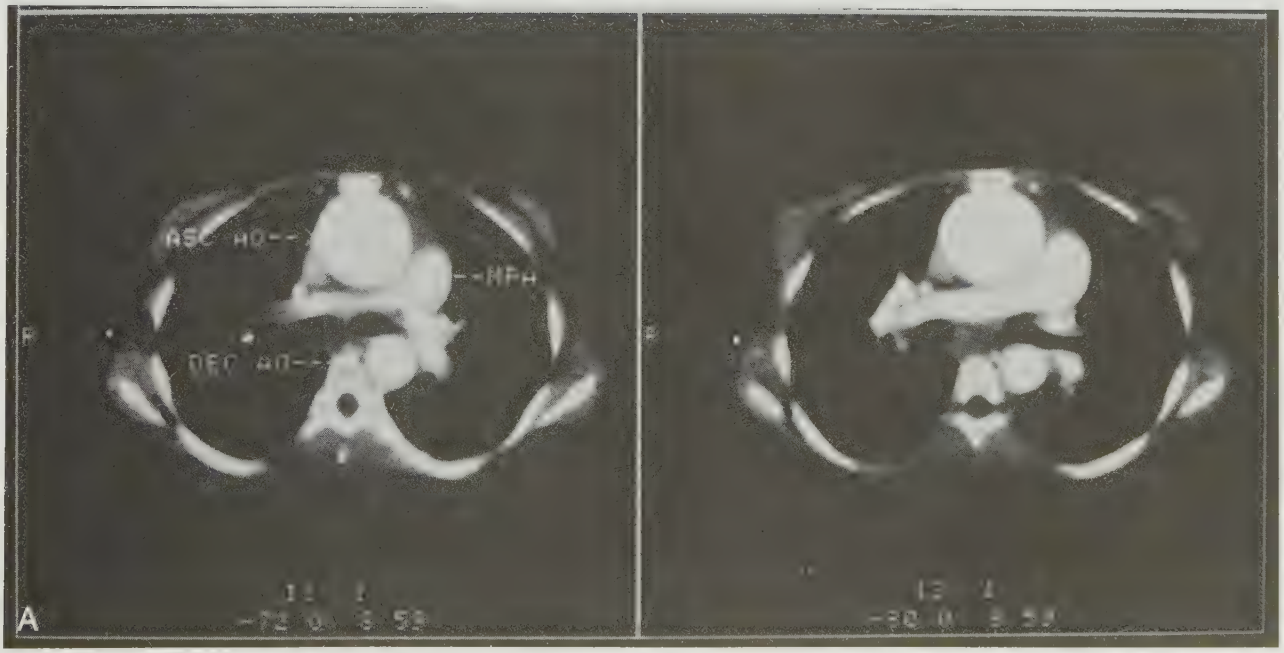

Fig. 52–15. Coarctation of the aorta, a Cine-CT study. (A) Two Cine-CT images performed in the volume mode 8 mm apart demonstrate relative dilatation of the ascending aorta (ASC AO) compared to the descending aorta (DEC AO). Also note the main pulmonary artery (MPA) that divides into left and right branches.

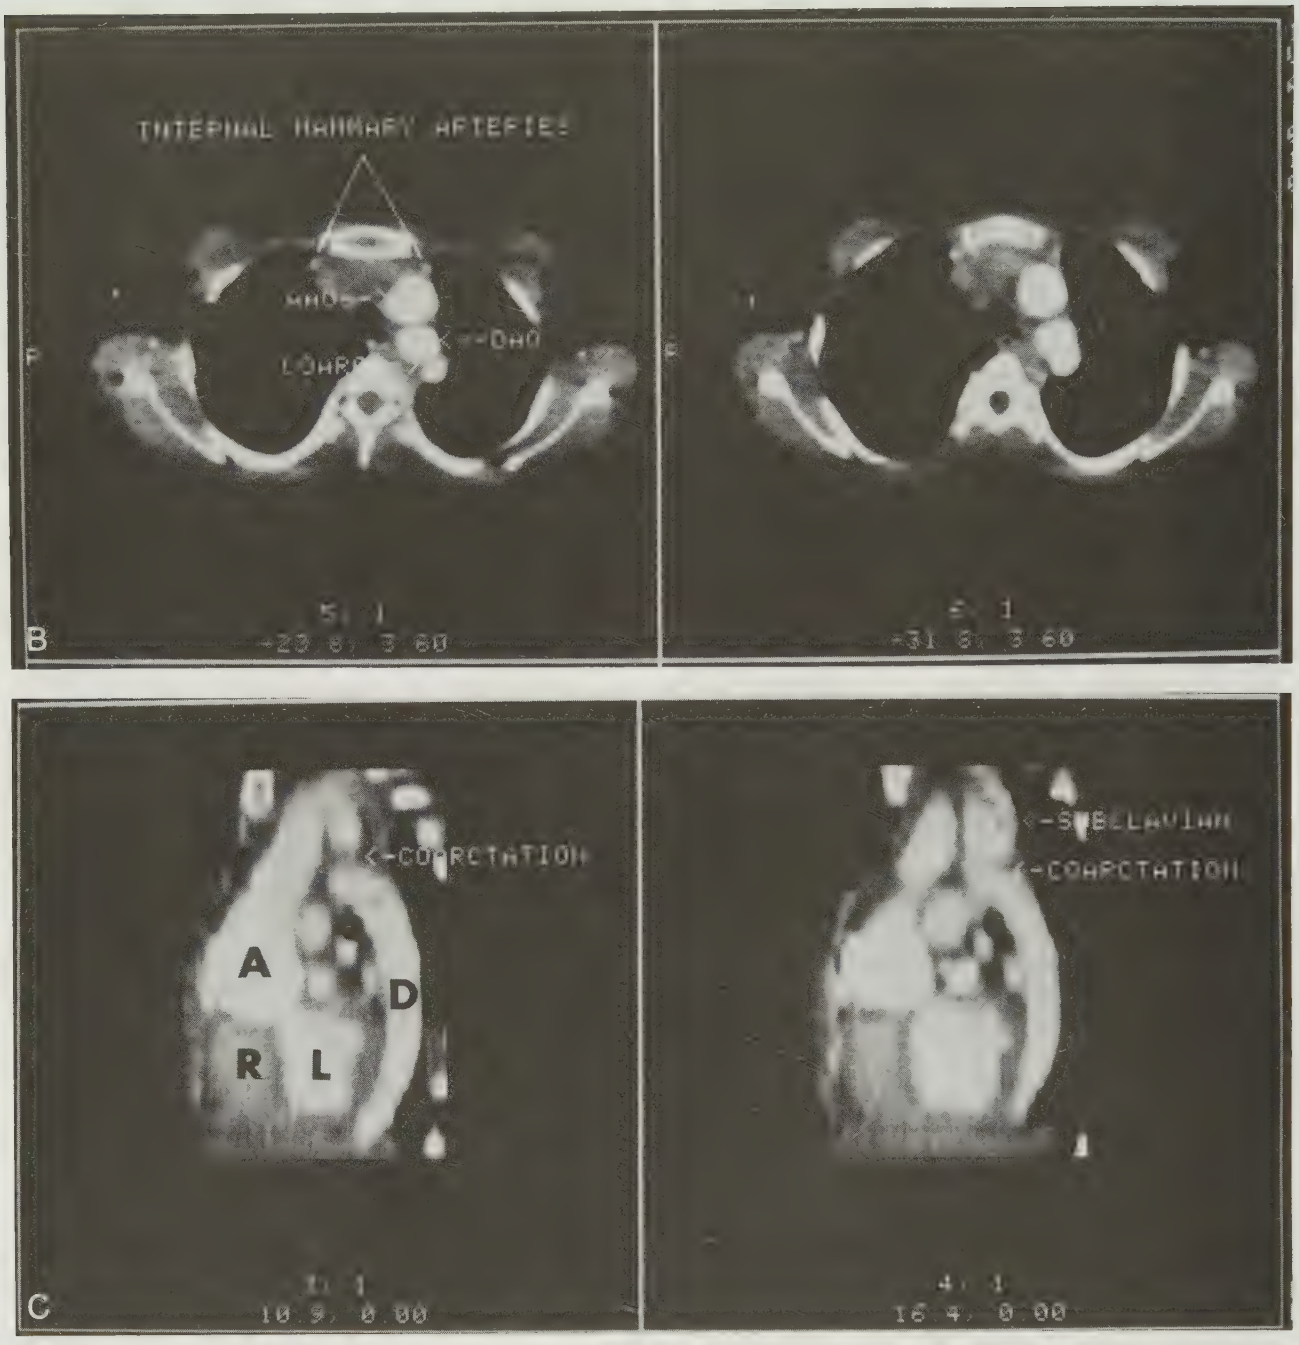

Fig. 52–15. continued. (B) A pair of Cine-CT images at the level of coarctation discloses the coarctation defect (COARCT) in the descending aorta (DAO) behind the ascending aorta (AAO). The internal mammary arteries are prominent. (C) Off-axis parasagittal reformatted images from data acquired from volume mode. Note the slightly dilated contrast-filled aortic root (A), coarctation, descending aorta (D), and left atrium and ventricle complex (L). The right atrium (R) is relatively low in density because the injected bolus of contrast has already dissipated. (Courtesy of W.J. Eldredge and S. Flicker, Deborah Heart and Lung Center, Browns Mills, N.J.)

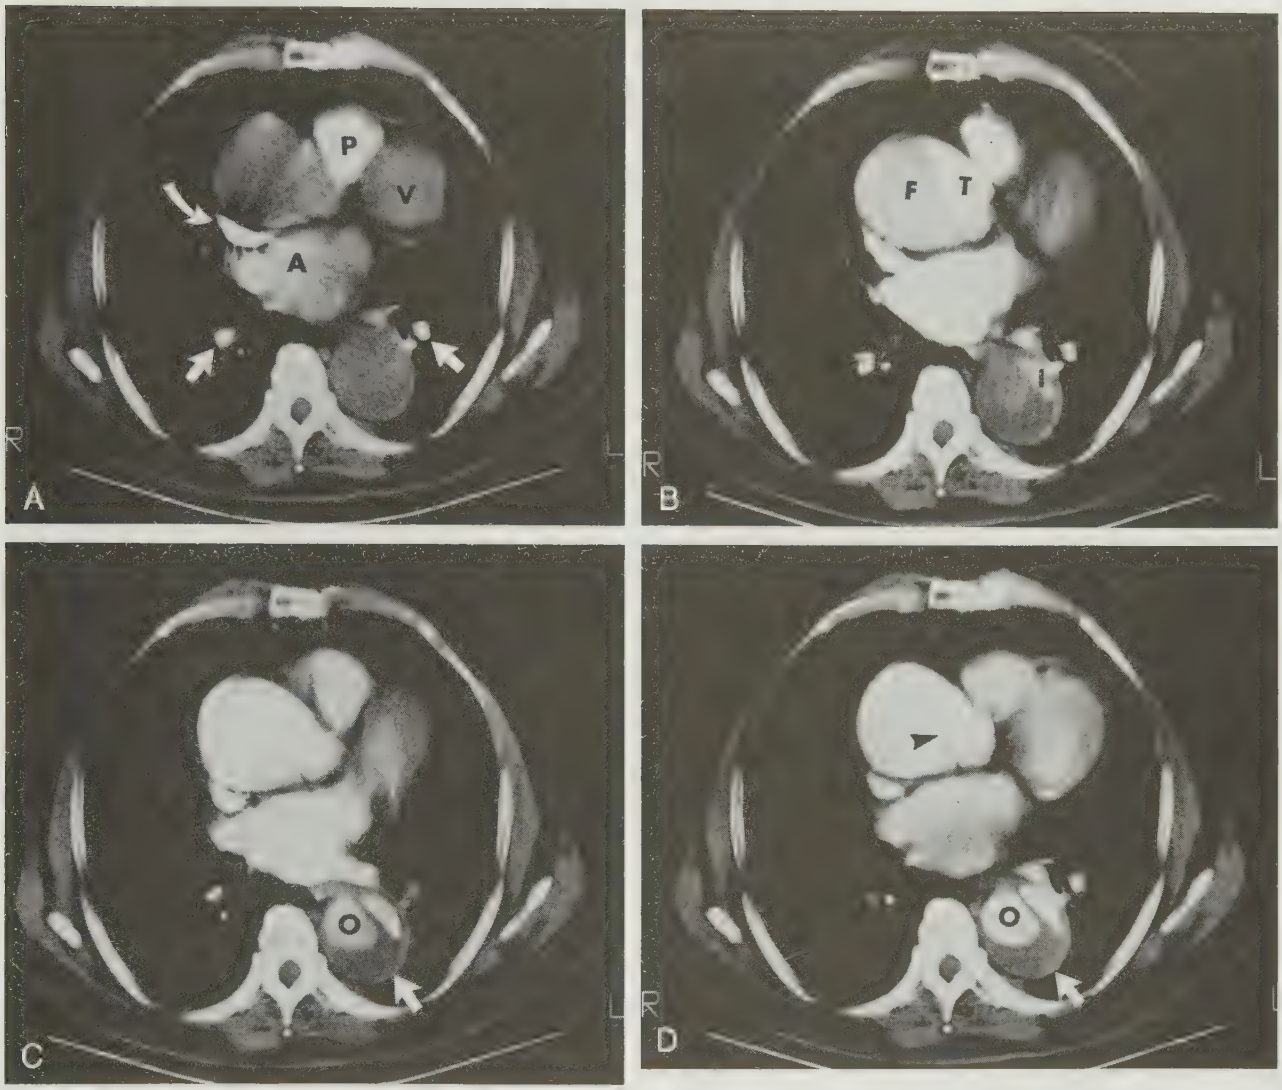

Fig. 52–16. Type A aortic dissection. Dynamic scanning at one level (proximal ascending aorta) with conventional CT scanning. (A) Early CT image 5 seconds after injection of contrast discloses contrast in the pulmonary artery (P), both lower lobe pulmonary artery branches (arrows), the superior vena cava (curved arrow), and the left atrium (A). The superior aspect of the left ventricle is also noted (V). (B) A CT scan 2 seconds after that shown in part A discloses contrast in the dilated ascending aorta in both the true (T) and false (F) lumens separated by the intimal flap. The true lumen (I) in the descending aorta is also opacified. The left atrium is better opacified than during the scan in part A. (C) A CT scan 2 seconds after that shown in part B demonstrates opacification of the patent portion of the false lumen in the descending aorta (O) and nonopacification of the thrombosed portion (arrow). (D) A CT scan 2 seconds after that shown in part C discloses the patent false lumen (O) and thrombosed portion (white arrow) with persistent good demonstration of the intimal flap of the ascending aorta (black arrowhead).

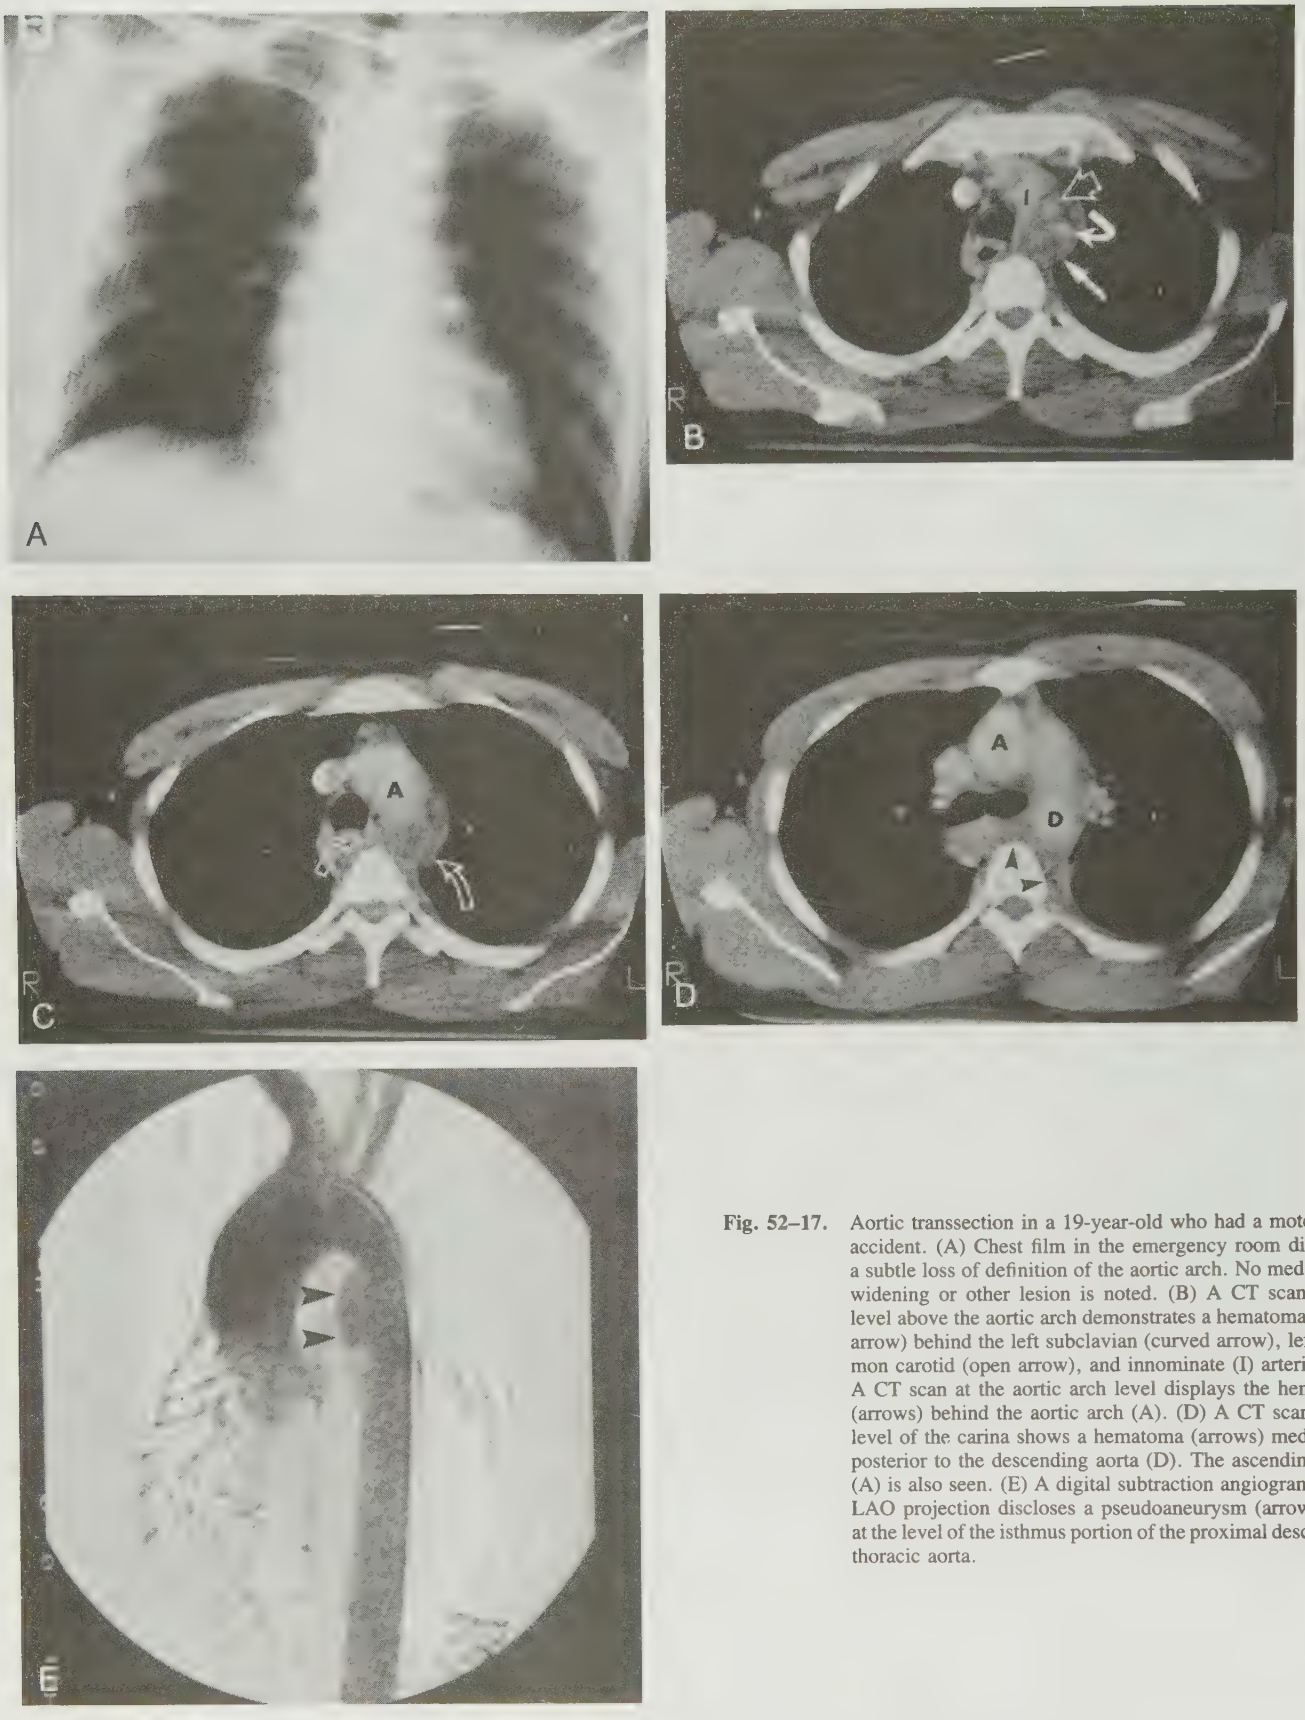

Fig. 52–17. Aortic transsection in a 19-year-old who had a motorcycle accident. (A) Chest film in the emergency room discloses a subtle loss of definition of the aortic arch. No mediastinal widening or other lesion is noted. (B) A CT scan at the level above the aortic arch demonstrates a hematoma (white arrow) behind the left subclavian (curved arrow), left common carotid (open arrow), and innominate (I) arteries. (C) A CT scan at the aortic arch level displays the hematoma (arrows) behind the aortic arch (A). (D) A CT scan at the level of the carina shows a hematoma (arrows) medial and posterior to the descending aorta (D). The ascending aorta (A) is also seen. (E) A digital subtraction angiogram in the LAO projection discloses a pseudoaneurysm (arrowheads) at the level of the isthmus portion of the proximal descending thoracic aorta.

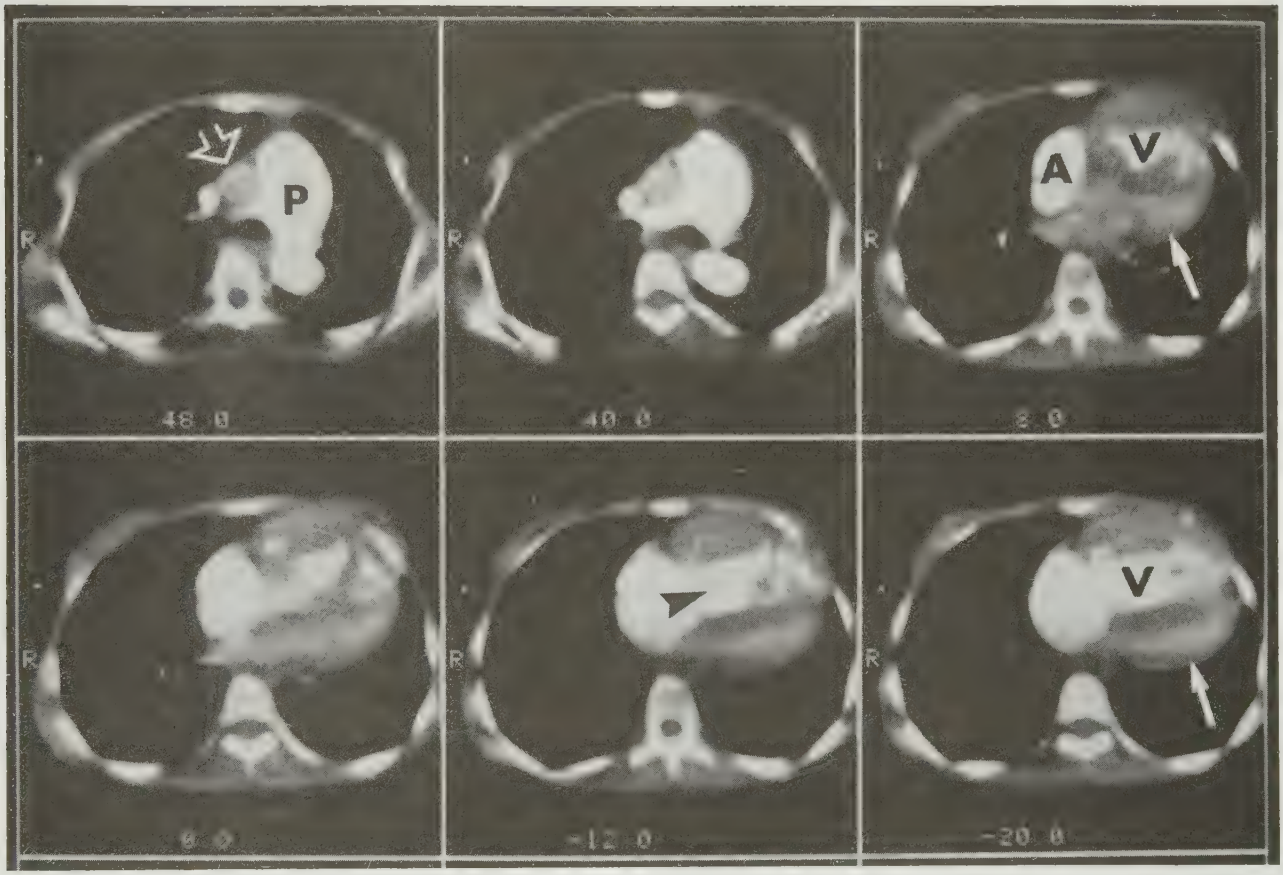

Fig. 52–18. Cine-CT of a patient with atrial septal defect and pulmonic stenosis in the volume mode. Images performed at several levels over 250 ms demonstrate dilatation of the pulmonary artery (P) compared to the ascending aorta (open arrowhead). There is hypertrophy of the contrast-filled right ventricle (V). Premature partial opacification of the left atrium (arrows) is related to the atrial septal defect. The tricuspid valve is also seen (black arrowhead). (Courtesy of Imatron, Inc. and W.J. Eldredge and S. Flicker, Deborah Heart and Lung Center, Browns Mills, N.J.)

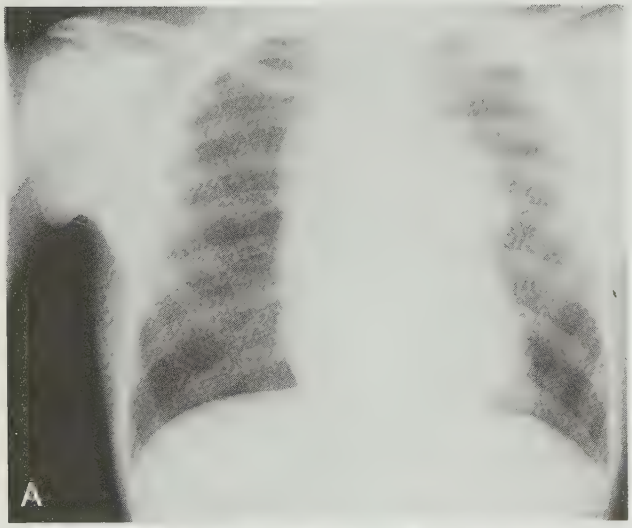
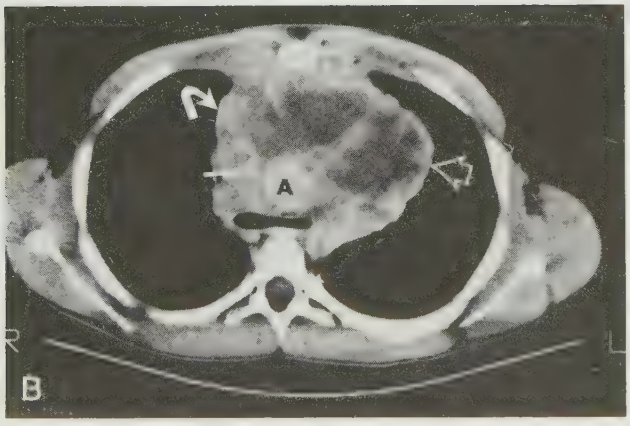
Fig. 52–19. A Cine-CT volume study of a 7-year-old with tetralogy of Fallot. Eight scans disclose the left aortic arch (curved arrow) and hypoplastic right and left pulmonary arteries (straight arrows) arising from the borderline enlarged main pulmonary artery (:). Both the left (L) and right (R) ventricles are slightly dilated. (Courtesy of W.J. Eldredge and S. Flicker, Deborah Heart and Lung Center, Browns Mills, N.J. and of Imatron, Inc.)





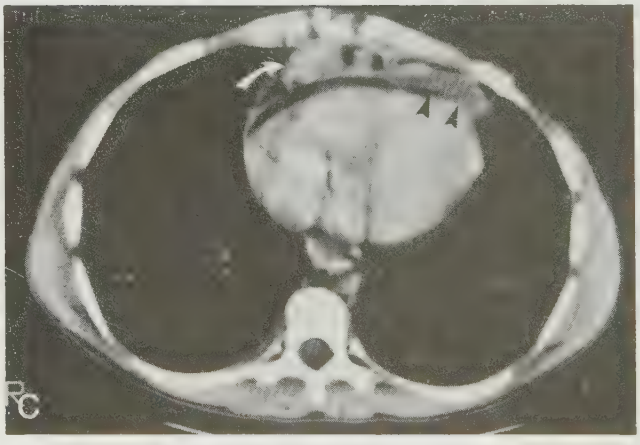


Fig. 52–20. Mediastinal masses in a 14-year-old with Hodgkin's disease. (A) Chest film exhibits asymmetric mediastinal enlargement. (B) A CT scan at the level of the carina discloses necrotic tumor masses (open arrowheads) anterior to the ascending aorta (A). The azygous vein (straight arrow) and superior vena cava (curved arrow) are distorted by enlarged lymph nodes. (C) A CT scan through the level of the ventricles demonstrates pericardial effusion (black arrowheads) just anterior to the left ventricle and adjacent low-density epicardial fat. Anterior mediastinal lymphadenopathy is also seen (curved arrow).

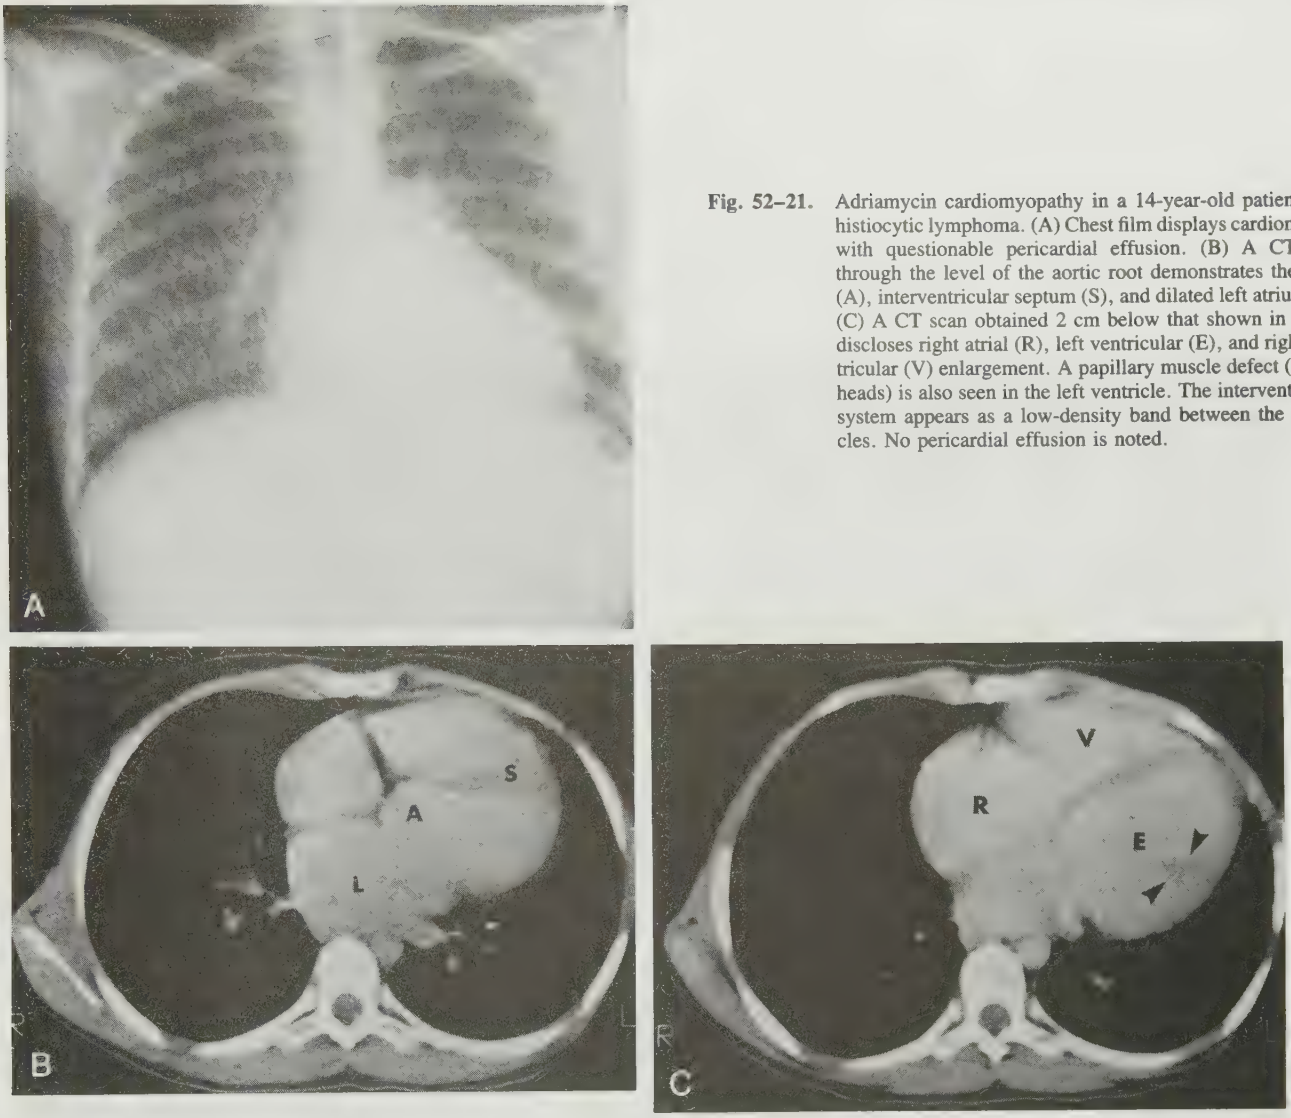

Fig. 52–21. Adriamycin cardiomyopathy in a 14-year-old patient with histiocytic lymphoma. (A) Chest film displays cardiomegaly with questionable pericardial effusion. (B) A CT scan through the level of the aortic root demonstrates the aorta (A), interventricular septum (S), and dilated left atrium (L). (C) A CT scan obtained 2 cm below that shown in part B discloses right atrial (R), left ventricular (E), and right ventricular (V) enlargement. A papillary muscle defect (arrowheads) is also seen in the left ventricle. The interventricular system appears as a low-density band between the ventricles. No pericardial effusion is noted.

current policy is that patients with suspected aortic injuries should receive urgent angiography.

Pulmonary emboli can occasionally be seen with CT when they are relatively large and affect the central vessels.[35] However, patients suspected of having pulmonary emboli should be studied with either pulmonary angiography or ventilation/perfusion scanning, since these techniques are more sensitive. In one study, however, organizing emboli in chronic thromboembolic pulmonary disease were better seen on CT than with angiography.[48]

Changes in pulmonary arteries other than emboli can also be seen both on conventional CT and Cine-CT scanning. Pulmonary valvular stenosis (Fig. 52–18), suprapulmonic stenosis (Fig. 52–19), aneurysms, and atresia have been demonstrated.[21,49]

Mediastinal Lesions

The child who presents with nonspecific clinical findings and an abnormal chest roentgenogram may require CT for additional anatomic information. Many abnormal mediastinal densities on conventional chest radiography can be properly classified into disease categories. CT is probably the most sensitive technique for detecting mediastinal lesions,[50] though MRI has shown great promise. Cardiovascular lesions can be separated from noncardiovascular lesions, including congenital cystic lesions (Fig. 52–4) and acquired tumors (Fig. 52–20). In addition, CT provides useful information about children who have neoplasms and have undergone potentially cardiotoxic chemotherapy whose cardiomediastinal silhouettes are abnormal (Fig. 52–21).

Cardiac Lesions

The development of two-dimensional echocardiography and cardiac radionuclide imaging has provided a quantum leap in the noninvasive diagnosis of pediatric and adult cardiac disease. Some conditions such as valvular heart disease and myocardial thickening or thinning that required cardiac catheterizations in the past can be estimated quite precisely with these techniques.

Dynamic conventional CT scanning has proven to be quite useful in the assessment of a variety of congenital diseases involving the great vessels.[39] However, demonstration of intracardiac congenital disorders with conventional CT including valvular processes is inconsistent. Echocardiography, cineangiography, and

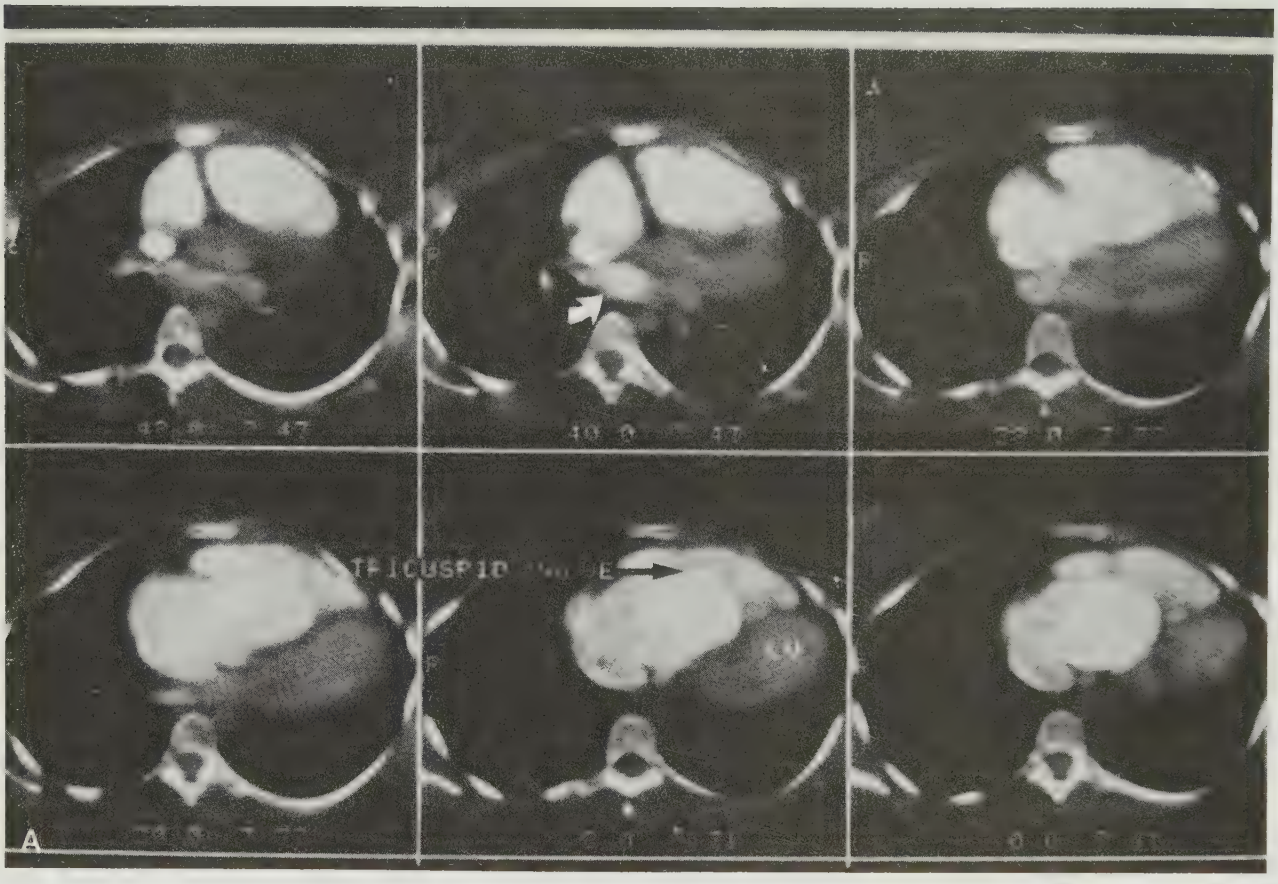

Fig. 52–22. Ebstein's anomaly with atrial septal defect in a Cine-CT study. (A) A volume mode study with six levels displayed shows enlargement of the right atrium with partial atrialization of the right ventricle (RV). The tricuspid valve is seen in an anomalous position (arrow). The left atrium (curved arrow) contains a small amount of contrast arising from the atrial septal defect.

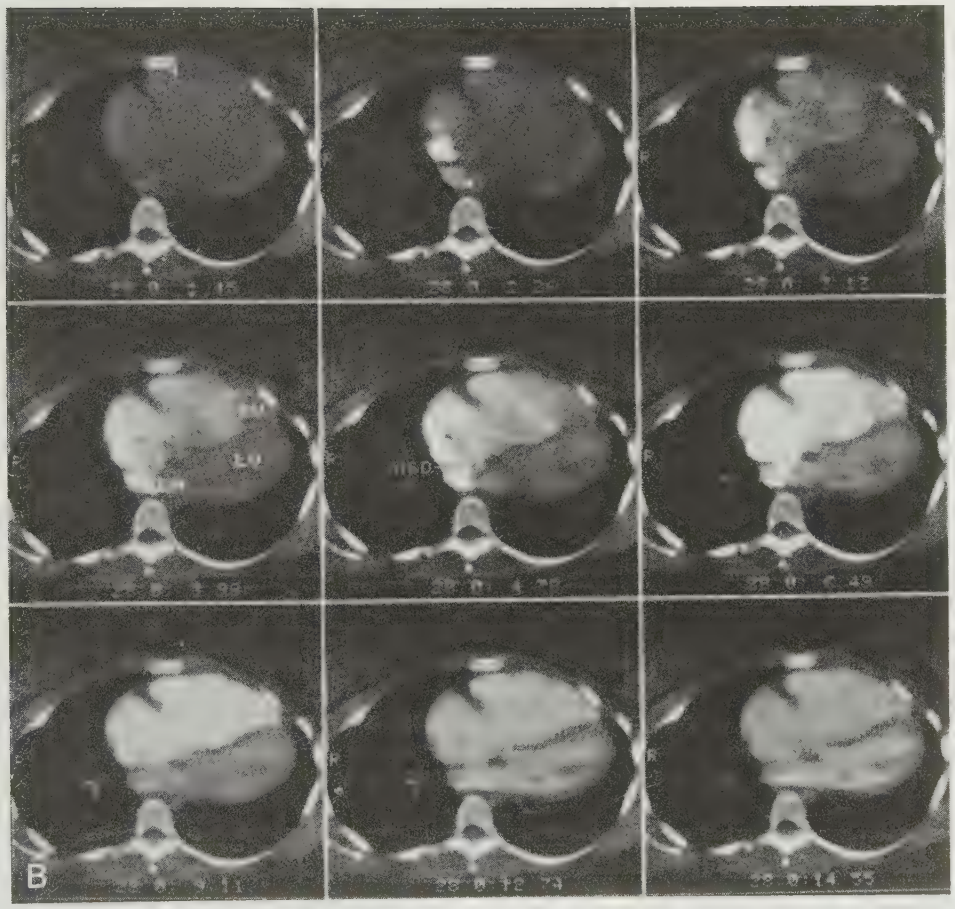

Fig. 52–22. continued. (B) A flow mode study exhibiting nine images obtained sequentially at the same level following injection of contrast. As contrast arrives, the right atrium (RA) and left atrium (LA) are opacified simultaneously. The atrial septal defect is also imaged. The right ventricle (RV) and left ventricle (LV) are also seen.

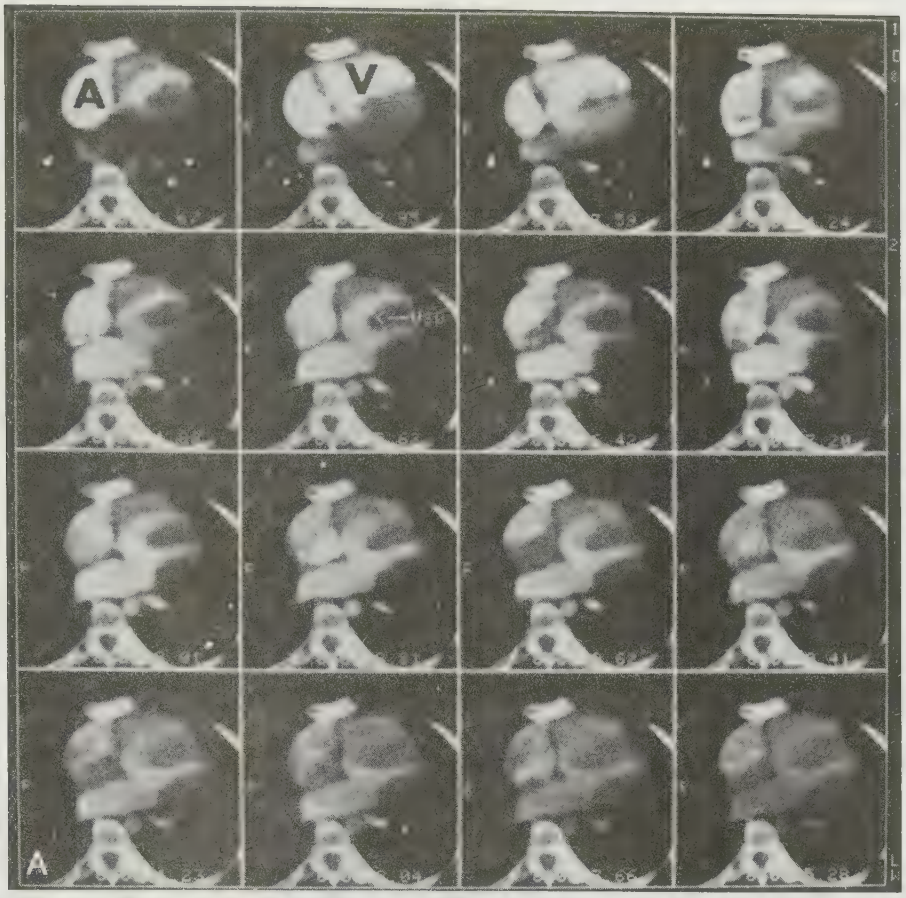
Fig. 52–22. continued. (C) Shunt calculation of atrial septal defect using time (abscissa)–density (ordinate, in CT numbers) curves. Gamma variates are placed to conform to both peaks (arrows). Computer-assisted calculations of the areas under both curves provide an estimation of shunt size. (Figures provided by Imatron, Inc. and W.J. Eldredge and S. Flicker, Deborah Heart and Lung Center, Browns Mills, N.J.)



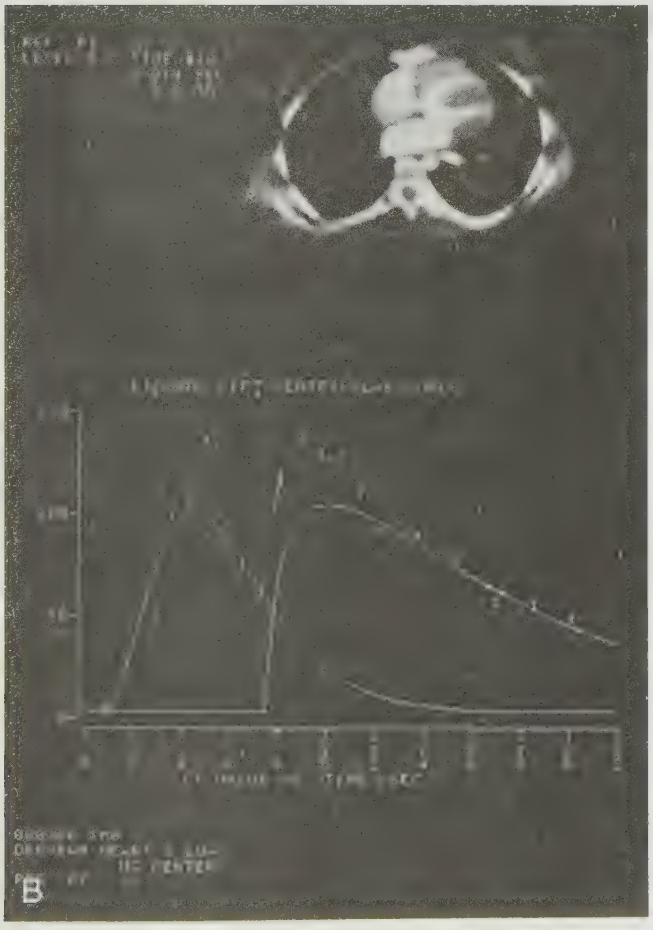


Fig. 52–23. Ventricular septal defect in a Cine-CT flow study with shunt calculation. (A) A Cine-CT flow study with 16 temporarily sequential images taken at the same level throughout one cardiac cycle. The injected contrast media courses through the heart beginning in the right atrium (A) and the right ventricle (V). The ventricular septal defect is visible, occupying approximately one-third of the length of the interventricular septum. (B) Time–density curves with cursor on the right ventricle disclosing a characteristic bimodal curve reflective of a shunt.

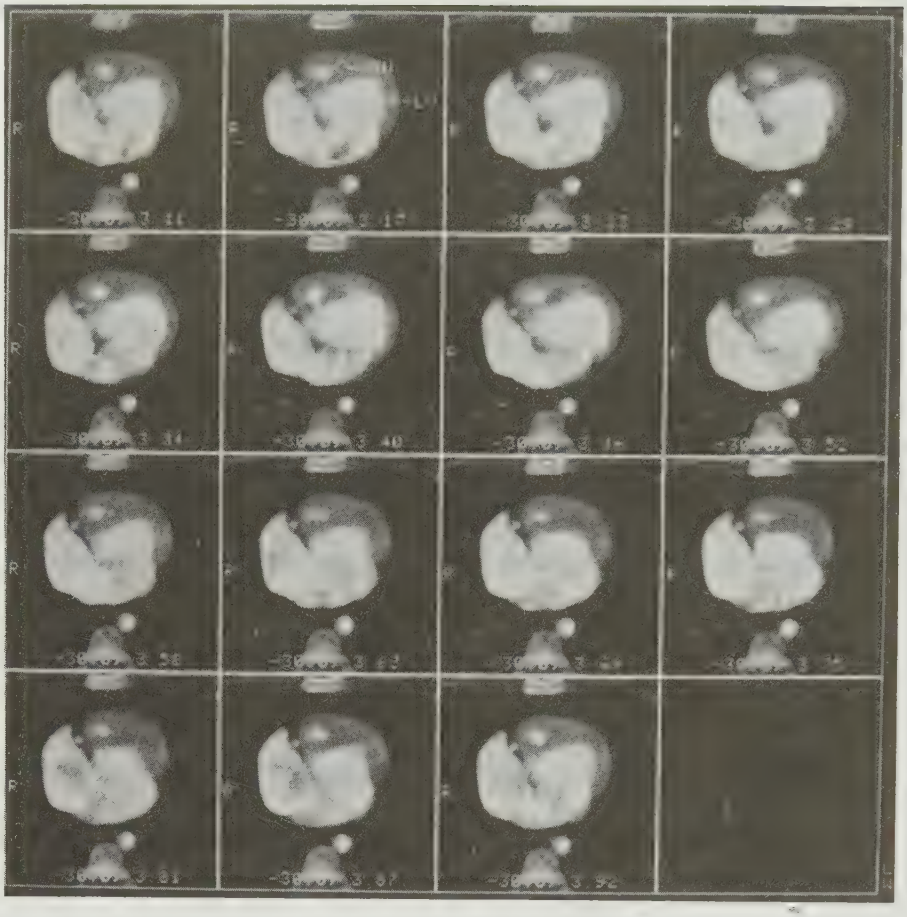

Fig. 52–24. A Cine-CT study of a young patient with hypoplastic right heart, atrial septal defect, and ventricular septal defect. The Cine mode is through the ventricles with a scan obtained every 58 ms (50 ms scan time and 8 ms interscan delay). Note the very small right ventricular cavity (RV) and moderate dilatation of the left ventricle (LV). Notice the thickening of the LV myocardium, especially at the LV apex level. (Courtesy of Imatron, Inc. and W.J. Eldredge and S. Flicker, Deborah Heart and Lung Center, Browns Mills, N.J.)

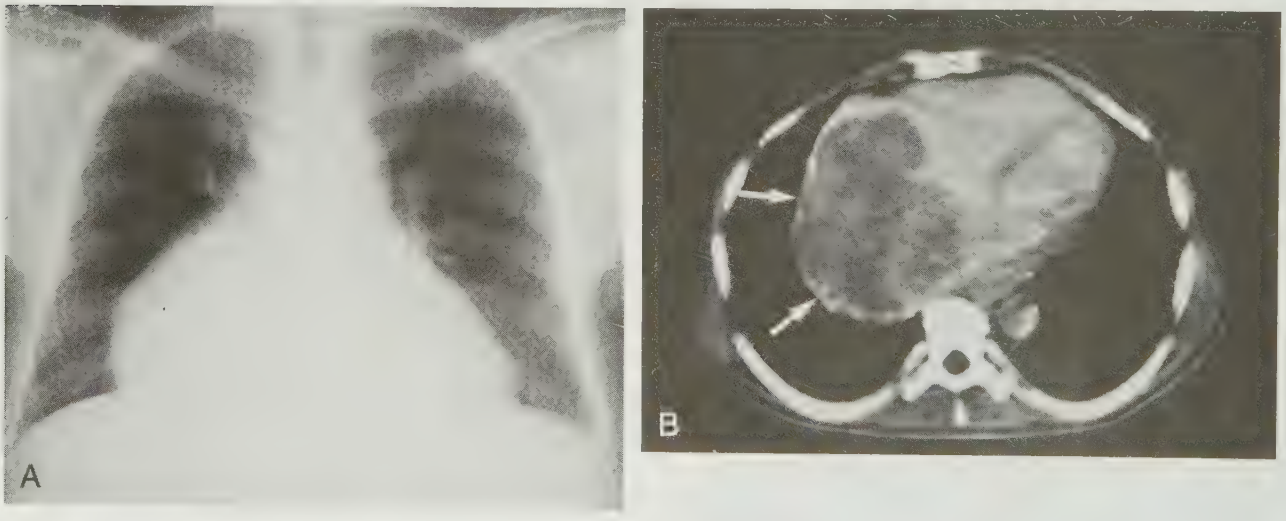

Fig. 52–25. A large right atrial tumor from hepatoma. This patient presented with malaise and an abnormal chest roentgenogram. (A) Chest film displays right atrial enlargement, possibly indicating Ebstein's anomaly, pericardial cyst, or right atrial tumor, perhaps a myxoma. (B) A CT scan discloses a large, primarily necrotic neoplasm (arrows) filling and expanding the right atrium. The right atrial wall cannot be separated from the mass, a feature raising the possibility of invasion.

Table 52–1. Anatomic Diagnoses

Diagnosis	*No. of Cases*
Aortic stenosis	5
Anomalous coronary artery	1
Atrial septal defect	22
Cardiomyopathies	10
Common atrium	1
Complete AV canal	8
Double-outlet right ventricle	3
d-transposition of the great vessels	10
Ebstein's anomaly	2
Hypoplastic right heart syndrome	4
l-transposition of the great vessels	4
Marfan's syndrome	2
Patent ductus arteriosus	4
Pulmonary atresia	13
Pulmonic stenosis	4
Single ventricle	19
Tetralogy of Fallot (preoperative)	15
Tetralogy of Fallot (postoperative)	11
Tricuspid atresia (preoperative)	6
Tricuspid atresia (postoperative)	2
Truncus arteriosus	1
Vascular ring	1
Ventricular septal defect	52

From Eldredge, W.J., and Flicker, S.: Evaluation of congenital heart disease using Cine-CT. Am. J. Card. Imag., *1*:38–50, 1987.

MRI are superior to conventional CT in these areas. Some congenital heart diseases such as septal defects can be diagnosed when dynamic scanning is used with the generation of time–density curves. Conventional CT can also detect Ebstein's anomaly and certain other configurational processes.

Cine-CT appears to offer a significant improvement over conventional CT and echocardiography in many congenital heart diseases.[19,21,24,48,49] Ebstein's anomaly (Fig. 52–22) and a variety of intracardiac shunt disorders including tetralogy of Fallot (Fig. 52–19), ventricular septal defects (Fig. 52–23), and atrial septal defects can be seen. Eldredge and Flicker[21] reported experience with over 200 patients with congenital heart disease studied with Cine-CT. A variety of lesions (Table 52–1) were seen in these patients, with Cine-CT making the correct diagnosis in over 90%. Cine-CT appears to be more accurate in the assessment of valvular disorders than conventional CT, though it is still probably not quite as sensitive as echocardiography.

Intracardiac shunts can be often demonstrated with Cine-CT and can be categorized by location. Calculations of the amount of shunt can also be performed by using time–density curve measurements and calculating the areas under the resulting bimodal curves.[17,26,37] In one study, Garrett and others created shunts between the main pulmonary artery and the left atrium in dogs. Cine-CT shunt calculations correlated well (r = 0.91) with oximetric values of 0 to 50%.[26]

Hypoplastic ventricular lesions are well seen with Cine-CT (Fig. 52–24). In experimental studies, Cine-CT more precisely defined the actual measurements of left ventricular and right ventricular casts than did biplane angiography.[51]

Physiologic evaluation of valvular disorders may also be possible with Cine-CT. In one experimental study, aortic insufficiency created by a basket was accurately assessed by Cine-CT compared with electromagnetic flow probes (r = 0.85).[52]

For intracardiac tumors and thrombi, CT is quite useful (Fig. 52–25).[27,37,53–57] In one study of 38 patients with CT and echocardiography,[56] CT displayed 22 intracardiac thrombotic lesions, while echocardiography identified only 6. The left atrium is particularly well seen with CT and poorly seen with echocardiography. Cine-CT likewise provides excellent anatomic details of intracardiac processes.

UNIT 3

INVASIVE DIAGNOSTIC METHODS

CHAPTER 53

Digital Subtraction Angiography

William W Pinsky
David W Jones

In the 1970s, researchers in the field of digital subtraction angiography (DSA) believed that cardiac imaging would be revolutionized by this new technique.[1] Because of unrealistic expectations, software development disappointments, and the inability to archive acquired data efficiently, the acceptance of DSA has not been universal. It has been difficult for managers to justify the added expense of including DSA capabilities to an already expensive diagnostic laboratory.

Recent equipment developments, including more sophisticated software and archiving techniques, have made DSA a more attractive feature to cardiac catheterization laboratories. It is the purpose of this chapter to describe the past use of digital subtraction angiography in the cardiac catheterization laboratory, to outline the mechanics of applying this technique in a pediatric cardiac catheterization laboratory, to present examples of usage of DSA technique in pediatric patients, and to contrast cineangiography and DSA modes while also showing how they might complement each other.

CARDIAC APPLICATIONS

In many areas of medicine, advances first apply to adult before pediatric patients. This has been true in digital cardiac imaging. In contrast to the uses in pediatric patients, the adult cardiac lab has employed DSA more for understanding ventricular function, myocardial perfusion, and coronary artery stenosis than for imaging by itself.[2–6]

Initially, the basic difficulty in the use of DSA for cardiac work involved the motion of the heart during the cardiac cycle and the chest during respiration. The patient basically had to be motionless so that images could be subtracted from a previously selected mask. Also the contrast medium had to be delivered in a bolus large enough so that it could be concentrated properly. The motion problem was solved greatly by being able to add a different technique to the ''mask-mode'' method. In the previous method, one had to utilize a single image with no contrast, ''the mask'' and then ''subtract'' this from each subsequent frame. The new method, called time interval-difference (TID) imaging,[1] takes a series of images and integrates them (for more detail, see Chapter 39). This meant that during processing of an image, the masking could be performed repeatedly using several different images. This has helped to reduce motion artifact. The mask-mode and TID techniques are complementary. One can have a series of images from which a mask can be selected without exposing the patient to additional radiation. This discounts the effects of motion.

Having solved this problem, several investigators developed techniques to evaluate wall motion of the left ventricle.[4,5,7] Intravenous DSA does have the capability to verify the patency of saphenous vein grafts.[8] DSA systems with 512 × 512 matrices at rates of 15 to 30 frames per second can provide high-quality coronary images. This technique has the possibility of giving greater resolution than current cine technique. This also allows for ''road mapping'' (image freeze frame) for interventional angioplastic procedures. Another way to assess the effects of coronary artery disease using DSA is to measure myocardial perfusion.[6] By calculating the integral video density of the myocardium after contrast material has been injected into a coronary artery, the amount of contrast material that has entered the myocardium

can be estimated. One can calculate the arrival time of the bolus of contrast by video density.

On the other hand, up to now, pediatric application has been mostly in the imaging modes. Although intravenous DSA was first touted to be sufficient,[9] it actually requires intracavitary injections to obtain adequate imaging. Based on some initial imaging results in the adult patient aiding in the diagnosis of congenital heart disease, Levin in 1983 published a prospective study to investigate the diagnostic accuracy and potential benefits of DSA in a pediatric cardiac population. He and his associates performed DSA on 42 patients between the ages of 2 months and 18 years.[10] They compared this technique to conventional cine and cut film angiography. The DSA was performed utilizing a 512 × 512 matrix in single plane at 30 frames per second. Contrast injections for the intracardiac DSA ranged from 27.5 to 42% of the conventional dose. They demonstrated that the millirads received by the patients were only a fraction of that of either the cut film or cine. The diagnoses included shunt, obstructive, and regurgitant lesions. The authors felt that the diagnostic accuracy was at least equal to the other conventional techniques. Publications by other authors demonstrating congenital abnormalities of the aorta and aortic arch,[11] intracardiac masses,[11,12] anomalies associated with intracardiac left-to-right shunts,[9,13] aneurysms of the atrial, and ventricular septa,[13] all support Levin's findings.

Tonkin has a more recent publication with a larger series of pediatric patients utilizing intra-arterial injections.[14] She found that improved contrast resolution was obtained using smaller catheters and smaller amounts of contrast material compared to conventional imaging. The immediate availability of the images resulted in shorter total processing time. It was Dr. Tonkin's feeling that intra-arterial digital subtraction angiography eventually may indeed replace conventional imaging techniques.

TECHNIQUE OF DSA

Digital subtraction imaging is approached with the same goals and methods and basic methodology of conventional angiography. Since DSA is computer based, patient information can be inserted into the system prior to initiating the procedure. The DSA system can be preconfigured for the type of study, e.g., cardiac chamber, pulmonary artery, etc., and to select frame rate, radiographic settings, matrix site, and single or biplane views. The patient needs to be sedated to minimize motion. After the catheter is placed in the appropriate chamber and the appropriate position of the tubes is obtained, radiographic techniques should be checked to be sure that optimal energy settings are obtained. In most systems, once the DSA mode is selected, then fluoroscopy can be utilized as before, however, when the camera is activated, if the acquisition is then aborted, acquisition cannot be restarted until one resets the computer processing. It is extremely important that all "bright areas" (e.g., lungs) be shielded from x-ray exposure. Therefore, strict attention to "coning down" is necessary, supplemented by placement of bolus filters (radiopaque wedges) to cover transitional areas. Images are obtained and injections are performed just as during conventional imaging. Separate masking is not necessary. After acquiring the injection, one can choose a mask from the initial frames, which do not have contrast. Immediately following acquisition, the image is available for review. Compared to cine angiography, the image can be manipulated by various filtering and edge enhancement techniques to offer a better image. These are electronic mathematical manipulations that rearrange the digital information to reconstruct the image. On-line measurements of valves and arteries can be performed at this time to aid in interventional procedures. This is the ultimate goal of road mapping.

Following a procedure, the digital image can be manipulated further for contrast, brightness, and various temporal and spatial filters. The image can be reviewed on the hard disk console itself or transferred from the console to video tape format for later review. Hard copies are obtained utilizing either a laser or multiformat camera. Archiving is somewhat of a problem. One can imagine the amount of computer space needed to archive a 512 × 512 matrix at 30 frames per second in biplane in a typical pediatric case. The average cine length is 6 seconds and if an average of 2 injections per catheterization procedure are obtained, this requires quite a bit of disk space. For this reason, information needs to be compressed by deleting unnecessary or unwanted images and then transferring the material for more permanent storage on a device such as a magnetic tape recorder. This is similar to what is done in CT scanning.

In our laboratory we are currently able to obtain 512 × 512 10-bit matrices at 30 frames per second biplane. By utilizing biplane C-arms, complete oblique and long axial views are obtainable. The following examples (Figs. 53–1 through 53–6) show the type of detail that can be obtained in patients with tetralogy of Fallot, coarctation of the aorta, ventricular septal defect, interrupted aortic arch, and pulmonary atresia. These images have all been stored on magnetic tape as digital data so that more processing can be obtained at a later date.

We are able also to obtain various types of physiologic and anatomic information as demonstrated by Figure 53–7. Figure 53–7 was obtained from a patient who is after repair of anomalous origin of the left coronary artery. Automatic ventricular contouring is performed with subsequent ejection fraction calculated. Regional wall motion can also be viewed.

COMPARISON OF DSA TO CONVENTIONAL IMAGING

We believe that the above example shows that digital subtraction angiography imaging is at least equal to that of conventional techniques. Why therefore should one be willing to have the added cost to the laboratory to have DSA?

One obvious reason is that more information can be obtained with a single contrast injection. A lower total case dose of contrast medium therefore can be employed. This is a major advantage in pediatric cardiology. There is a dose-related toxicity associated with contrast medium, particularly in small infants. Large doses of contrast medium have been associated with rapid changes in acid–base balance, which can be detrimental to the cardiovascular system. In addition, osmolality changes also occur even with the newer isotonic mediums. Levin showed in his study that there is a marked reduction in radiation exposure to the patient as well as to the physician with digital subtraction angiography.[10] High doses of radiation are known potentially to be deleterious. Since many

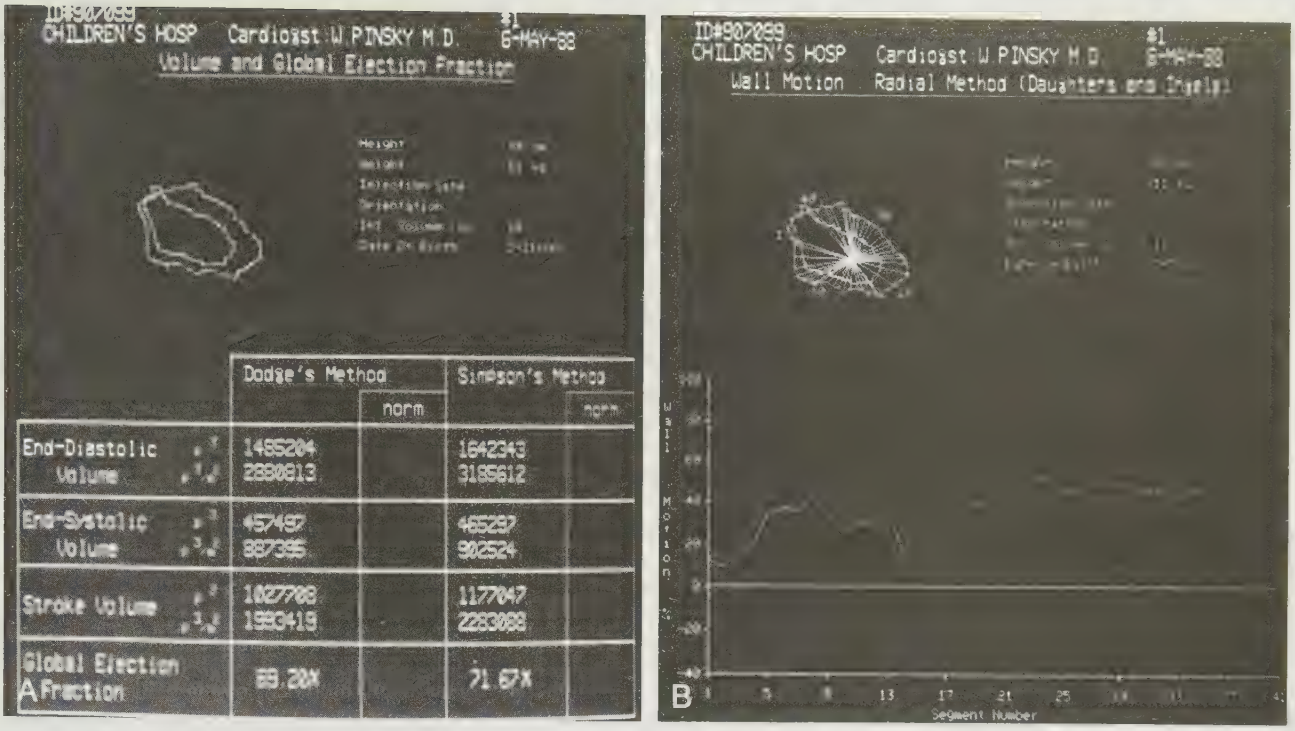

Fig. 53–7. Demonstration of on-line calculation function of DSA to generate ejection fraction from the global standpoint in (A) and in (B) utilizing the radial method to look for areas of localized wall motion abnormalities. This patient, after surgery to correct anomalous left coronary artery reimplantation, has areas of decreased motion in segments 14 and 15 as demonstrated by the graph in B.

pediatric patients undergo repeated cardiac catheterization their total radiation exposure generally is larger than in adults. Because smaller doses of contrast medium can be used, smaller catheters may be utilized. This is of benefit to reduce potential damage to the vascular access areas as well as to minimize intracardiac complications. Smaller doses of contrast medium for injection potentially will allow a greater number of injections when needed. Another advantage is the immediate availability of the images for review. This may shorten the procedure because of more firsthand knowledge of images acquired. Time in the catheterization laboratory is certainly related to morbidity.

FUTURE DEVELOPMENTS

Currently, digital subtraction angiography imaging is superb. Further advancements may be made in imaging as new filtering techniques are developed. There are basically mathematical applications to help with edge enhancement in particular.

Future advancements will be made in utilizing digital subtraction angiography to aid in the physiologic understanding of the lesions. This would include utilizing optical density for calculation of shunt size and regurgitant fractions, more accurate calculations of cardiac output, and volume calculations of chambers that do not fit the conventional geometric shapes utilized. For example, in postoperative Fontan patients, calculation of atrial size and function may aid in the understanding of postoperative hemodynamics.

Further development in digital data storage may also be able to improve the speed and efficiency of this technique. Even storing the data on magnetic tapes has its limiting factors. On the near horizon will be the ability to store digital information on tapes as small as those used for microcassette recorders. Optical disks are already available and may be an alternative to the magnetic tapes.

Whether or not digital subtraction angiography can supplant cineangiography remains to be seen. With improved efficiency and greater information content, DSA may assume an increasing role.

CHAPTER 54

Cardiac Catheterization—Hemodynamic Measurements

Thomas A Vargo

This chapter is written primarily for the pediatric cardiologist who needs to learn basic hemodynamic principles and calculations. The chapter is not encyclopedic. The reader who wishes to learn more about a specific area may read one of the excellent textbooks or monographs devoted exclusively to cardiac catheterization.[1–5]

Throughout this chapter we have included historical background about hemodynamic measurements. We believe that this helps us accomplish two major goals: to understand which hemodynamic information and calculations are (were) important, and to understand how to use this information so that some of the data obtained at catheterization will be clinically relevant.

CARDIAC CATHETERIZATION—GENERAL COMMENTS

Almost all cardiac catheterizations in infants and children are performed with fluid-filled catheters. Blood sampling and angiography, important procedures in pediatric cardiac catheterizations, can only be done using fluid-filled catheters. Pressure recordings are not as accurate when obtained with fluid-filled catheters as they are when the pressure is recorded with microtransducer manometer–tipped catheters. However, manometer-tipped catheters are not suitable for use in most pediatric cases, as will be discussed later.

Catheters used for angiography usually do not have end holes and cannot be used for measuring pulmonary capillary wedge (PCW) pressures. In general, end-hole catheters are not used for angiography because of the increased likelihood of both intramyocardial staining and catheter recoil during injection through end-hole catheters. In sick children it is often advisable to use only one catheter, to allow the catheterization to be done as quickly and safely as possible. Thus, the physician must decide prior to the catheterization what information is to be obtained and which catheter or catheters should be used. For example, in a newborn with transposition of the great arteries (TGA) in whom a balloon atrial septostomy is to be performed, there is usually no reason to measure the PCW pressures, so there would be no reason to use an end-hole catheter.

If possible, the hemodynamic data should be obtained first, with an end-hole catheter. After this, the catheter is switched for an angiographic catheter. Contrast material will change the patient's steady state and alter the hemodynamic data. A suggested protocol for obtaining hemodynamic data is shown in Table 54–1. In children, there are times when it is neither possible nor practical to follow these guidelines. Intracardiac pressures, oxygen saturations, and cardiac output change dramatically whenever the child's steady state changes. These changes can occur if:

1. the patient awakens,
2. the patient requires sedation,
3. angiography is performed (for example, if one enters a chamber that may be difficult to re-enter later on, one should perform any necessary angiography before obtaining the remainder of the hemodynamic information; in complex congenital heart lesions, the general rule is "get whatever information you can while you are there, you may never be back"),
4. a significant amount of time is spent in entering various cardiac chambers in cases with unusual cardiac anatomy,

Table 54–1. Desired Sequence for Obtaining Pressure and Oxygen Saturation Data

Sequence	Pressures Recorded	Oxygen Saturation Obtained*
1. RPCW	Yes	No
2. RPCW→RPA	Yes	Yes
3. RPA→MPA	Yes	Yes
4. LPCW	Yes	No
5. LPCW→LPA	Yes	Yes
6. LPA→MPA→RVO	Yes	Yes
7. RVO→RVI	Yes	Yes
8. RVI→RA	Yes	No
9. LIV	No	Yes
10. SVC	No	Yes
11. RA high	No	Yes
12. RA low	No	Yes
13. IVC	No	Yes
14. LV	Yes	Yes
15. LA	Yes	Yes
16. RPV	Yes	Yes
17. LPV	Yes	Yes
18. LA→RA	Yes	No

Abbreviations: RPCW and LPCW = right pulmonary and left pulmonary artery capillary wedge positions; RPA, LPA and MPA = right, left, main pulmonary arteries; RVO and RVI = right ventricle below the pulmonic valve and right ventricular body, respectively; LIV = left innominate vein; SVC and IVC = superior vena cava and inferior vena cava; RA and LA = right atrium and left atrium; LV = left ventricle; RPV and LPV = right and left sided pulmonary veins; → = catheter withdrawal pressure recordings.

*Oxygen saturations are only obtained at the end of a pressure withdrawal recording.

The above suggested sequence must be modified depending upon the patient's cardiac lesion. If possible, we usually begin our recordings of pressure and oxygen saturations in the PCW position as it is usually quicker to withdraw the catheter from the pulmonary artery to the other cardiac chambers than to begin in the atria and push the catheter forward into the various cardiac chambers. We begin in the PCW position that is first obtained, if the left PCW position was obtained first, withdrawal tracing would start there. Each pressure recording is obtained at a scale which fills the entire paper while continuing to show the entire pressure curve. A simultaneous systolic arterial pressure (usually femoral artery) is simultaneously recorded whenever the pressure is measured in the MPA, RV and LV. A femoral artery oxygen saturation is obtained at the beginning and end of this sequence of obtaining hemodynamic data. Systolic and diastolic pressures are measured in all arteries and ventricles. Mean pressures are measured in the wedge positions, both atria, all arteries, and the pulmonary veins. "a" and "v" waves are measured in the wedge positions and in both atria.

5. one is not able to enter the left side of the heart from a prograde venous catheterization.

All these factors can alter the patient's cardiovascular status enough to invalidate the hemodynamic information obtained.

We prefer to use woven Dacron catheters because we find them to be easy to manipulate, to retain their shape well, to give reasonably accurate pressure records, and to be excellent angiographic catheters. However, one's experience should dictate which types of catheter he or she uses for cardiac catheterization. We believe the ability to do "skilled purposeful catheterizations" is being lost by the popularity of balloon-flotation catheters. There are times when the nonfloating, standard catheters are preferable. Thus, we disagree with the statement in an excellent textbook that "abnormal positions of the heart chambers and of the great vessels associated with cardiac dilatation or with congenital malformation present difficulties even to experienced laboratory cardiologists" and that "these problems have been largely overcome by the introduction of balloon-tipped flow-directed catheters. . . ."[6]

For example, balloon catheters usually do "float" easily into the pulmonary artery of most patients, but in patients with either a massively dilated right ventricle (RV) or severe regurgitation of the tricuspid or pulmonary valve it is frequently impossible to enter the pulmonary artery with a balloon catheter. We find in these cases that it is much easier to enter the pulmonary artery with a large bore standard catheter that is appropriately curved, as these catheters are not "pushed back" by the valvular regurgitation as are the soft balloon catheters.

However, since the balloon-tipped flow-directed catheter is the catheter most commonly used in pediatric patients, we will mention some of our recommendations about the use of these catheters. Carbon dioxide should always be used to inflate the ballon whenever there is a possibility that rupture of the balloon would result in gas embolism to the systemic circulation. In our opinion, this includes all children with congenital heart lesions, as the catheter will often be manipulated into the systemic circulation, even in patients who are thought to have neither a right-to-left shunt nor any other communication between the venous and systemic circulations. Some physicians forget to flush the catheter with carbon dioxide (CO_2) prior to its use, not realizing that the lumen contains air and has a volume which is about one quarter the size of the inflated balloon. Because of possible bacterial contamination in the CO_2, the CO_2 should be filtered with a 0.22-micron filter prior to its use for balloon inflation. When such a catheter is inserted into the circulation to obtain blood samples, the single end hole of the "wedge catheters" will frequently be stuck against a vascular wall or the side of the heart; in most cases minimal inflation of the ballon will free the catheter tip and permit a blood sample to be obtained.

A balloon-flotation catheter is advantageous because 1) it is simple to use, 2) it is relatively safe, especially in babies (in whom the majority of cardiac perforations occur), 3) the pulmonary artery can be entered relatively quickly in children with TGA, 4) in patients with an inter-atrial communication, the aorta can often be entered from the left ventricle (LV) rather than having to perform a retrograde catheterization, 5) wedge pressures are usually easily obtained, 6) in patients with ventricular inversion (corrected TGA) complete AV block is usually less common when using balloon catheters to enter the pulmonary artery, 7) less skill and training are needed to use such catheters, 8) angiography catheters with inflated balloons have less chance of causing intramyocardial extravasations of contrast, and 9) angiography balloon-tipped catheters can be "pushed" into the ventricles, causing less chance of recoil of the catheter into the atrium during injection of contrast material.

One disadvantage of balloon-flotation catheters is that the angiographic catheters allow injection of only relatively small volumes of contrast material. These catheters sometimes should not be used when large volumes are needed such as for ventriculography in children with large left-to-right shunts.

Balloon catheters can cause rupture of the pulmonary artery, especially if they are inflated while positioned distally in a branch of the pulmonary artery.[7,8] As mentioned, rupture of the balloon

can also cause air and bacterial emboli, although this will usually not cause damage if filtered CO_2 has been used.

PRESSURE DATA

Pressure measurements are the most important of the hemodynamic data obtained during cardiac catheterization. Elevated pressure due to stenosis of a valve is the main determinant of whether valvular surgery (or balloon dilation) is performed. Pulmonary hypertension often determines whether surgery is recommended in patients with left-to-right shunts. A difference in atrial pressures is one of the reasons for performing atrial septostomy in children in whom blood flow must cross the atrial septum, such as those with TGA, total anomalous pulmonary venous return, and mitral atresia.

The pressure of a cardiac chamber could be measured by connecting the catheter to a tall glass tube filled with fluid. Since the LV pressure in aortic stenosis could be 200 mm Hg or greater, this would require a tube of water at least 8 feet, 11 inches tall. Obviously this is not practical, and pressures are measured instead with transducers, which are discussed in Chapter 30. Tall glass tubes also cannot be used to measure the rapidly changing cardiac phasic pressures because the fluid level moves too slowly. Instead, the pressure inside a tall thin glass tube would be closer to the average or mean pressure in that cardiac chamber. Again, since tall tubes are not practical, mean pressures are now calculated electronically. While phasic pressures should be obtained from every cardiac chamber, mean pressures are obtained only in the veins, arteries, and atria. Mean pressures are used for the calculation of vascular resistances, which will be discussed later.

Before starting the catheterization, the pressure transducer is placed at the level of the heart and is opened to air; the pressure recorder is then calibrated so it will read "0" at atmospheric pressure. This is known as the zero reference point and means that a fluid-filled catheter exposed to atmospheric pressure will read 0 mm Hg when its tip is at the same level as the transducer. In pediatric cases, the level of the transducer, or the zero reference point, is set at the midchest position in the supine patient. In children, the midchest level is essentially at the level of the entrance of the superior vena cava (SVC) and inferior vena cava (IVC) into the right atrium. In adults there are at least six different positions where the transducer can be placed for setting the zero reference point, all of which are attempts to try to have the transducer set at the same level as the heart.[9]

For a correct reading the transducer must be at the same level as tip of the catheter, or the pressures will be incorrect depending on the difference between the height of the transducer and the catheter tip. If the tip of a fluid-filled catheter is elevated above the transducer, there will be a positive pressure of 1 mm Hg for each 1.36 cm of elevation above the zero reference point (mercury is 13.6 times denser than water). Similarly, a negative or reduced pressure will be recorded if the catheter tip is below the level of the transducer. For example, if the tip of the catheter is 4 cm lower than the transducer, the pressure will be 3 mm Hg lower than if the catheter tip and transducer were at the same level.

It would be preferable to change the level of the transducer to the level of the catheter tip with each pressure measurement, but this is not practical as the differences in pressures during cardiac catheterization in children are usually only 1 to 2 mm Hg from the true zero reference point. This difference is insignificant in measuring ventricular systolic, pulmonary, and aortic pressures. However, an improper zero reference point can materially change the atrial and ventricular diastolic pressure measurements; this is especially true in adults and large children, who have a much greater anteroposterior (AP) chest diameter than do babies, whose AP diameter is only about 10 cm.

To obtain accurate pressure measurements, the catheter, all tubing and stopcocks, the transducer, and the recording system (taken as a whole unit) should reliably reproduce the actual pressure curve. This requires that there is no amplitude distortion of any of the sine wave frequencies that make up the pressure curve. A cardiac pressure curve (according to my simplification of Fourier analysis) is the sum of all its sine wave frequencies, from the lowest frequency, which is the heart rate, up through its maximum frequency, which is 10 times the heart rate. To illustrate this, at a heart rate of 120 beats per minute, the frequency is 2 cycles per second, or 2 Hz; in order to get an accurate reproduction of the pressure curve at this heart rate the entire catheter–tubing–transducer–recorder system must not have any amplitude distortion of any of the sine wave frequencies from 2 through 20 Hz. At a heart rate of 180 beats per minute, there should not be any frequency distortion up to 30 Hz. The larger the bore of the catheter, the stiffer the catheter, the shorter the tubing, and the fewer stopcocks, the better the frequency response will usually be. For most pediatric catheterizations, the catheter–transducer–recorder systems should have a nondistorted frequency response up to 10 to 30 Hz. In practicality, it is only in babies, who have fast heart rates and in whom smaller catheters are used, that a relatively poor frequency response causes problems in pressure measurement during routine cardiac catheterization.

Despite meticulous calibration, whenever two catheters are used for simultaneous pressure recordings, the tracings are rarely the same. Because of this, it is often better to perform a withdrawal tracing (e.g., from the LV to the aorta) than two simultaneous tracings, even though simultaneous tracings do make it easier to compare pressure gradients. Whenever two catheters are used, one should make sure that the transducers provide similar data by switching the tubing between the two catheters to confirm that both transducers result in identical pressure curves. Another way to confirm that the readings are correct is to place the two catheters in the same cardiac chamber, in which case the pressure tracings should be equal and be superimposed on each other.

If pressures appear to be erroneous, the catheter–tubing–transducer–recorder system should be checked and recalibrated. Causes of falsely low pressures include a clot or loose connection in the catheter or catheter system, a kinked catheter, entrapment of the catheter in a portion of the heart (usually in ventricular muscle), and air bubbles in the tubing or transducer not allowing transmission of the pressure wave. On the other hand, if entrapment forces the catheter against a blood vessel wall, a falsely high pressure can be recorded. Air bubbles can also create standing waves, which increase the amplification of the pressure wave causing an exaggerated overshoot on the initial portions of both the systolic and diastolic ventricular pressures.

Manometer-tipped catheters should be used when exact pressure measurements are required. Even though the pressure curves with manometer-tipped catheters are superior, these catheters are rarely used in children because of their disadvantages:

1. They are fragile and expensive.
2. They require delicate zeroing and calibration.
3. They "drift" easily after calibration.
4. They are relatively stiff.
5. The smallest catheter with side holes for performing angiography is size 7F.
6. The flow rate (and therefore the volume) that can be injected is limited compared to standard catheters (10–15 mL/sec for a 7F manometer-tipped catheter).

As shown in Figure 54–1, there is not much difference between the pressure recorded with a manometer-tipped catheter and a fluid-filled one.[10] Thus, with the disadvantages just listed there is not much reason to use these catheters in children. The two main abnormalities in the pressure recordings obtained with the fluid-filled catheters are the "overshoot" and the delay of about 30 to 40 msec for the pressure wave to be transmitted to the transducer. The major reasons for using manometer-tipped catheters are for research applications, where, for example, by using two manometers on the same catheter, precise gradients can be determined.

The positioning and direction of the catheter can affect the pressure measurement.

1. Catheters will read lower pressures when they are in an area with higher velocity of the blood flow (Bernoulli effect). For example, the pressure in a narrow segment of a stenotic pulmonary artery branch can be lower than the pressure downstream, where the pulmonary artery is of normal size.
2. If the tip of the catheter or one of its openings is in the atrium but lying against the mitral or tricuspid valve, catheter impact artifact during opening or closing of the atrioventricular valve can give a strikingly tall but artifactually elevated atrial wave, which can be confused with an abnormal "a," "c," or "v" wave.
3. Because forward flow can convert kinetic energy into pressure, end-hole catheters generally add 2 to 4 mm Hg when facing the flow of blood, and subtract 2 to 3 mm Hg when they are in the direction of the flow. In some cases, it is possible for a femoral or brachial arterial line facing the flow to have the pressure 10 mm Hg higher than if the line faced downstream.
4. The motion of the catheter in the beating heart along with fluid acceleration may produce superimposed waves of as high as 7 to 10 mm Hg. This is called catheter whip artifact and seems to be particularly common in the pulmonary artery, where artifactual superimposition of systolic readings can be as great as 10 mm Hg.

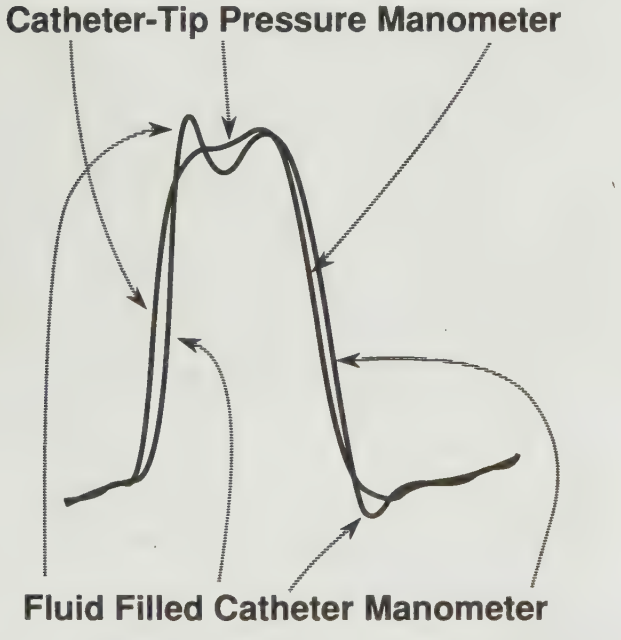

Fig. 54–1. Comparison of pressure recordings between a fluid-filled catheter and a manometer-tipped catheter. Note the similarities of these simultaneous left ventricular pressure records obtained with the catheter-tip pressure manometer and with a fluid-filled catheter. The main "errors" with the fluid-filled system are the "overshoot" at the beginning of systole, the "undershoot" at the beginning of diastole and the delay in the pressure response of the catheters. (Reproduced with permission from Cardiovasc. Res., *12*:566, 1978.)

In essence, the heart beats inside a "mild vacuum." Normal intrathoracic pressure is about 0 to 8 mm Hg less than atmospheric pressure. Thus, part of the atrial pressures and the early diastolic pressures in the ventricles often are less than "zero" or atmospheric pressure (less than the "zero reference point"). Dehydration, crying, and hyperpnea can be associated with intracardiac pressures well below the zero reference point. The right atrium especially can have subatmospheric pressures. Therefore, it is possible for air to be introduced into the right atrium if the catheter is disconnected from either the transducer or its tubing. Whenever we disconnect a catheter with its tip in the atrium, we keep the catheter hub at a low enough level that blood flows backwards from it. Raising the catheter hub can introduce air, which could then be flushed into the body when the catheter is connected back to the flushing system. Large amounts of air can be introduced into the right atrium if the femoral vein sheath is not kept occluded whenever the catheter inside it is withdrawn or exchanged.

Normal pressure measurements in children during cardiac catheterization are listed in Table 54–2.[11–13] This information is essentially "old" data; it was based primarily on children who had a normal heart. Younger cardiologists may not remember that

Table 54–2. Normal Intracardiac Pressures in Children (in mmHg)

	Average	*Range*
Right atrial mean	1–4	−3 to 8
Right ventricular, systolic	24–29	13–42
Right ventricular, end diastolic	3–5	0–10
Pulmonary arterial, systolic	20–22	11–36
Pulmonary arterial, diastolic	7–10	3–21
Pulmonary arterial, mean	11–12	6–22
Pulmonary arterial wedge or left atrial, mean	6–9	2–14
Left ventricular, systolic	100–106	72–133
Left ventricular, diastolic	7–10	3–14
Systemic arterial, systolic	108	77–150
Systemic arterial, diastolic	61–64	50–83
Systemic arterial, mean	70–81	67–105

These values are derived from references 11, 12 and 13. The author believes that the average values are reasonable, but that often the ranges listed are greater than what usually occurs in normal children.

before echocardiography, cardiac catheterization was frequently performed in children with functional murmurs who turned out to have normal hearts.

Pulmonary Capillary Wedge Pressure

Pulmonary capillary wedge pressures are used to estimate the pulmonary venous and left atrial pressures. The mean PCW pressure is usually close to the mean left atrial pressure, with the PCW pressure usually 1 mm Hg higher than the left atrial pressure.[14–16] The PCW pressure is attenuated compared to the left atrial pressure and the "c" wave is usually not seen. Differences in the level of the catheter tip can cause a 5 to 7 mm Hg difference in wedge pressures between a posterior pulmonary segment and an anterior pulmonary segment.[17] In our experience PCW pressures in the same patient are within 2 mm Hg of each other.

For calculating pulmonary vascular resistance, direct measurement of the pulmonary venous pressure or the left atrial pressure is preferable to estimating it from the PCW pressure. However, entering the left atrium is not always possible, and even if a left atrial pressure is obtained, the pulmonary veins may not be entered. In patients with lesions such as cor triatriatum, the PCW pressure may be the only way to estimate the pulmonary venous pressure. Except for those who are exceedingly skilled with the transseptal technique, it may not be desirable to enter the left atrium in certain patients, such as those who have had a Mustard operation or those who have had a large patch closure of an ostium primum atrial septal defect.

The transmission of the phasic contour waveform from the left atrium to the wedge pressure is usually delayed by 20 to 100 msec, depending on the length from the tip of the catheter to the transducer as well as on the type and diameter of the tubing used.[3,9,16]

Infrequently, we have seen abnormally elevated or low pressures in the pulmonary wedge position from forcing the catheter too vigorously into the wedge position; presumably this is because the catheter tip is forced against a blood vessel wall. In these cases the pressure is attenuated and withdrawing the catheter slightly will usually give a typical phasic PCW tracing.

In many cases it is difficult to tell if the catheter is completely wedged or not, as the pressure contour will seem to be somewhere in between a typical pulmonary artery and a PCW pressure. In addition, in patients with a large pulmonary blood flow, it is often difficult to "wedge" the catheter. Furthermore, in patients with large shunts there is a watershed effect of pressures flowing from the PCW position to the pulmonary vein to the left atrium, and the PCW pressure will be higher than the left atrial pressure.[18] To determine whether the catheter is truly wedged, one should withdraw the catheter on a continuous pressure tracing. If the catheter is wedged, the pressure will usually increase suddenly to a typical pulmonary artery pressure curve and the catheter will tug when it is released from the wedge position. If a good "tug" is not felt, the catheter may not have been wedged. One can demonstrate that the catheter is wedged if aspirated blood has 95% arterial saturation. We rarely do this because it often takes so long to obtain a PCW blood sample that clot formation will occlude the catheter.

Pulmonary Artery Pressure

The diastolic pressure of the pulmonary artery (PA) is usually 1 to 3 mm Hg higher than the mean PCW pressure. The PA systolic pressure should be about the same as the right ventricular pressure. The dicrotic notch represents closure of the pulmonic valve in the beginning of diastole.

Pulmonary artery pressures will vary depending on whether an end-hole or a side-hole catheter is used. As previously discussed, end-hole catheters frequently read a different pressure than side-hole catheters, depending on velocity of flow and the direction the catheter is facing (it is possible for it to be facing the flow of the pulmonary artery if the catheter enters the pulmonary artery through a surgical shunt anastomosis or a patent ductus arteriosus). Occasionally, the pressure will be higher in a pulmonary artery branch than in the main pulmonary artery, usually the left pulmonary artery.

If there is a large ventricular septal defect or ductus arteriosus, the pulmonary artery systolic pressure equals the aortic systolic pressure because there is no restriction of pressure from the left side to the right side of the heart. In patients with a large ventricular shunt, the greater the volume of pulmonary blood flow, the lower the diastolic and mean pulmonary artery pressures will be compared to the aortic diastolic and mean pressures. Obviously, since the systolic pressures are equal, the pulse pressure in the pulmonary artery will also be greater than that in the aorta.

Sometimes it is impossible to obtain a typical pulmonary artery pressure curve in patients who have an exceedingly tight pulmonary artery band or severe branch stenosis. In these cases, if the catheter can even be manipulated across the narrow area it may completely occlude the lumen and one will obtain a PCW pressure rather than a pulmonary artery pressure.

Right Ventricular Pressure

After the pulmonary artery pressure is recorded, the catheter should be withdrawn slowly into the right ventricle (RV) to determine whether there is a gradient across the pulmonic valve. After obtaining the right ventricular outflow tract pressure the catheter is withdrawn from just below the pulmonic valve to the body of the RV to see if there is a subvalvular gradient. When withdrawing the catheter from the pulmonary artery, the catheter tip should be kept pointed in a cephalad direction (by continued clockwise torque). Otherwise, the catheter will usually "drop" from the pulmonary artery into the body of the RV, in which case one would be unable to tell from a pressure tracing whether any gradient present was due to valvular or subvalvular obstruction. If precise determination of the outflow tract gradient is needed, then an end-hole, double-lumen, or manometer-tipped catheter must be used. Usually this is not necessary because even if the withdrawal tracing is poor, determination of the location of the stenosis is best demonstrated by angiography.

When premature ventricular contractions (PVCs) are induced by mechanical stimulation with the catheter, the pressure response can frequently be used to tell whether or not the patient with right ventricular hypertension has pulmonary stenosis or a large ventricular septal defect (VSD). If there is a large VSD, the right ventricular systolic pressure will remain equal to the aortic and left ventricular systolic pressure after the PVC. If there is pulmonic stenosis without a VSD, the RV pressure will increase significantly during the post-PVC beat; this is because there is usually a significantly increased stroke volume following a PVC, and all the extra blood must cross the pulmonic valve. Also, in pulmonic stenosis without a VSD, the pressure curve during right ventricular

contraction and relaxation is similar to an isosceles triangle, with a narrow base and relatively tall equal sides.

Right ventricular diastolic pressure is essentially equal to simultaneous right atrial pressures. Diastole begins at approximately "0" mm Hg (the zero reference point), rises slowly, and has a peak, due to atrial contraction, just before systole begins. The end-diastolic pressure of the RV is usually the nadir of the pressure wave that occurs after the atrial "a" wave. As in the left ventricle, it is questionable whether early diastolic pressure ("end systolic") should be recorded or not. We believe that it should. Congestive heart failure, restrictive cardiomyopathy, and pericardial constriction can cause all diastolic pressures to be elevated (including the early diastolic pressure). However, others assume that the early diastolic pressure should be close to the zero reference point and that only the end-diastolic pressure needs to be measured.

Right Atrial Pressure

The right atrial pressure is obtained on a withdrawal tracing from the RV to the right atrium (RA). The atrial pressure consists of "a," "c," and "v" waves. The "a" wave corresponds to atrial systole and is the first wave after the "P" wave of the ECG. The "c" wave is the deflection that occurs in early systole and corresponds to tricuspid valve closure. It is not clinically useful in pediatric cardiology. The "v" wave reflects filling of the atrium in late systole against the closed atrioventricular valve. In the RA the "a" wave is usually greater than the "v" wave by about 2 to 3 mm Hg. The "v" wave reaches its peak just before the tricuspid valve opens. There is a large "v" wave if tricuspid regurgitation is present. The "x" descent is the descending pressure that occurs after the "a" wave. The "x" descent continues to fall even after the tricuspid valve closes due to continued relaxation of the right atrium along with descent of the atrioventricular ring during ventricular systole. The "y" descent is the decreasing pressure which occurs after the "v" wave and is due to opening of the tricuspid valve. In normal individuals, right atrial pressure is essentially identical to pericardial pressure.[19]

By convention, pressures are taken at end expiration if respiration is quiet. The pressure in the RA can be less than atmospheric pressure and in inspiration may be as much as 7 to 9 mm Hg less than atmospheric pressure, especially if the patient is crying. Airway diseases cause the greatest fluctuations in pressure in the right atrium because of the marked changes in intrathoracic pressure during respiration.

Left Ventricular and Arterial Pressures

Systemic arterial and left ventricular (LV) pressures should be obtained simultaneously. Femoral and brachial arterial systolic pressures are usually 7 to 15 mm Hg greater than the LV pressure, and may be as much as 30 mm Hg greater.[17,20] Femoral artery diastolic pressure is usually lower than central aortic pressure by 2–6 mm Hg. Thus, if the femoral artery systolic pressure is 5 mm Hg less than the peak LV systolic pressure, the actual peak systolic gradient across the aortic valve would be approximately 15 mm Hg. The elevated systolic pressures in the peripheral arteries appear to be due to pulse amplification as the pressure waves are reflected back from arterial branch points, including the bifurcation of the abdominal aorta.[21]

There are many causes of an abnormally low incisura or dicrotic notch. In general, the causes are all associated with a large stroke volume. The greater the LV output, the wider the pulse pressure and the lower the diastolic pressure and dicrotic notch. In pediatric patients, the most common causes of an increased LV output are surgical systemic to pulmonary arterial shunts, patent ductus arteriosus (PDA), aortic regurgitation, anemia, fever, and exercise. Severe aortic stenosis, on the other hand, can cause a narrow pulse pressure with a wave on the ascending limb of the pressure tracing (known as an anacrotic notch) present on the ascending portion of the pressure curve. The LV pressure curve will have an isosceles triangular shape in aortic stenosis, but not as much as occurs with pulmonic stenosis.

Left ventricular diastolic pressures are similar to right ventricular diastolic pressures though LV pressures are higher, partially because of the greater wall thickness of the left ventricle and reduced compliance compared to the RV. Exactly where to determine the end diastolic pressure, in either the LV or the RV, is sometimes difficult to determine. With simultaneous atrial and ventricular pressure recordings, it is easy to determine the end diastolic pressure because it is at the point just before systole where the left atrial and LV pressure curves cross each other. Without simultaneous pressure recordings, the exact location of the end diastolic pressure is more difficult to determine. With a single pressure curve, the end diastolic pressure is usually at the nadir of the ventricular diastolic pressure, which occurs after the pressure wave due to the transmitted atrial "a" wave.

Left Atrial Pressure

In the left atrium (LA) the "v" wave is the dominant wave rather than the "a" wave. The "v" wave is related to pulmonary blood flow and is increased when pulmonary blood flow is increased, such as in a VSD with left-to-right shunting. The "v" wave is also partially due to pulmonary venous contraction. If ever there is a question of mitral stenosis, simultaneous left ventricular diastolic and PCW or LA pressures should be obtained. With mitral stenosis, the LA can usually only be entered using the transseptal technique, and therefore often only one catheter is inserted into the LV and the LA. If there is mitral stenosis, there is a gradient between the "a" wave and the LV end diastolic pressure. Mitral regurgitation causes an accentuated "v" wave.

We have developed a technique of measuring simultaneous left-sided pressures with the transseptal technique (Fig. 54–2). The LV pressure is measured with a catheter that is smaller than the lumen of the transseptal sheath. LA pressure is measured via a side arm connected to the sheath. Using this method requires meticulous attention to flushing and other technical details to ensure that clots and air bubbles are neither introduced into nor allowed to form within the sheath. After the LV and LA pressures are recorded, we confirm that the pressure records from the sheath and catheter are identical by withdrawing the LV catheter into the LA to make sure that the two pressures do superimpose. In order to obtain simultaneous and withdrawal pressures in the aorta, LV and LA, we often "float" a balloon catheter into the aorta from the sheath and then begin a series of catheter and sheath withdrawals, as demonstrated in Figure 54–2.

After LA pressures are obtained, the catheter is withdrawn from the LA to the RA, with LA pressure usually two to three times greater than RA pressure. In the presence of a large atrial septal defect, the atrial pressures are usually equal; however, equal pressures do not guarantee a large communication since the right atrial

Fig. 54–2. Example of three simultaneous pressures: patient with subaortic stenosis and coarctation (numbers on side of tracing are pressures in mm Hg). The pressure in the left ventricular inflow (LV in) area is measured using a Mullins transseptal sheath. A fluid-filled catheter inside the sheath is withdrawn from the ascending aorta (Asc Ao) to the LV outflow (LV out) position. The gradients across the subaortic area and coarctation are confirmed by systolic pressures of approximately 75 mm Hg in the femoral artery (FA), 105 mm Hg in the Asc Ao, 140 mm Hg in the LV out, and 200 mm Hg in the LV in. In this tracing there is about an 80 msec delay between the upstroke of the Asc Ao and FA pressures. Also note on the right side of the tracing that the LV in and the LV out diastolic pressures exactly coincide. Later in this case we pulled the tip of the transseptal sheath into the left atrium on a "higher gain" and noted no diastolic gradient across the mitral valve (thus, no mitral stenosis).

pressure may be elevated for another reason, e.g., Ebstein's disease, tricuspid atresia, or postoperative tetralogy of Fallot. However, if the pressures are significantly different and all the blood flow has crossed an atrial septal defect (ASD) in either direction (such as in mitral atresia, tricuspid atresia, or total anomalous pulmonary venous return), then the pressure difference confirms that blood flow is restricted.

Pulmonary Venous Wedge Pressure

There are cases where one is unable to measure the pulmonary artery (PA) pressure directly. PA pressures can be estimated by pulmonary venous wedge pressures which are assessed by wedging the catheter into a pulmonary vein. At that time, the pressure curve will resemble a PA pressure curve.

Wedged pulmonary venous pressures correlate with PA pressures.[22] If the mean pulmonary vein wedge pressure is less than 19 mm Hg, then the mean PA pressure is low and is usually less than 20 mm Hg. If the mean pulmonary vein wedge pressure is greater than 19 mm Hg, then the PA pressure is usually elevated, often with significant PA hypertension.

Pulmonary venous wedge pressures used to be the only way to estimate PA pressure in many cases of either TGA or pulmonary atresia. The development of balloon flotation catheters has made it possible to enter the PA in most cases of TGA. It is also frequently possible to enter the PA in children in whom the only blood flow to the lungs is by way of a shunt anastomosis. In those rare cases when this is not possible, pulmonary venous wedge pressures should be assessed.

OXIMETRY

This section discusses oximetry, which is the measurement of oxygen saturation of hemoglobin in a sample of blood. However, we will also use the term *oximetry* to mean any measurement of oxygen in the blood, especially when these measurements are important in calculating cardiac hemodynamics.

Oxygen saturation is the proportion of oxygen combined to hemoglobin divided by the oxygen capacity, and is described by the formula:

$$O_2 \text{ saturation} = \frac{(O_2 \text{ content} - \text{dissolved } O_2) \times 100}{O_2 \text{ capacity}}$$

The *oxygen content* is the total amount of oxygen present in a blood sample. It is a combination of the oxygen bound to hemoglobin plus the *dissolved oxygen*. The latter is the amount of oxygen dissolved in the plasma. The *oxygen capacity* is the theoretical maximal amount of oxygen that can be taken up by the hemoglobin. The oxygen capacity (in mL O_2/L) can also be calculated by multiplying the hemoglobin (in g/dL) by 13.6. This is because each gram of hemoglobin in a liter of blood will combine with 13.6 mL of oxygen when the hemoglobin is fully (100%) saturated.[23,24]

Early in the history of cardiac catheterization, oximetry was the primary means of diagnosing an intracardiac shunt. The detection of small shunts was not possible by oximetry, primarily because the determination required relatively large volumes of blood and there was a time delay before the oximetry result was available. Shunts less than 30 to 50% of the total cardiac output could not be detected by these older and relatively insensitive oximetry methods. Thus, to this day, the misconception persists that a shunt can only be definitely diagnosed by a "step up" or increase in oxygen saturation of 3 to 7% (Table 54–3). With present-day techniques, small shunts can be detected by oximetry. However, these shunts are usually currently diagnosed by echocardiography or cineangiography.

In current practice, oxygen saturation values can be repeated quickly (5 to 20 sec to obtain a reading), using small volumes (0.1 to 0.5 mL) for each specimen. Because of this, we can now diagnose much smaller shunts, as shown by the following extreme example. If one took 100 blood samples in the pulmonary artery and they all had an 80% oxygen saturation, while 100 samples in the right ventricle had a 79% saturation, then the patient would almost certainly have a very small left-to-right shunt into the pulmonary artery. Multiple samples are also used to help locate a shunt. For example, if a patient has one pulmonary vein entering the superior vena cava, one can sample repeatedly until the area

Table 54–3. Oximetric Detection of Intracardiac Shunts by Percent Increase or Decrease in Saturation

Cardiac Chambers Sampled	*One Sample*	*Multiple Samples*
Superior vena cava and right atrium	7%	5%
Right atrium and right ventricle	5%	3%
Right ventricle and pulmonary artery	4%	3%
Left atrium or pulmonary vein and left ventricle or systemic artery	−3%	−2%

Increases (step up) in oxygen saturation samples between two cardiac chambers which are diagnostic of the presence of a left-to-right shunt in the distal chamber. We believe that a "step down" from the left atrium or pulmonary vein to the left ventricle or systemic artery of −3 to −2% is necessary to diagnose a right-to-left shunt. References 25–28.

of the elevated saturation is localized and then usually probe with the catheter to enter the abnormally draining pulmonary vein.[25–28]

Oximetric values also have an important role in calculating the magnitude of a shunt and determining whether surgery is necessary. A pulmonary-to-systemic flow ratio of greater than 2.0:1 usually indicates a large left-to-right shunt and a defect that should be surgically closed just because of the volume of the shunt. Furthermore, right-to-left shunting and the amount of systemic desaturation often determines when to perform surgery in patients with cyanotic congenital heart lesions.

When pediatric heart catheterization became a "routine" procedure in the 1950s, oxygen contents were measured by the Van Slyke technique and other manometric methods.[29] These methods required 15 to 30 minutes to obtain a reading; they were technically difficult to perform, and required significant expertise to get a correct reading. While the Van Slyke method is the standard for oximetric determinations, most pediatric laboratories now use the spectrophotometric method to determine oxygen saturation.[30,31] Spectrophotometry is based on Beer's law, which states that "the absorption of light by a solution is a function of the concentration of its solute(s) and the depth of the solution." The absorption coefficients for light transmission of oxyhemoglobin and desaturated hemoglobin can be measured at two different wavelengths, and the difference in the amount of light absorbed is proportional to the concentration of each form of hemoglobin. From this difference in absorption, the concentration of oxyhemoglobin and desaturated hemoglobin are determined, and thus the oxygen saturation can be computed.

In the red range (630 to 660 nm), the light transmission of oxyhemoglobin and desaturated hemoglobin are different, while in the infrared (770 nm and above) and green (510 nm) range the transmissions are similar. One type of modern spectrophotometer measures in the red and infrared ranges at wavelengths of 670 nm and 930 nm. Oxyhemoglobin is measured in the red range and total hemoglobin in the infrared range. Other spectrophotometers measure in the green and red range. We have not found that one type is better than the other.

The spectrophotometric method is quick, accurate, precise, does not require using heparinized syringes, and is subject to few errors. Most errors in spectrophotometry are due to substances in the blood that interfere with light absorption. Spectrophotometric readings will be inaccurate if large amounts of carboxyhemoglobin are present, but usually this will only cause inaccuracies if it is present in significant concentrations, as in heavy smokers. Also, indocyanine green causes interference with the light source of many spectrophotometers, because it has a spectral absorbency in the range of 700 to 850 nm with peak absorbency at 800 to 810 nm. Thus, green dye curves should preferably be done after the oximetry has been done. Elevated bilirubin levels can also affect the absorption of spectrophotometric methods.

Spectrophotometry has about 1% error at 95% oxygen saturation and about 2.5% error at 70% saturation. It is relatively accurate to values of 40 to 50% saturation; spectrophotometric oximetry is not reliable at saturations lower than this. However, at such low values, precise determination of saturations is not usually necessary because it is obvious that something "must be wrong" with the patient, and the calculation of hemodynamic data in these cases is usually not important. If necessary, saturations below 50% can be determined by the blood gas method.

The next most common way to determine oxygen saturation in pediatric catheterization laboratories is by calculating the saturation from the oxygen dissociation curve (Fig. 54–3). The calculation of the saturation from the dissociation curve depends on the affinity of oxygen for hemoglobin, which depends on multiple factors including the temperature, pH, P_{CO_2}, and amount of fetal hemoglobin. The advantage of the blood gas method is that oxygen content can be calculated, which is important in those breathing high concentrations of oxygen. Like most laboratories we routinely use spectrophotometry and usually only obtain blood gases during the catheterization to confirm that a simultaneous oxygen saturation is the same as by spectrophotometry.

We attempt to begin the catheterization by obtaining oximetric and pressure measurements in rapid sequence, as outlined in Table 54–1. In many cases we can obtain all the saturations and pressures in 5 minutes or less. In our experience it is more rapid to begin in the PCW position than in the SVC position (because time can be spent getting to the PA and PCW). Obviously, the less time it takes to obtain the data, the more likely that the child will remain in a steady state during the hemodynamic portion of the catheterization.

Shunts can cause inaccurate readings themselves, as demonstrated by the following examples. Pulmonary artery oxygen saturations will be elevated if the blood sample is taken from an area where a ductus arteriosus or aortopulmonary anastomosis is directing its jet of fully saturated blood into the sampling catheter. On the other hand, one will not obtain a true pulmonary artery oxygen saturation if the collateral supply to the lungs is distal to the point where the sample was taken. The right ventricular outflow tract (and even the proximal pulmonary artery) may have an abnormally elevated saturation if the sampling location is in the stream of a VSD. We routinely sample in the left innominate vein because we have found many cases of unsuspected left-to-right shunts due to partial anomalous pulmonary venous return from the left upper lung into this vein. In such a case, the oxygen

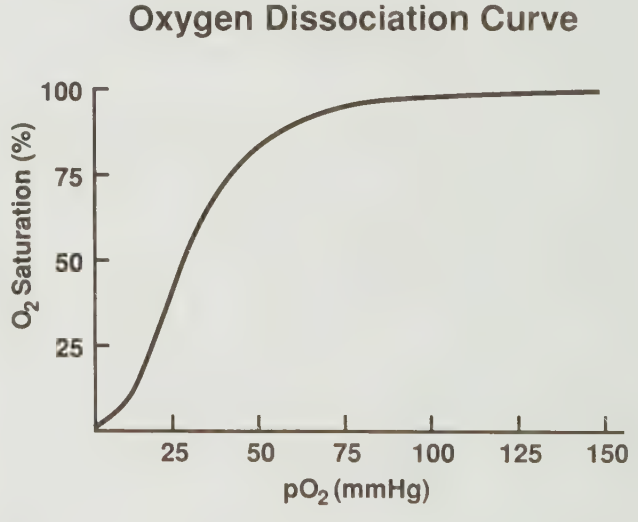

Fig. 54–3. Oxygen dissociation curve: this curve can be used to determine how much dissolved oxygen (pO_2) is present at given oxygen saturation (O_2 sat) and vice versa. At pO_2 values above 150 mm Hg, assume that the O_2 sat is essentially 100%.

saturation in the SVC will be higher than in the "true" mixed venous blood.

There are two major problems in oximetry. Namely, what is the definition of "mixed venous blood," and how to determine what it is when there is a left-to-right shunt? The *mixed venous blood* is the sum of all of the blood leaving the systemic vascular bed, which then enters the heart. Because of streaming from all the veins entering the heart, complete mixing (and a true average) of the blood does not occur until blood enters the pulmonary artery. Thus, the pulmonary artery oxygen saturation is used for the mixed venous blood sample in patients without a shunt. However, the pulmonary artery saturation cannot be used when there is a left-to-right shunt because the pulmonary artery contains both the mixed venous blood plus the blood from the shunt.

In patients who have left-to-right shunts it is often difficult to determine what the average oxygen saturation is in the venous blood proximal to the shunt, especially if there is an ASD. This is because the blood entering the right atrium is, in essence, coming from eight different veins: the coronary sinus, the SVC, the azygous vein, the IVC, two hepatic veins, and two renal veins, and the saturations differ markedly from each of these veins.

If there is a left-to-right shunt there are many different methods used to attempt to determine the mixed venous blood oxygen saturation. Most of these involve various combinations of SVC and IVC blood samples.[32] However, the saturation of the SVC approximates the pulmonary artery saturation closely enough that we routinely use only the SVC saturation for the mixed venous saturation (except when there is a proximal shunt, such as supracardiac total anomalous pulmonary venous drainage).[33] SVC saturations are often erroneously high if one inadvertently samples from the azygous vein instead.[34]

We routinely obtain an IVC saturation (below the hepatics); however, there is marked normal variation in this value. While the patient is awake and breathing room air the saturation in the IVC is higher than in the SVC; the reverse occurs in patients receiving general anesthesia.[35] Another reason for not using the IVC samples for oximetry is that barely moving the catheter will cause significant differences in oxygen saturations. The greatest streamlining and variation of oxygen saturations occurs in the area of the IVC and right atrial junction. Samples obtained close to the coronary sinus may have saturations as low as 25 to 40%, while saturations obtained from the renal veins may be greater than 90%[36]; saturations from the two hepatic veins will be between the coronary sinus and renal vein sample values, and may vary significantly from the remainder of the IVC blood flow.

For qualitatively detecting an intracardiac shunt by oximetry all that is needed is to have a significant "step-up" of oxygen saturation in the right heart or a "step-down" in the left heart. However, to measure the volume of a shunt, one needs to know the oxygen consumption and the oxygen saturations in the pulmonary artery, the pulmonary veins, a systemic artery, and the SVC (we use the SVC saturation for the mixed venous saturation, as discussed). The saturations in the PA, pulmonary vein (PV), and systemic artery (SA) do not have nearly as many potential errors as does the mixed venous (MV) saturation. We will now discuss how to quantitate intracardiac shunts and blood flow by oximetry. Several formulas for this calculation are shown in Table 54–4.

Qp is the amount of blood flowing through the pulmonary capillary bed (pulmonary flow), and Qs is the amount of blood flowing through the systemic capillaries (systemic flow). A left-to-right shunt is the amount of oxygenated blood that bypasses the systemic vascular bed. A right-to-left shunt is the amount of desaturated blood that bypasses the pulmonary vascular bed. Qep (effective pulmonary flow) is the quantity of mixed venous blood that carries desaturated blood from the systemic capillaries to be oxygenated by the lungs. It is equal to the quantity of pulmonary venous blood that carries oxygenated blood from the lungs to the systemic capillaries. Qp/Qs is the ratio of pulmonary blood flow to systemic blood flow; it is always calculated so that the denominator is 1; Qp/Qs is the only one of these formulas that does not require the oxygen consumption for its calculation.

Table 54–4. Formula for Calculating Blood Flow Using Oximetric Data

$$Qp = \frac{VO_2}{PVO_2 - PAO_2} = \frac{VO_2}{(PVsat - PAsat)\ (O_2\ capacity)}$$

$$Qs = \frac{VO_2}{SAO_2 - MVO_2} = \frac{VO_2}{(SAsat - MVsat)\ (O_2\ capacity)}$$

$$Qep = \frac{VO_2}{PVO_2 - MVO_2} = \frac{VO_2}{(PVsat - MVsat)\ (O_2\ capacity)}$$

$$QP/QS = \frac{SAsat - MVsat}{PVsat - PAsat}$$

Left-to-right shunt = Qp − Qep

Right-to-left shunt = Qs − Qep

Net shunt = (left-to-right shunt) − (right-to-left shunt)

O_2 capacity = 13.6 × gm hgb/dL

Abbreviations: VO_2 = oxygen consumption. PVO_2, PAO_2, SAO_2, and MVO_2 = O_2 content of the pulmonary veins, pulmonary arteries, systemic arteries, and mixed venous blood, respectively. PVsat, PAsat, SAsat, and MVsat represent pulmonary vein, pulmonary artery, systemic artery and mixed venous O_2 saturations, respectively. Qp = pulmonary blood flow, Qs = systemic blood flow which is the cardiac output, Qep = the effective pulmonary blood flow.

All blood flows are measured in liters of blood flowing per minute, as the units of VO_2 are mL of O_2 consumed per minute and the units of O_2 content are mL of O_2 per liter of blood. In this chapter O_2 content is measured in ml O_2/L of blood rather than ml O_2/dL of blood, as is done in many other texts. The O_2 content of blood contains both dissolved O_2 and the O_2 combined with hemoglobin. While breathing room air the amount of O_2 dissolved in the blood is insignificant compared to the amount of O_2 combined with hemoglobin, and dissolved O_2 is not used for the calculation of blood flows. Frequently, Qp/Qs is the primary means of diagnosing the magnitude of an intracardiac shunt. If one compares the complete formulae for Qp and Qs one can see that VO_2 and O_2 capacity cancel out so that only the systemic artery, mixed venous, pulmonary vein and pulmonary artery saturations are needed to calculate the ratio of pulmonary to systemic blood flow.

The terms Qp, Qs, Qep, left-to-right shunt, and right-to-left shunt are best explained by a series of box diagrams and examples of calculations. Oxygen consumption (VO_2) will be discussed in the next section; in order to perform the calculations in these examples, it is necessary to use arbitrary values for VO_2. In the first three examples the hemoglobin is 13 g/dL, the O_2 capacity is 176.8 mL O_2/L, and the VO_2 is 88.4 mL O_2/min.

Example 1 (Fig. 54–4). A patient with a VSD has aortic and

pulmonary vein oxygen saturations of 96%, a pulmonary artery saturation of 86%, and an SVC saturation of 76%. In this case one should be able to deduce that the amount of mixed venous blood returning to the lungs is equal to the volume of the left-to-right shunt, because the pulmonary artery saturation of 86% is exactly midway between the mixed venous saturation of 76% and the aortic saturation of 96%. The calculations in this case are:

$$Qp = \frac{88.4}{(0.96 - 0.86)176.8} = 5 \text{ L/min}$$

$$Qs = \frac{88.4}{(0.96 - 0.76)176.8} = 2.5 \text{ L/min}$$

$$Qep = \frac{88.4}{(0.96 - 0.76)176.8} = 2.5 \text{ L/min}$$

$$\text{Left-to-right shunt} = 5 - 2.5 = 2.5 \text{ L/min}$$

The left-to-right shunt is equal to the Qep; thus, total blood flow through the pulmonary circulation is twice the systemic flow (Qp/Qs = 2/1). It is obvious that Qp is a combination of blood returning to the lungs from the body plus the left-to-right shunt.

Example 2 (Fig. 54–5). Assume that the previous patient had a pulmonary artery band placed and that the VO_2, hemoglobin, and O_2 capacity remain the same. However, the patient now has only a right-to-left shunt without a left-to-right shunt. For calculation purposes the pulmonary vein oxygen saturation is 95%, the aortic saturation 85%, and the mixed venous and pulmonary artery saturations are both 70%. The following calculations apply:

$$Qp = \frac{88.4}{(0.95 - 0.70)176.8} = 2 \text{ L/min}$$

$$Qs = \frac{88.4}{(0.85 - 0.70)176.8} = 3.3 \text{ L/min}$$

$$Qep = \frac{88.4}{(0.95 - 0.70)176.8} = 2 \text{ L/min}$$

$$\text{Right-to-left shunt} = 3.3 - 2.0 = 1.3 \text{ L/min}$$

Because of the right-to-left shunt, the blood flow through the lungs has to be less than the blood flow through the body. Thus:

$$Qp/Qs = \frac{2}{3.3} = 0.6/1$$

As always, the amount of blood flowing through a vascular bed is the Qep plus any blood shunted back to that vascular bed.

Example 3 (Fig. 54–6). Imagine that the band is not quite as constricting and there is bidirectional shunting with a pulmonary vein oxygen saturation of 97%, aortic saturation of 90%, pulmonary artery saturation of 86%, and SVC saturation of 66%. Again, assume the same VO_2 and O_2:

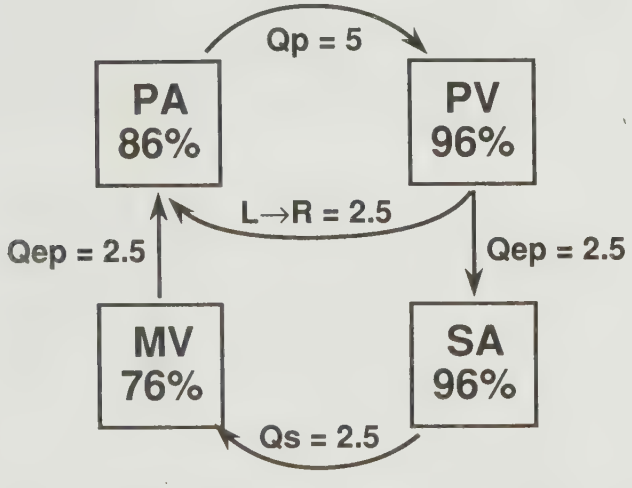

Fig. 54–4. Example 1, diagram of a left-to-right shunt: in these and the next few similar diagrams the boxes represent the pulmonary artery (PA), pulmonary vein (PV), aorta (Ao) or systemic artery (SA), and mixed venous (MV) or superior vena cava (SVC). Each box contains the values for the oxygen saturations obtained in each location. In these diagrams, aorta and systemic artery are used interchangeably, as are superior vena cava and mixed venous. The arrows represent the blood flow from one "box" (or cardiac chamber) to the next in liters per minute. See Example 1 in the text for further explanation. See Table 54–4 for explanation of Qp, Qs, left-to-right (L→R) shunt, etc. For making the diagrams simpler to understand, the word "shunt" is left out of "L→R shunt" (and "R→L shunt").

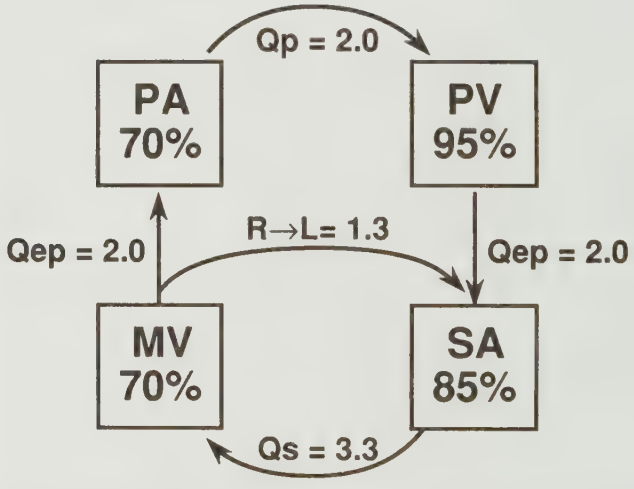

Fig. 54–5. Example 2, diagram of right-to-left shunt: see Figure 54–4 and text for further explanation.

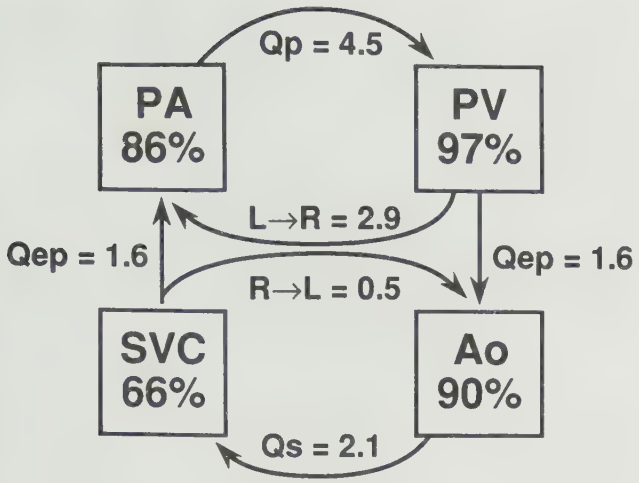

Fig. 54–6. Example 3, a bidirectional intracardiac shunt: see Figure 54–4 and text for further explanation.

Thus,

$$Qp = \frac{88.4}{(0.97 - 0.86)176.8} = 4.5 \text{ L/min}$$

$$Qs = \frac{88.4}{(0.90 - 0.66)176.8} = 2.1 \text{ L/min}$$

$$Qep = \frac{88.4}{(0.97 - 0.66)(176.8)} = 1.6 \text{ L/min}$$

$$\text{Left-to-right shunt} = 4.5 - 1.6 = 2.9 \text{ L/min}$$

$$\text{Right-to-left shunt} = 2.1 - 1.6 = 0.5 \text{ L/min}$$

$$\text{Net shunt} = 2.9 - 0.5 = 2.4 \text{ L/min}$$

$$Qp/Qs = \frac{4.5}{2.1} = 2.14/1$$

As is always true, the Qep remains the same on both sides of the diagram, because the amount of mixed venous blood going to the lungs to be oxygenated is equal to the amount of pulmonary venous blood that delivers oxygen to the tissues.

Note that in the first three examples the Qp/Qs can be determined without calculating Qp or Qs, nor is the VO_2 or O_2 capacity required. This will be true *whenever the patient is breathing room air* because only the oxygen saturations are needed for the calculations, as VO_2 and O_2 capacity cancel out:

$$\frac{Qp}{Qs} = \frac{\dfrac{VO_2}{(PV - PA \text{ sat})\ (O_2 \text{ capacity})}}{\dfrac{VO_2}{(Ao - MV \text{ sat})\ (O_2 \text{ capacity})}} = \frac{Ao - MV \text{ sat}}{PV - PA \text{ sat}}$$

Thus, for Example 1: $\dfrac{Qp}{Qs} = \dfrac{96 - 76}{96 - 86} = 2/1$

For Example 2: $\dfrac{Qp}{Qs} = \dfrac{85 - 70}{95 - 70} = 0.6/1$

For Example 3: $\dfrac{Qp}{Qs} = \dfrac{90 - 66}{97 - 86} =$ 2.18/1 (a slight difference due to rounding off)

In our opinion, the formula for "net shunt" (which is the difference between the left-to-right shunt and the right-to-left shunt—see Table 54–4 for calculation) is a meaningless number, but it is sometimes used in older literature. To emphasize this point, a patient could have a massive left-to-right shunt of 5 L/min with a similar massive right-to-left shunt of 5 L/min and the net shunt would be 0. However, in such a case there would obviously be very abnormal hemodynamics—in actuality, this situation does occur in patients with TGA.

The formulas used and the description of blood flow in TGA is the same as for any other lesion. Desaturated blood that returns to the systemic circulation is a right-to-left shunt, oxygenated blood that returns to the lungs is a left-to-right shunt, and so on. Representative values for oxygen saturation in a patient with TGA are 96% in the pulmonary veins, 88% in the pulmonary artery, 69% in the aorta, and 50% in the SVC. Patients with TGA usually have hemoglobin values higher than in the previous three examples, so that for this example (Fig. 54–7) we will make the hemoglobin 18 g/dL, the O_2 content 244.8 mL O_2/L, and the VO_2 122.4 mL O_2/min. The following calculations apply to this patient with TGA.

$$Qp = \frac{122.4}{(0.96 - 0.88)244.8} = 6.25 \text{ L/min}$$

$$Qs = \frac{122.4}{(0.69 - 0.50)244.8} = 2.6 \text{ L/min}$$

$$Qep = \frac{122.4}{(0.96 - 0.50)244.8} = 1.1 \text{ L/min}$$

$$\text{Left-to-right shunt} = 6.25 - 1.1 = 5.15 \text{ L/min}$$

$$\text{Right-to-left shunt} = 2.6 - 1.1 = 1.5 \text{ L/min}$$

The diagram in Figure 54–7 looks the same as the previous three diagrams. However, it can be seen that the right-to-left and the left-to-right shunts are much larger than the Qep.

The box diagrams in Figure 54–8 better demonstrate the anatomy and hemodynamics of TGA, as they demonstrate the aorta receiving the desaturated blood from the vena cava and the pulmonary artery receiving oxygenated blood from the pulmonary veins. Figure 54–8 demonstrates that the so-called "parallel circulation" of blood that occurs in TGA is due to the significant right-to-left and left-to-right shunts.

It is apparent from Figure 54–8 that if a patient with TGA had an ASD and no other defect, the only way blood could go from the lungs to the body (and vice versa) would have to be through the ASD. In TGA the blood flowing across the ASD is, in essence, normal blood flow. That is to say, this is how the oxygenated

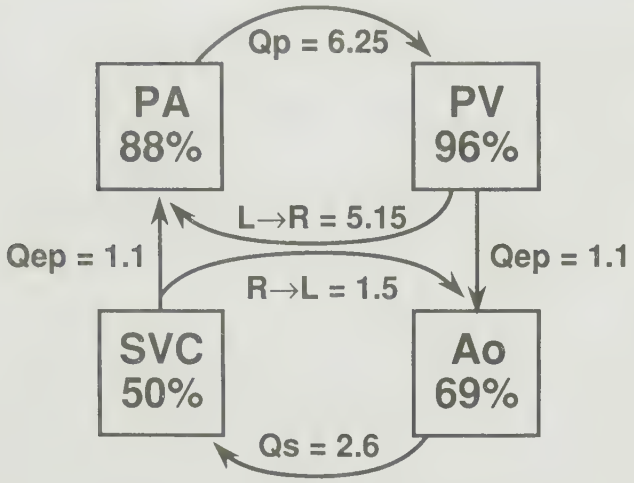

Fig. 54–7. Example of bidirectional shunting in transposition of the great arteries: see Figure 54–4 and text for further explanation.

blood reaches the body, and the desaturated blood reaches the lungs. Hemodynamically, blood flowing from the left atrium to the right atrium in TGA is not a left-to-right shunt, but is the Qep; similarly, the blood flowing from the right atrium to the left atrium in TGA is not a right-to-left shunt but is the Qep.

Finally, in TGA the amount of blood flowing from the lungs to the body has to equal the amount of blood flowing from the body to the lungs. While this is obvious in this example of TGA, it is also true in every person, or all the blood would eventually be in either the pulmonary vascular bed or the systemic vascular bed.

Is it important to include the dissolved oxygen in calculating pulmonary blood flow? While breathing room air the answer is "no," as the amount of dissolved oxygen is usually only about 1% of the amount of oxygen combined with the hemoglobin. However, while breathing oxygen the answer is often "yes," as the volume of dissolved oxygen is much larger, as will now be demonstrated.

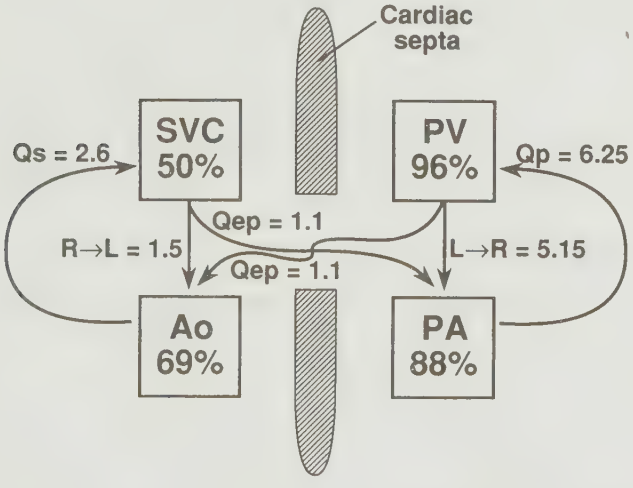

Fig. 54–8. Rearranged "correct" diagram for transposition of the great arteries. Comparison of this figure with Figure 54–7 shows that even though the arrows and boxes are rearranged, the blood flow is unchanged between the two figures. However, this figure better represents a patient with transposition of the great arteries because the aorta arises from the right ventricle and SVC, while the pulmonary artery arises from the left ventricle and the left atrium. Thus, patients with TGA automatically have large right-to-left and left-to-right shunts, respectively.

For this example we will use calculations based on a "normal" person who has a VO_2 of 150 mL O_2/min, a hemoglobin of 15 g/dL, an arterial oxygen saturation of 95%, and arterial Po_2 of 80 mm Hg, a venous saturation of 70%, and a venous Po_2 of 40 mm Hg. Dissolved oxygen in the blood contains 3.26 mL O_2/L at an oxygen tension of 100 mm Hg (or 0.03 ml O_2/mm Hg in 1.0 L of blood). Remember that at an oxygen saturation of 100%, each gram of hemoglobin in a liter of blood will combine with 13.6 mL of O_2; thus, if the hemoglobin is 15 g/dL the O_2 capacity would be 204 mL O_2/L. The hemoglobin of the arterial blood will contain 193.8 mL O_2/L; in the venous blood the hemoglobin will contain 142.8 mL O_2/L. The volume of dissolved oxygen in the arterial and venous blood will be 2.4 and 1.2 mL O_2/L, respectively.

The Qp using only oxygen combined with hemoglobin in this example is

$$Qp = \frac{150}{193.8 - 142.8} = 2.94 \text{ L/min}$$

The Qp using the oxygen content is

$$Qp = \frac{150}{(193.8 + 2.4) - (142.8 + 1.2)} = 2.87 \text{ L/min}$$

An insignificant difference!

The lower the red cell mass and the higher the FiO_2, the greater the percentage of dissolved oxygen in the blood. Whenever there is anemia, there will be less oxygen bound to hemoglobin. Whenever there is a high concentration of inspired oxygen, the amount of dissolved oxygen in the blood increases. However, even in a person with a hemoglobin of 10 g/dL and an arterial oxygen tension of 600 mm Hg, the dissolved oxygen still only accounts for 14% of the oxygen content.

For practical purposes, the dissolved oxygen becomes important only when determining the pulmonary blood flow in patients with left-to-right shunts who are breathing high concentrations of oxygen. For example, let us assume a child has a VO_2 of 150 mL O_2/min with a hemoglobin of 12 g/dL, the O_2 capacity is, therefore, 163.2 mL O_2/L (13.6 × 12 = 163.2). Representative values for such a patient with a large left-to-right shunt breathing 100% oxygen are 1) pulmonary vein oxygen saturation of 100% with an oxygen tension of 500 mm Hg, and 2) pulmonary artery saturation of 95% with a dissolved oxygen tension of 80 mm Hg. The oxygen content in the pulmonary venous blood is 178.2 mL O_2/L, consisting of 163.2 mL bound to hemoglobin and 15 mL of dissolved oxygen. In the pulmonary artery the oxygen content is 157.4 mL O_2/L, consisting of 155 mL bound to hemoglobin and 2.4 mL dissolved in the plasma. In this case the Qp using only the oxygen combined with hemoglobin is

$$Qp = \frac{150}{163.2 - 155.0} = 18.3 \text{ L/min}$$

However, if the oxygen content is used, the Qp is

$$Qp = \frac{150}{178.2 - 157.4} = 7.2 \text{ L/min}$$

A striking difference! As this example demonstrates, the dissolved oxygen must be used whenever calculating Qp in a patient breathing oxygen who has a large left-to-right shunt.

Normal values for oxygenation saturations are shown in Table 54–5. A high cardiac output and a left-to-right shunt are the two most common causes of elevated values in the pulmonary artery. A low cardiac output, low systemic arterial oxygen saturation, and increased oxygen extraction (such as occurs with anemia or high metabolic rates) all cause low saturations in the "right heart." Abnormally high arterial saturations are almost always due to the patient receiving oxygen. Low saturations in the "left heart" are usually due to lung disease, such as atelectasis or pulmonary edema, or to intracardiac right-to-left shunts. Whenever a low arterial oxygen saturation is unexpectedly obtained, one should obtain an arterial blood gas to determine if the patient's hypoxemia is associated with hypoventilation (or acidosis) from causes such as excessive sedation or lung disease. Treatment should be instituted as indicated.

Oxygen saturations are important in determining pulmonary vascular resistance and pulmonary blood flow, especially in patients with left-to-right shunts who have pulmonary hypertension. If the patient has not been in a steady state, for whatever reason (though in young children and babies it is usually due to awakening and crying), the values obtained for oximetric and pressure measurements will vary too much to be meaningful. If exact measurements for calculation of pulmonary resistance are felt to be necessary, we sedate the patient with enough medication to keep the patient asleep for 15 minutes. We first measure pressures and oxygen saturations in room air. We then repeat these measurements while the patient is breathing oxygen, as pulmonary blood flow often increases (and resistance decreases) during oxygen inhalation; additionally, the sedation may cause hypoxemia and hypercarbia.[37] By following the protocol discussed in the Resistance section of this chapter we are usually able to obtain the majority of the hemodynamic data required in children with pulmonary hypertension.

Table 54–5. Normal Oxygen Saturation

Site	*Average*	*Range*
Superior vena cava	74%	67–83%
Inferior vena cava	78%	65–87%
Right atrium	75%	65–87%
Right ventricle	75%	67–84%
Pulmonary artery	75%	67–84%
Left atrium	95%	92–98%
Left ventricle	95%	93–98%
Systemic artery	95%	92–98%

There is a wider variation in the saturations in the inferior vena cava compared to the superior vena cava, and in the right atrium compared to the right ventricle. These differences in oxygen saturation are due to different saturations of the veins which enter the inferior vena cava and right atrium. For example a very high saturation may be obtained in the inferior vena cava if one samples near the entrance of the renal veins; similarly, a very low saturation in the right atrium may be obtained if one samples near the orifice of the coronary sinus. This oxygen saturation data should be considered approximate because of the significant difference in data obtained from various series plus the amount of sedation and anesthesia varies widely throughout the United States and the rest of the world. References 11, 17, 26, and 39.

Pulmonary venous saturations are also extremely variable. Because of this, many cardiologists use the left atrial saturation for the average or mixed pulmonary venous saturation. However, we routinely use the pulmonary vein saturation, realizing that there can be a marked variance in pulmonary vein oxygenation. The lower (most dependent) portion of the lung has the lowest oxygen saturations.[38] Also, the lung has disproportionate flow, with the left upper lobe having a small percentage of the total lung flow, while the right lower lobe has about three times more pulmonary blood flow. In children with a congenital heart lesion, atelectasis is often present (especially in the left lung when the left atrium is enlarged and compresses the bronchus) and will cause desaturation from the corresponding pulmonary vein.

No matter how meticulous one is in obtaining oximetric data, the results will never be entirely correct because of unavoidable inaccuracies in how we are able to obtain blood samples. These inaccuracies include variation in the steady state, physiological shunting, and sampling errors due to the shunts themselves. Fortunately, these inherent errors do not materially affect most hemodynamic data. For accurate hemodynamic information it is preferable to measure the patient's pressure and oxygen saturation while the patient is quiet, not anxious, and free of any medications that might affect pulmonary or systemic blood flow. In children this is almost impossible, as almost all anesthetics and sedatives cause vasodilatation, which usually diminishes the left-to-right shunt (or increases the right-to-left shunt). We routinely use ketamine, which increases systemic resistance and will increase any left-to-right shunt (or diminish a right-to-left shunt). Blood samples and pressures should be obtained before injection of contrast material, although in many complex congenital heart lesions this is not practical, as mentioned earlier.

Most individuals have physiological right-to-left shunts from thebesian and coronary veins entering the left ventricle and left atrium, and from bronchial veins draining into the left atrium or pulmonary vein. Physiological left-to-right shunting occurs whenever the bronchial arteries drain into the pulmonary artery. These volumes are usually small and are never taken into account except for the patient who has a large bronchial arterial collateral blood supply.

There are various congenital cardiovascular anomalies in which it is virtually impossible to calculate the pulmonary or systemic blood flow (or their vascular resistance). In most patients this is because the proportion of blood flow to the body or lungs is not calculable. For example, in a patient with a large left-to-right shunt due to arterial collaterals entering the distal pulmonary vascular bed, it is usually impossible to obtain a blood sample distal to the shunt. On the other hand, in a patient who has a right-to-left shunt through a PDA it is essentially impossible to determine what the proportion of desaturated blood flowing to the descending aorta is compared with the oxygenated blood flowing into the ascending aorta. Similarly, in coarctation of the aorta one cannot determine what the overall average arterial pressure is because the proportion of blood flowing to the upper half of the body compared to the amount flowing to the lower half is unknown.

Double Left-to-Right Shunts

Various formulas are available for calculating left-to-right shunts at two levels (e.g., an ASD and a VSD). The results of such calculations are almost always inaccurate because they as-

sume complete mixing of the blood (which probably never occurs) in each cardiac chamber that has a shunt.

Rather than using the formulas for determining two left-to-right shunts, the easiest way for us to figure out this type of calculation is to determine the Qp, Qs, Qep, and the left-to-right shunt *as if only one shunt were present*. Let us assume that we have a patient (demonstrated in Fig. 54–9) who has an ASD and a VSD with a 70% mixed venous oxygen saturation, a pulmonary artery saturation of 90%, and arterial saturation of 95%. In this patient the VO_2 is 100 mL O_2/min, the O_2 capacity is 163.2 mL O_2/L (therefore, the hemoglobin is 12 g/dL as 163.2 ÷ 13.6 = 12). Thus, Qep and Qs calculate to be 2.45 L/min, Qp 12.25 L/min, and the total left-to-right shunt to be 9.80 L/min.

$$Qs = \frac{100}{(0.95 - 0.70)163.2} = 2.45 \text{ L/min}$$

$$Qep = \frac{100}{(0.95 - 0.70)163.2} = 2.45 \text{ L/min}$$

$$Qp = \frac{100}{(0.95 - 0.90)163.2} = 12.25 \text{ L/min}$$

$$\text{Left-to-right shunt} = 12.25 - 2.45 = 9.80 \text{ L/min}$$

The only problem remaining is deciding which portion of the left-to-right shunt is by way of the ASD and which portion is by way of the VSD. Just looking at the percent saturations in Figure 54–9, one might assume that the atrial and ventricular shunts are equal because the saturation increases 10% in the right atrium and 10% in the right ventricle. However, this is not true because equal volumes of fully saturated blood will increase the mixed venous saturation more in the proximal than in the distal right-sided chamber. In this example, it will require approximately five times more 95% saturated blood to raise the right atrial saturation from 80% to 90% than was needed to raise the mixed venous saturation from 70% to 80%.

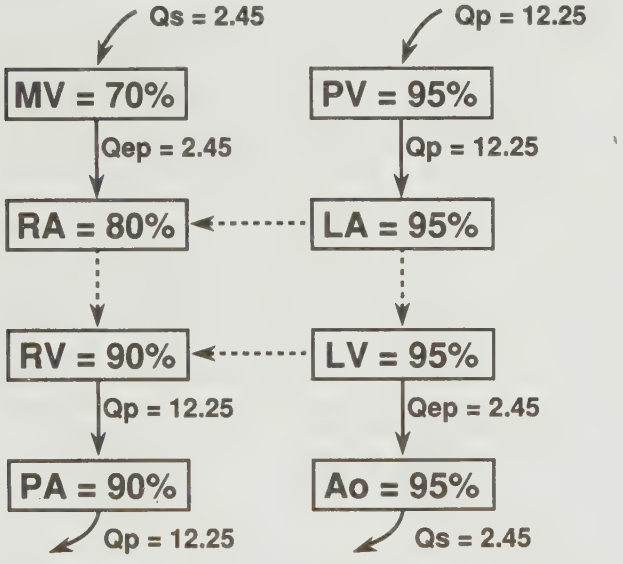

Fig. 54–9. Total intracardiac shunting in a patient with two left-to-right shunts: the location of the boxes in this diagram is somewhat different than in the other recent figures. As discussed in the text, Qp calculates to be 12.25 L/min, and both Qep and Qs calculate to be 2.45 L/min. Thus, the left-to-right shunt is 9.80 L/min. All that remains to do with this diagram is to decide how much of the shunt is at the atrial level and how much is at the ventricular level; these last two shunts (and blood flows) are indicated by dashed lines in this figure because they have not yet been calculated.

Getting back to how calculate a double left-to-right shunt, we have already worked out what the flows are except for what they are inside of the heart. The next step is to assume that the only shunt present is the left-to-right shunt at the atrial level, as shown in Figure 54–10. If this is the case, the right atrial saturation would remain at 80%, but the pulmonary artery saturation would also be 80%. Thus, the Qp, if there was not a VSD, would be 4.08 L/min and the left-to-right atrial shunt would be 1.63 L/min. *Therefore, if the left-to-right shunt at the atrial level is 1.63 L/min when the pulmonary artery saturation is 80%, and the total left-to-right shunt is 9.80 L/min when there is a VSD, then the left-to-right shunt from the VSD has to be 8.17 L/min.*

While we believe that it is easier to "logically" calculate two left-to-right shunts using the method just shown, Figure 54–11 shows a formula for calculating two left-to-right shunts.

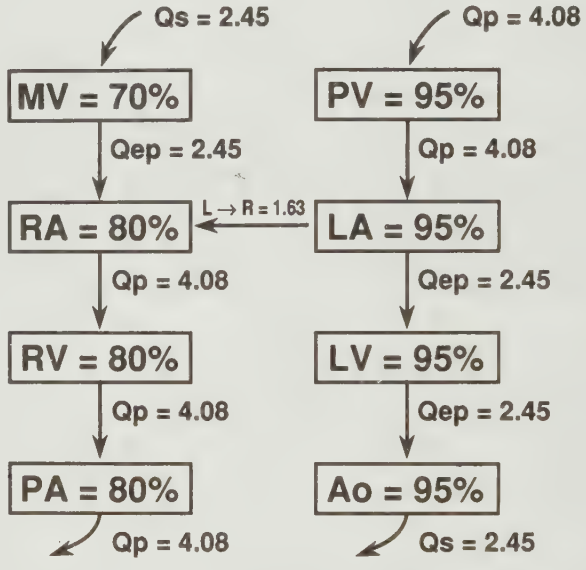

Fig. 54–10. Calculating the first intracardiac shunt in a patient with two left-to-right shunts: assume the same patient as in Figure 54–9, but the VSD closed temporarily; otherwise the shunt at the atrial level remains the same. In this case QP would be 4.08 L/min.

$$Qp = \frac{100}{(0.95 - 0.80)(163.2)} = 4.08$$

Therefore, the left-to-right shunt at the atrial level would be 1.63 L/min (4.08 − 2.45). Suppose the VSD spontaneously opens and all of the intracardiac shunts remain the same except that the right ventricular and pulmonary artery saturation increased to 90%. Since we know from Figure 54–9 that the total left-to-right shunt is 9.80 L/min, then 8.17 L/min must occur at the ventricular level; because, as we just determined, the atrial shunt was 1.63 L/min. This calculation is also described in the text.

$$S = \text{flow} \times \frac{a - b}{c - a}$$

where:

S = left to right shunt into a chamber
flow = blood flowing forward into a chamber
a = oxygen saturation or content in the chamber receiving the shunted blood
b = oxygen saturation or content in the chamber proximal to the shunt
c = pulmonary venous oxygen saturation or content

∴ shunt at ASD in figure 9 would be 1.63 L/min

$$S = 2.45 \times \frac{80\% - 70\%}{95\% - 80\%} = 1.63$$

and ∴ shunt at VSD would be 8.16 L/min as flow = 1.63 +2.45, a = 90%, b = 80%, c = 95%

$$S = 4.08 \times \frac{90\% - 80\%}{95\% - 90\%} = 8.16$$

Fig. 54–11. Formula for calculating two left-to-right shunts: see text for explanation and compare values with Figures 54–9 and 54–10.

OXYGEN CONSUMPTION

Classically, cardiac output (CO) is measured by the Fick principle. The formula is

$$CO = \frac{VO_2}{AVO_2 \text{ difference}}$$

The cardiac output is the quantity of blood delivered to the systemic circulation over a period of time and is usually expressed in liters of blood flowing each minute (L/min). The *arterial venous oxygen (AVO$_2$) difference* is the amount of oxygen extracted from the circulation as the blood flows through a vascular bed and is usually expressed in volumes percent (mL O$_2$/100 mL). The *oxygen consumption (VO$_2$)* is the amount of oxygen taken up by the tissues and is usually expressed in mL of oxygen consumed by the body each minute (mL O$_2$/min). In the catheterization laboratory, VO$_2$ is measured as the amount of oxygen breathed in by the lungs; this is not always the same as the oxygen consumed by the tissues.

In the previous section on oximetry there were multiple examples of calculating the CO, except there it was abbreviated as Qs. Also, there were many examples of how to determine the AVO$_2$ difference, which is the difference in oxygen content across a vascular bed. From all the examples in the oximetry section, it is apparent that the Fick principle also applies to the flow across the pulmonary vascular bed, where

$$Qp = \frac{VO_2}{AVO_2 \text{ difference across the lungs}}$$

This section will concentrate on the most difficult part of measuring the CO (or the Qs or the Qp), which is how to determine the VO$_2$. But first we will use a simple example to demonstrate the Fick principle. The reader will recognize that this example is identical to the examples in the previous section, but that the equation is expressed slightly differently. A patient who is known to have a VO$_2$ of 240 mL O$_2$/min and an AVO$_2$ of 4 vol%, will have a cardiac output of 6 L/min, as shown by the following calculation:

1. Four vol% is the AVO$_2$ difference in a person with a hemoglobin of 15 g/dL, 95% saturated arterial blood, and 75% saturated venous blood.
2. The VO$_2$ was 240 mL O$_2$/min.
3. The AVO$_2$ difference is 4 vol%, which is 4 mL O$_2$/dL or 40 mL O$_2$/L.
4. Therefore, the cardiac output is

$$\frac{VO_2}{AVO_2 \text{ difference}} = \frac{240 \text{ mL } O_2/\text{min}}{40 \text{ mL } O_2\text{L}} = 6 \text{ L/min}$$

This is exactly what Adolph Fick postulated in 1870.[40] He stated that the difference of oxygen in the arterial and venous blood had to be supplied by the lungs, and that from this fact one could calculate the cardiac output. Fick never did the experiments himself, but, based on animal data, he calculated that the human VO$_2$ would be 5 mL O$_2$/sec, and the amount of blood ejected during each systole would be 77 mL. His estimates were close to present-day normal values: a VO$_2$ of 5 mL O$_2$/sec is 300 mL O$_2$/min; and the cardiac output calculated to be 5.39 L/min, as he assumed the heart rate to be 70 beats per minute (77 mL × 70 BPM = 5390 mL/min).

The normal oxygen consumption for children 5 to 15 years old is about 110 to 160 mL O$_2$/min (per M^2), and for 0 to 5 years old it ranges from 160 to 200 mL O$_2$/min (per M^2).[28,41–43] The normal cardiac output for most children is about 4.0 to 5.0 L/min (per M^2), with slightly higher values for newborns.[39,41,42]

The classic way of measuring VO$_2$ is to collect all the expired air in a Douglas bag over a 3- to 5-minute period. The volume of expired air (VE) is measured with a Tissot spirometer and the amount of oxygen is measured with an oxygen analyzer (sometimes the amount of CO$_2$ is also measured). The amount of oxygen taken up by the lungs and consumed by the body is calculated by multiplying the volume of expired air collected in the bag by the fractional difference between inspired and expired oxygen. Since dry room air has 20.93% oxygen, all one has to know to calculate VO$_2$ is the volume of air in the bag and the concentration of oxygen in the expired air. For example, if 3750 mL of air was collected over a 5-minute period and the fraction of oxygen in the expired air was 0.1793, then the VO$_2$ would be 22.5 mL O$_2$/min. FiO$_2$ and FeO$_2$ stand for the fraction of inspired and expired oxygen, and that VE is measured in volume per minute. Thus, the formula for VO$_2$ is

$$VO_2 = VE(FiO_2 - FeO_2)$$

$$VO_2 = (3750 \div 5)(0.2093 - 0.1793) = 22.5 \text{ mL } O_2/\text{min}$$

For exact measurement of the amount of oxygen consumed, the inspiratory volume of air (VI) should be used, and the "true" formula for measuring oxygen consumption is VO$_2$ = [(VI) × (FiO$_2$)] − [(VE) × (FeO$_2$)]. Which is, of course, correct, as VO$_2$ has to be the difference between the volume of O$_2$ in inspired air and the volume of O$_2$ in the expired air. For practical purposes VO$_2$ is usually determined without measuring VI, as the VE is usually equal to or only slightly less than the VI.

An additional error not taken into account with the first formula for VO$_2$ is that the amount of oxygen breathed in is often different from the amount of carbon dioxide breathed out (CO$_2$). Originally

this was known as the respiratory quotient, but the term respiratory exchange ratio (RER) is now used. The formula is

$$RER = \frac{VCO_2}{VO_2}$$

While metabolizing carbohydrates, the RER is 1.0. While metabolizing fat, the RER is about 0.70. The RER when metabolizing protein is around 0.82. The explanation for this is that during metabolism fats and proteins require proportionately more oxygen than do carbohydrates.[44] Carbohydrates are made up of equal amounts of carbon and oxygen. Thus, in the breakdown of glucose the RER will be 1.0, because 6 moles of O_2 form 6 moles of CO_2 and water, as shown in the following formula:

$$C_6H_{12}O_6 + 6\ O_2 \rightarrow 6\ CO_2 + 6\ H_2O$$

However, when palmitin, the triglyceride of palmitic acid, is metabolized 145 moles of O_2 are consumed but only 102 moles of CO_2 and 98 moles of water are produced. Thus, the RER is 102/145 = 0.70.

$$2C_{51}H_{98}O_6 + 145\ O_2 \rightarrow 102\ CO_2 + 98\ H_2O$$

Depending on how VO_2 is measured, if VE is assumed to equal VI (RER = 1.0), whenever the RER is 0.8, VO_2 will be underestimated by about 4%. If the RER is 0.9, the VO_2 will be underestimated by about 2%. For practical purposes if one assumes VE = VI, the RER will never be so low that one would underestimate VO_2 by more than 6 to 7%. An example of how VO_2 is underestimated is shown in the next paragraph.

Let us assume that we have a patient who inhaled 5000 mL of air during a minute. From this 5000 mL of air he extracts 250 mL of O_2 and exhales 200 mL of CO_2. By definition his RER would be 0.8. Since the volume of nitrogen (and the other inert gases) does not exchange in the lungs, the VE would be 4950 mL instead of 5000 mL because 50 mL of O_2 was not replaced by CO_2. Though VI cannot be measured, it can be calculated from the fact that the volume of inspired air multiplied by the fraction of the sum of each of its component gases is equal to the volume of expired air multiplied by the fraction of the sum each of its component gases. The formula for this is

$$(VI \times FiN_2) + (VI \times FiO_2) + (VI \times FiCO_2)$$

$$= (VE \times FeN_2) + (VE \times FeO_2) + (VE \times FeCO_2)$$

Using the above formula we will now calculate the error in the example in the above paragraph if we assume the formula for $VO_2 = VE(FiO_2 - FeO_2)$ if the RER is 0.8; this is shown in Table 54–6. The fractions of nitrogen, oxygen, and CO_2 in dry inspired air are always 0.7904, 0.2093, and 0.0003 respectively (line 1). In the 5000 mL of inspired air, the volume of the three gases would be distributed as shown in line 2. Line 3 shows the amount of O_2 inhaled and CO_2 exhaled when the VO_2 is 250 ml and the RER is 0.8. Line 4 shows the volume of each of these gases in the expired air. The expired air has the same amount of nitrogen, but has 250 mL less of O_2 and 200 mL more of CO_2. The fraction of each gas is shown in line 5. If the formula $VO_2 = VE(FiO_2 - FeO_2)$ is used to calculate VO_2, then we obtain a value of 240 mL/min as shown in line 6. This is 10 mL less than the true value of VO_2 of 250 mL as shown in line 7. Thus, with this RER of 0.8, the VO_2 will be underestimated by 4% with this formula.

The reason for this error is that by measuring VE one always understimates VI whenever the RER is less than 1.0. The example in Table 54–6 did not consume 240 mL O_2 from 4950 mL of air, he actually consumed 250 mL O_2 from 5000 mL of inspired air. In this example if the extra 50 mL of CO_2 had been added to the VE (i.e., an RER of 1.0), then the value for the VO_2 would have been correct as $VO_2 = VE(FiO_2 - FeO_2) = 5000\ (0.2093 - 0.1593) = 250$ mL O_2/min. Similarly, if the correct formula for measuring oxygen consumption had been used, i.e., $VO_2 = (VI \times FiO_2) - (VE \times FeO_2) = (5000 \times 0.2093) - (4950 \times 0.1609) = 250$ mL O_2/min, then VO_2 would not have been underestimated.

Formulas are available for correcting the VO_2 when the RER is less than 1.0. These are based on the assumption that nitrogen does not exchange in the lungs and therefore $(VI) \times (FiN_2) = (VE) \times (FeN_2)$. Nitrogen cannot be measured in most laboratories, but VE, FeO_2, and $FeCO_2$ are relatively easy to measure. Thus, the various formulas used for obtaining an accurate value for VO_2 factor out nitrogen and substitute oxygen and carbon dioxide for nitrogen. This is demonstrated in Table 54–7, which shows how one of these formulas is derived. The formula on line 5 of the table will correct the VO_2 whenever VE is less than VI. Since the error for neglecting to measure CO_2 and correcting for RER is small, most laboratories use the simplified formula for calculating VO_2; namely $VO_2 = VE(FiO_2 - FeO_2)$. VO_2 by this formula is usually within 6 to 7% of the actual VO_2, as discussed earlier.

Fortunately, VO_2 no longer needs to be measured by the cumbersome and complex Douglas bag method. Presently VO_2 is almost always measured by the polarographic method.[45,46] In this method, a known amount of air is passed through a hood placed over the patient's head and the concentration of oxygen is determined at the outlet end of the hood. Since the volume of the air blowing through the hood is known, plus the initial concentration of oxygen is known to be 20.93%, the concentration of oxygen

Table 54–6. Error in VO_2 When RER is 0.8

	N_2	O_2	CO_2	*Total*
1. Fraction of VI	0.7904	0.2093	0.0003	1.000
2. VI Volumes	3952 mL	1046.5 mL	1.5 mL	5000 mL
3. O_2/CO_2 exchange	N/A	−250 mL	+200 mL	−50 mL
4. VE volumes	3952 mL	796.5 mL	201.5 mL	4950 mL
5. Fraction of VE	0.7984	0.1609	0.0407	1.000
6. Calculated $VO_2 = VE\ (FiO_2 - FeO_2) = 4950\ (0.2093 - 0.1609) = 239.6$ mL O_2/min				
7. "True" $VO_2 = (VI \times FiO_2) - (VE \times FeO_2) = (5000 \times 0.2093) - (4950 \times 0.1609) = 250$ mL O_2/min				

Table 54–7. Derivation of Formula for Measuring VO_2 When RER <1.0

1. Since there is no exchange of nitrogen in the lungs:

$$VI = (VE) \times \left(\frac{FeN_2}{FiN_2}\right)$$

2. A. FiN_2 is always 0.7904,
   B. FeN_2 is the fraction of gas which remains after the CO_2 and O_2 fractions are subtracted, which is $[1 - (FeO_2 + FeCO_2)]$
   C. Therefore, the formula on the line 1 is the same as

$$VI = \frac{VE\,[1 - (FeO_2 + FeCO_2)]}{0.7904}$$

3. The formula for VO_2 is: $VO_2 = [(VI)\,(FiO_2)] - [(VE)\,(FeO_2)]$
4. By substituting the formula on line 2C for VI, the formula on line 3 becomes:

$$VO_2 = \left[\left[\frac{VE\,(1 - (FeO_2 + FeCO_2)}{0.7904}\right] \times [FiO_2]\right] - \left[(VE) \times (FeO_2)\right]$$

5. A. FiO_2 is always 0.2093
   B. VE can be factored out from the formula in line 4
   C. and with rearranging, the formula on line 4 becomes:

$$VO_2 = VE\left[\left(\frac{0.2093}{0.7904} \times (1 - [FeO_2 + FeCO_2])\right) - FeO_2\right]$$

6. Using the values present in Table 54–6 demonstrates that the above formula gives the correct VO_2.

$$VO_2 = 4950\left[\left(0.2648\,[1 - (0.1609 + 0.0407)]\right) - [0.1609]\right] = 250 \text{ ml } O_2/\text{min}$$

at the outlet end can be used to calculate how much oxygen has been taken up by the patient. The readings for VO_2 are automatically displayed in a very short time after the child is placed under the hood. Older instruments used a RER of 1.0 for calculation of VO_2; more modern models use a RER of 0.85, which is closer to the actual RER in most patients.

Many times, it is not practical to measure the oxygen consumption. In this case one can use the tables of LaFarge and Miettinen to estimate VO_2.[43] These tables are based on age, sex, and heart rate. They assume that the patient has been premedicated with the standard "Toronto mixture" of meperidine, chlorpromazine, and promethazine, with some children receiving chloral hydrate as additional sedation. Because these tables are frequently used they are reproduced in Table 54–8.

All of the means of measuring VO_2 are subject to error, even if the RER of the patient is 1.0. Direct collection of air may result in leakage of air from the seal or tubing between the patient and the bag. The polarographic method may have too high or low air flow for accurate measurements. Oxygen consumption tables are based on calculations of average values for many children and may not pertain to an individual patient especially when the catheterization is done at a different institution using different techniques. The amount of oxygen that one measures is the amount of oxygen inhaled; if the patient either hyper- or hypoventilates, the oxygen inhaled will not equal the amount of oxygen actually delivered to the pulmonary and systemic capillaries. All measurements of VO_2 assume that the patient is in a steady state and that the oxygen consumption and cardiac output are constant. If they are not, the amount of oxygen inserted into the pulmonary vascular bed will not necessarily equal the oxygen consumed by the tissues.

Also, we are actually measuring the aortic oxygen content rather than the pulmonary venous oxygen content. Thus, any of the bronchial or thebesian venous blood that drains into the pulmonary veins, left atrium, or left ventricle will cause the aortic saturation to be less than the true sum of the pulmonary venous blood saturation, though in most cases this is estimated to be less than 2 to 5 mL O_2/L. Similarly, bronchial collateral arterial supply to the pulmonary vascular bed, which is often increased in children with cyanotic forms of congenital heart lesions, will result in an unmeasurable left-to-right shunt as the sample of blood taken from the pulmonary artery will almost always be proximal to where these arteries enter the pulmonary vascular bed. In this case, if the left-to-right shunt is large, the AVO_2 difference across the lungs will be underestimated and it will be impossible to calculate Qp or the cardiac output (Qs).

Finally, as with all tests, there is an inherent error in determining both the VO_2 and the AVO_2 difference; the total error in determination of the cardiac output by the Fick oxygen method has been estimated to be about 10%.[47]

When expired air is collected, its volume is measured at the *ambient* (room) *temperature* and barometric *pressure,* plus it is fully *saturated* with water vapor—abbreviated as VE_{ATPS}. Because oxygen volumes are given at standard temperature (273 degrees Kelvin or 0 degree Celsius) and pressure (760 mm Hg) which is dry (all water vapor removed), it is customary to convert VE_{ATPS} to *standard temperature* and *pressure, dry*—abbreviated as VE_{STPD}. This conversion of VE_{STPD} from VE_{ATPS} is done using Boyle's law (the volume of a gas varies inversely with its pressure) and Charles' law (the volume of a gas varies directly with its temperature). In converting VE_{ATPS} to VE_{STPD} it is necessary to add the room temperature (in degrees C) to the Kelvin temperature (273 degrees), and to subtract the partial pressure of water vapor from the barometric pressure. There are tables that show what the water vapor is at different temperatures. However, at the usual room temperature, of 20 to 25°C the partial pressure of water vapor is 18 to 24 mm Hg.

Table 54–9 shows a typical calculation of converting VE_{ATPS} to VE_{STPD}: VE_{ATPS} was 5000 mL. The room temperature was 22°C (at 22°C the vapor pressure of water is 19.8 mm Hg) and the barometric pressure was 759 mm Hg. Note that in this example in Table 54–9, the VE_{STPD} was exactly 90% of the VE_{ATPS}. At most room temperatures at sea level, the conversion factor from VE_{ATPS} to VE_{STPD} will always be approximately 0.9.

RESISTANCE

The calculation of vascular resistance is analogous to measuring electrical resistance by Ohm's law. The formula for electrical resistance is R = E/I which is the drop in voltage across a wire divided by the amperes flowing through the electrical wire. The formula for hydraulic or vascular resistance is R = P/Q which is

Table 54–9. Conversion of a Volume Measured at Ambient Temperature and Barometric Pressure Saturated with Water Vapor to Standard Temperature and Pressure Without Water Pressure

1. According to Charles' and Boyle's laws:

$$\frac{PV_{STPD}}{T} = \frac{P'V'_{ATPS}}{T'}$$

2. which is

$$\frac{760 \times VE_{STPD}}{273} = \frac{(P_B - P_{H2O}) \times (VE_{ATPS})}{273 + °C}$$

3. A. Assume that VE was 5000 mL, room temperature 22°C (which gives a partial pressure of water of 19.8 mm Hg), and that the barometric pressure was 759 mm Hg.

   B. Incorporating these values and rearranging the formula on line 2:

$$VE_{STPD} = \frac{(759 - 19.8)\,(5000)\,(273)}{(760)\,(273 + 22)} = 4500 \text{ mL}$$

the drop in pressure across a vascular bed divided by the volume of blood flowing through the vessels.

The calculation for resistance for blood flow is based on Poiseuille's law which states that:

$$R = \frac{P_{in} - P_{out}}{Q}$$

Q is the flow, P_{in} is the mean inflow pressure, P_{out} is the mean outflow pressure, and R is the resistance.

Even though Poiseuille was interested in blood flow, his law was based upon the flow of simple fluids through rigid, cylindrical glass tubes that were constant in shape. It is obvious that resistance must also vary depending upon the size of the tubes and the viscosity of the fluid going through those tubes. The formula for Poiseuille's law is

$$R = \frac{8\,\eta l}{\pi\, r^4}$$

Where r^4 stands for the radius to the fourth power, η for the viscosity of the fluid, l for the length of the vessels, and π for pi.

To use Poiseuille's law for vascular resistance assumes that there is

1. Constant blood viscosity
2. Constant radius and length
3. That the pressure and flow is nonpulsatile
4. That the amount of fluid entering is equal to the amount leaving

None of this is true. Blood is not a uniform homogenous fluid. Blood vessels are elastic and change in size. Blood pressure and flow are obviously pulsatile. Pulmonary vascular resistance increases in an exponential fashion as polycythemia develops, especially at hematocrit values greater than 54%.[48] Furthermore, blood flow is not linearly proportional to the pressure; blood vessels have a "critical closing pressure";[49] and the higher the outflow pressure is, the less the total resistance is.[50] Despite these inaccuracies in measuring vascular resistance, the concept of resistance as opposition to blood flow is firmly established and is used clinically in pediatric cardiology.

Resistance is mainly important in pediatrics when a child has pulmonary hypertension. By rearranging the formula for resistance so that P = QR, it can be seen that increased pressure in the pulmonary artery, which is pulmonary hypertension, can be due to either increased flow or resistance, (assuming that outflow pressure is not elevated such as from mitral stenosis). If there is pulmonary hypertension and the pulmonary blood flow is increased, resistance ordinarily will be normal or only mildly increased, as occurs with a VSD with massive left-to-right shunting. Similarly, if resistance is markedly elevated, as occurs with Eisenmenger's syndrome, then pulmonary blood flow will be relatively minimal.

Review of Poiseuille's law demonstrates that the main factor that determines resistance is the radius. Thus, a radius that is half the size of another blood vessel will have 16 times greater resistance. As an example of this, if all of the blood vessels in the lungs that normally have a 40-micron radius develop narrowing of every one of these blood vessels to 20 microns, then the resistance will become 16 times greater (20^4 is one sixteenth of 40^4).

All patients with a large VSD and no other heart lesion always have pulmonary hypertension as the systolic pressures in the right ventricle, left ventricle, pulmonary artery, and aorta are always equal, because there is no restriction of pressure between the two ventricles. As just mentioned, if pulmonary vascular resistance is low, then pulmonary blood flow will be high in a child with a large VSD; vice versa, if flow is high, resistance is low. *The resistance of the pulmonary vascular bed is directly proportional to the narrowing of the small pulmonary blood vessels.*

Children with an abnormally elevated pulmonary vascular resistance have significant microscopic changes with narrowing of these blood vessels, as described by Heath and Edwards.[51] In these patients surgically closing a VSD does not decrease their pulmonary hypertension. This was recognized early in the history of pediatric cardiac surgery when patients with elevated pulmonary artery pressure had a much higher mortality from surgery and frequently did not have lowering of their pressure following surgery[52,53]: thus, the term "irreversible pulmonary hypertension."

A patient with a VSD who has pulmonary hypertension and has five times the normal amount of pulmonary blood flow obviously cannot have markedly narrowed pulmonary blood vessels. In this case, if the VSD is closed the pulmonary pressure will return to normal. But what about a patient with pulmonary hypertension with a Qp/Qs of 2.0/1? It is in these children with moderately increased flow and pulmonary hypertension in whom calculation of resistance becomes valuable.

Table 54–10 contains formulae for calculating resistance. In calculating resistance it is necessary to have a pressure drop across the vascular bed as shown in Figure 54–12. Previously, many had used the term total pulmonary resistance (TPR) for resistance, and state that this is the pressure the right ventricle faces. However, TPR is a meaningless term because it does not take into account the pressure drop across the vascular bed. For example, if the inflow pressure is 100 mm Hg but the outflow pressure is also 100 mm Hg, then there can be no flow. "TPR" is essentially never used now, because PCW pressure or left atrial pressure is almost always measured during cardiac catheterizations, though this was not necessarily so 25 years ago. Also, in the earlier studies where TPR was used for calculating resistance, left atrial pressure was fortunately usually normal so that whenever there was any increase in TPR it was usually due to narrowing of the pulmonary vascular bed.

There are differing viewpoints as to which is the preferable way to measure pulmonary resistance. Some prefer to use the actual pulmonary vascular resistance (Rp) because this measures the overall reactivity of the pulmonary blood vessels and sometimes this may be independent of any changes in the hemodynamic status of the systemic vascular bed. However, whenever there is a left-to-right shunt, the pulmonary and systemic circulations are interrelated and Rp can never be entirely independent of systemic vascular resistance (Rs). Also, measuring pulmonary resistance requires measuring pulmonary blood flow which may not be accurate, especially in patients who have left-to-right shunts with streamlining of blood into the pulmonary artery.

Calculating Rp/Rs does not require measuring pulmonary or systemic blood flow. Thus, the error in determining VO_2 is eliminated and the error in determining pulmonary AVO_2 difference is reduced. However, changes in the systemic vascular resistance

Table 54–10. Formulae for Vascular Resistance

$$Rp = \frac{\overline{PA}p - \overline{PV}p}{Qp}$$

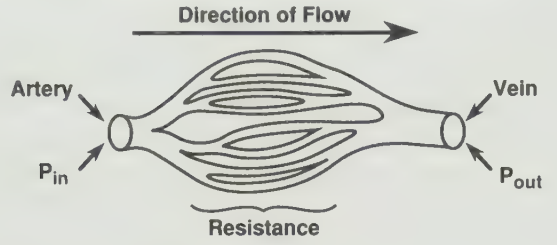
$$Rs = \frac{\overline{AO}p - \overline{RA}p}{Qs}$$

$$\frac{Rp}{Rs} = \frac{\overline{PA}p - \overline{PV}p \times Qs}{AOp - RAp \times Qp}$$

$$TPR = \frac{\overline{PA}p}{Qp}$$

$$TSR = \frac{\overline{AO}p}{Qs}$$

Abbreviations: $\overline{PA}p$, $\overline{PV}p$, $\overline{AO}p$, and $\overline{RA}p$ are the mean pressures of the pulmonary artery, pulmonary vein, aorta, and right atrium. TSR and TPR are the total systemic and pulmonary resistance. Qp and Qs are pulmonary and systemic blood flows. Mean pulmonary capillary wedge pressure or mean left atrial pressure may be substituted for $\overline{PV}p$, any mean systemic arterial pressure may be substituted for $\overline{AO}p$, and mean superior vena cava pressure may be substituted for $\overline{RA}p$. All of these substitutions assume that there is no obstruction to blood flow such as superior vena cava obstruction from a Mustard operation. Rp and Rs are pulmonary and systemic vascular resistances.



Formula:

$$R = \frac{P_{in} - P_{out}}{Q}$$

where:

R = resistance: units = $mmHg \cdot L^{-1} \cdot min$
Q = flow: units = L/min
P_{in}, P_{out} = arterial & venous mean pressure, respectively: units = mmHg

Example of calculation on pulmonary vascular resistance where pulmonary arterial mean pressure is 20 mmHg, pulmonary venous pressure is 5 mmHg and pulmonary blood flow is 5 L/min:

$$R = \frac{20 - 5 \text{ mmHg}}{5 \text{ L/min}} = 3 \text{ mmHg} \cdot L^{-1} \cdot min$$

Fig. 54–12. Resistance of a vascular bed: vascular resistance occurs primarily at the small arteries, arterioles, capillaries, venules, and small veins. Also, as can be deduced from this figure, if the arterial pressure is the same as the venous pressure there can be no flow, which is another way of emphasizing why both arterial and venous pressure must be known in order to calculate vascular resistance.

Table 54–11. Some Factors That May Change Pulmonary Vascular Resistance

1. Changes in pulmonary venous pressure
2. Changes in pulmonary blood flow
3. Changes in pulmonary blood volume
4. Changes in alveolar pressures
5. Changes in intrathoracic pressure
6. Pulmonary edema
7. Changes in size of pulmonary vascular bed
8. Red blood cell concentration
9. Platelet count
10. Blood viscosity
11. Autonomic nervous system tone
12. Intravascular chemoreceptors
13. Intravascular mechanoreceptors
14. Changes in neuroregulation of ventilation
15. Changes in oxygen saturation
16. Changes in ventilation
17. Changes in acid base balance
18. Catecholamines, endogenous
19. Catecholamines, exogenous
20. Acetylcholine
21. Tolazoline
22. Serotonin
23. Histamine
24. Prostaglandins

may result in an abnormally high or low Rp/Rs ratio independent of any changes in the pulmonary vascularity. Despite this potential drawback, some prefer to use the resistance ratio (Rp/Rs), as factors which may be affecting both vascular beds such as cardiac output, blood viscosity, cardiovascular active drugs, degree of sedation, hormonal and neurological factors, and metabolic status will tend to equally affect the systemic and pulmonary vascular bed and will usually "cancel each other out." Table 54–11 lists many factors which can cause changes in the pulmonary vascular resistance.[54]

In patients who have pulmonary hypertension with an elevated pulmonary vascular resistance one should make sure that there are not extrinsic factors causing the hypertension. Such extrinsic factors almost always cause an elevated resistance because they cause vasoconstriction of the smooth muscle in the walls of the small pulmonary blood vessels, which results in a decrease in the effective radius of the pulmonary vascular bed. In practicality, the most common cause of an elevated pulmonary resistance during cardiac catheterization of children is due to sedation, with hypoxemia and hypercarbia causing pulmonary vasoconstriction. The administration of oxygen besides being a direct pulmonary vasodilator also will eliminate any hypoxemia which may be present on the basis of hypoventilation.

We believe that oxygen often is the only agent that is needed to determine whether or not an elevated pulmonary vascular resistance is due to pulmonary vasoconstriction. If the pulmonary resistance diminishes significantly using oxygen as outlined in the protocol in Table 54–12, then there probably is a significant amount of pulmonary vasoconstriction and the pulmonary hypertension in this case may be "reversible." Some authors believe that additional agents such as tolazoline should be used whenever there is an elevated pulmonary resistance.

Brammel and Vogel in discussing the Eisenmenger's syndrome believe that all patients with a pulmonary vascular resistance of equal or greater than 600·dynes·sec·cm^{-5}·M^2 should receive tolazoline, and if the resistance decreases to less than 450·dynes·sec·cm^{-5}·M^2, then there is a chance that the pulmonary vascular resistance is reversible.[55]

Normal systemic vascular resistance is 9–12 mm Hg·min·L^{-1}·M^2 in infants and 13 to 18 mm Hg·min·L^{-1}·M^2 in older children. Normal pulmonary vascular resistance is usually less than 2 mm Hg·min·L^{-1}·M^2.[17] Using representative values for pressures from Table 54–2 and the formula from Table 54–10, the normal Rp/Rs is less than 0.1/1. Note that in this calculation Qp/Qs is 1.0/1 as normal individuals have equal pulmonary and systemic blood flows. Thus:

$$\frac{Rp}{Rs} = \frac{12 - 7 \text{ mm Hg}}{80 - 3 \text{ mm Hg}} \times \frac{1}{1.0} = \frac{5}{77} = <0.1/1$$

The units most commonly used to measure pulmonary and systemic resistance are mm Hg·min·L^{-1} as one measures the pressure drop in mm Hg, and measures the cardiac output in L/min. These are also known as hybrid resistance units or HBU, and are also called Wood units,[56] the latter named after the famous cardiologist Paul Wood. In determining resistance there seems to be some confusion as to whether the units should be "divided or multiplied" when the units in the denominator are placed in the same line as the numerator. Often resistance units will be expressed as mm Hg/L/min, or indexed as mm Hg/L/min/M^2, which is dis-

Table 54–12. Protocol for Calculating Pulmonary Resistance in Children With Left-to-Right Shunts and Pulmonary Hypertension

A. Place catheters in pulmonary artery and systemic artery.
B. Measure oxygen consumption while breathing room air.
C. While breathing room air:
   1. Obtain pulmonary artery O_2 saturation and pressures.
   2. Measure simultaneous systemic arterial O_2 saturation, pressure and blood gases.
   3. Withdraw catheter to SVC.
   4. Obtain SVC O_2 saturation and pressure.
   5. Insert catheter into left atrium.*
   6. Obtain left atrial O_2 saturation and pressure.
D. Have patient breathe oxygen (FiO_2 >0.5) by face mask for 5 to 10 minutes, and then while the patient is still breathing oxygen, obtain the following:
   1. Insert catheter back into pulmonary artery.
   2. Obtain pulmonary artery O_2 saturation, pressure and blood gases.
   3. Obtain simultaneous systemic arterial O_2 saturation, pressure and blood gases.
   4. Withdraw catheter to SVC.
   5. Obtain SVC O_2 saturation and pressure.
   6. Insert catheter into left atrium.*
   7. Obtain left atrial O_2 saturation, pressure and blood gases.

*If unable to enter the left atrium, pulmonary capillary wedge pressures may be obtained in the pulmonary artery and assumed to be equal to the left atrial pressures. In this case, assume that the left atrial saturation is equal to the systemic arterial saturation. Later in the catheterization, confirm that the left atrial saturation is equivalent to systemic arterial saturation by injecting green dye into the IVC and SVC with sampling in the systemic artery to confirm that no right to left shunt is present.

We withdraw the catheter to the SVC rather than the right atrium because we have found the SVC saturation to correlate better with the pulmonary artery saturation in normal individuals. If the left atrium is entered and the left atrial saturation or arterial blood gases are significantly higher than the systemic arterial saturation or blood gas then one must assume that some right to left shunting is present.

After the above data has been obtained, calculate pulmonary and systemic resistances both while breathing room air and while breathing oxygen. In the calculations made while breathing oxygen, one must include the dissolved oxygen as part of the oxygen content.

cussed at the end of this section. The correct units of measurement are

$$R = \frac{P}{Q} = \frac{\text{mm Hg}}{\text{L/min}} = \frac{\text{mm Hg·min}}{\text{L}} = \text{mm Hg·min·L}^{-1}$$

By multiplying by 80, hybrid units can be converted to the cgs system where the units are dynes·sec·cm^{-5}. These are also known as the absolute resistance units or ARU.

The important question is: *Is the resistance too elevated to consider doing cardiac surgery?* In general, an Rp of less than 5 units·M^2 and a resistance ratio of less than 0.4/1 often means that the pulmonary hypertension may be due to increased pulmonary blood flow and it is possible that the pulmonary pressure will diminish with repair of the lesion. An Rp of greater than 10 units·M^2 and Rp/Rs of greater than 0.7/1 usually means that surgery will have a significantly increased mortality and/or that the pulmonary hypertension will not resolve following surgery.

The trouble with applying these values for determining whether to perform surgery is that the studies on which these numbers are based were performed at multiple centers; the studies were done in different lesions, the sedation and duration of catheterization were different from institution to institution, etc. Additionally, some series used surgical results, other used postoperative catheterization results, others used lung biopsy results, and other used autopsy results. Therefore, it is difficult to state, from a resistance standpoint, exactly when the pulmonary resistance is too elevated to perform cardiac surgery. Table 54–13 summarizes the results of some of these reports.

One of the areas of confusion we have seen in measuring resistance and indexing it to body surface area (BSA) is that there is confusion as to whether resistance is divided or multiplied by the BSA. It is *multiplied* by the BSA, as was first pointed out to us by Dr. Dwight McGoon.[63] The formula for pulmonary vascular resistance is:

$$\frac{\overline{PAp} - \overline{PVp}}{Qp}$$

To index the resistance value according to body size, the initial instinct seems to be to divide the units of resistance by the body surface area (BSA). However, simple logic exposes the fallacy of that approach. Let us suppose that a 1-year-old baby and an adult each has a large VSD. The pulmonary artery minus the pulmonary venous pressure could be quite similar in the two, but pulmonary blood flow would obviously be several times higher in the adult because of the much larger lungs in the adult. Thus, the value for calculated pulmonary resistance prior to "indexing" for BSA would be much lower in the adult than the child.

The purpose for indexing is to allow more meaningful comparisons between patients of widely differing sizes. However, to divide their resistance levels by the square meters of BSA would exaggerate their differences rather than make them more comparable. Thus, the correct indexing method is to multiply (not divide) the calculated resistance by the BSA.

The same results would be obtained regarding indexing if the formula for estimating resistance included the use of pulmonary blood flow index in the denominator:

$$\frac{\overline{PAp} - \overline{PVp}}{Qp/M^2\ BSA} = \frac{(\overline{PAp} - \overline{PVp}) \times M^2\ BSA}{QP}$$

$$= \frac{(\overline{PAp} - \overline{PVp}) \cdot M^2}{QP}$$

For example, a patient with a mean pressure of 37 mm Hg in the pulmonary artery and 7 mm Hg in the PCW with a cardiac output of 1.0 L/min and a BSA of 0.33 M^2 has a resistance of 30 HRU as:

$$\frac{37 - 7\ \text{mm Hg}}{1.0\ \text{L/min}} = 30\ \text{HRU}$$

To index this, one should multiply by the BSA to get the correct value of 10 HRU·M^2 (30 × 0.33 = 10). However, if one divided the HRU by the BSA, the incorrectly calculated value would be 91 HRU/M^2.

INDICATOR DILUTION CURVES

In the 1950s and 1960s dye curves were the most common way of estimating cardiac output; they were equally important in de-

Table 54–13. "Irreversible" Pulmonary Hypertension

Reference	*"Irreversible Level"*	*Lesion*	*Hospital Mortality*	*Comments*
52	PA systolic pressure >80% of SA systolic pressure	VSD	26%	Surgery in 1956–63
53	TPR >6.6 mm Hg·min·L^{-1}	VSD	29%	Not indexed to surface area
57	Rp >8 units·M^2	Truncus arteriosus	39%	Two patients with Rp of 8.6 and 11.4 units·M^2 suddenly died late postoperatively of PVOD
57	Rp/Rs >0.6	Truncus arteriosus	54%	
58	Rp >12 units·M^2	Truncus arteriosus	100%	Same institution as reference 57 but 3 years earlier
61	Rp/Rs >0.75	VSD	54%	Rp/Rs of 0.45–0.75 had same survival rate as Rp/Rs of <0.45

Abbreviations: PA = pulmonary artery, SA = systemic artery, TPR = total pulmonary resistance, Rp = pulmonary vascular resistance, Rs = systemic vascular resistance, PVOD = obstructive pulmonary vascular disease, VSD = ventricular septal defect, TGA = transposition of great arteries.

COMMENTS: The term "irreversible level" is used to mean that at pressures or resistances greater than listed, the patients in the series who had surgery had a high incidence of surgical mortality from PVOD.

Mair et al. (reference 58) speculated that patients with truncus arteriosus who had a single pulmonary artery could have twice the pulmonary resistance (Rp of 20 units·M^2 or less) than patients who had a two pulmonary artery system. Newfeld et al. (reference 59) in a study of lung specimens of 200 patients with TGA found that those with an Rp <5 units·M^2 did not have PVOD while those with an Rp >10 units · M^2 usually did have PVOD. DiSesa (reference 60) found that in three patients with bidirectional shunts with elevated pulmonary artery pressures who had an Rp/Rs of <0.5 were successfully operated with a significant reduction in pulmonary artery pressure postoperatively and a similar reduction in Rp. Clarkson et al. (reference 62) studied autopsy material from 35 patients with TGA and suggested that corrective operations for TGA should not be performed unless the Rp is substantially less than 10 units·M^2.

tecting abnormal intracardiac shunts and valvular regurgitation. Until 30 years ago Evan's blue (T-1824) was the main indicator dye used. This dye had two main drawbacks: 1) It stained the tissues and was cosmetically unattractive causing the patient to have a slate blue coloration that lasted for up to two weeks depending on the dose used.[64] This discoloration would often disappear within half a week, but would reappear with exercise. It also provided difficulty in evaluating cyanotic patients after catheterization. 2) It has a maximal light absorption of 630 to 650 mu, which is the red region. At this range the reduced hemoglobin and oxyhemoglobin have enough difference in light absorptions so that any change in the ratio of the two hemoglobins (which is the oxygen saturation) affected Evan's blue dye curves.

Multiple other indicators have been used including: other dyes, hydrogen gas,[65] freon,[66] ascorbate,[67] nitrous oxide,[68] and radioactive agents.[69] At the present time these are essentially only of historical interest and are described well in Chapters 6 and 7 of Zimmerman's textbook.[70,71]

As we discuss indicator dilution curves in their historical perspective, it will become apparent why they used to be important. Measurement of cardiac output at the time required cumbersome methods for both collection of oxygen and measuring oxygen content. Indicator dilution curves were much more sensitive in detecting cardiovascular shunts than was oximetry.[72] Otherwise, left-to-right intracardiac shunts had to be detected by increases ("step up") of oxygen saturation and were not accurate below levels of 3 to 10% (see oximetry section) or a Qp/Qs of below 1.3 to 1.5/1. Currently, the problems of measuring cardiac output have been markedly improved with the thermodilution technique, measuring oxygen consumption by the polargraphic method, and oxygen saturations can quickly be measured by spectrophotometry.

Historically, earlier angiographic techniques and results were relatively poor compared to today's standards. Angiograms were often done without fluoroscopic visualization, as the equipment for taking radiographs was usually separate from the fluoroscopic unit. Usually only six radiographs were taken each second, and small shunts and mild valvular regurgitation were often not visualized. Now echocardiograms and angiography at 60 frames per second will detect almost any small intracardiac shunt. In fact, the images of individual cineangiographic frames at the present time are superior to the 6 frame per second regular size radiographs taken 25 years ago. For example, prior to present day cineangiography, determining whether or not a patient had a PDA by angiography usually required moving the patient and/or x-ray table and injecting contrast material "blindly" in the aorta to see whether or not a ductus was present. Injecting a dye in the aorta and discovering its immediate appearance in the pulmonary artery used to be a much easier way than angiography to determine if a PDA was present.

Indicator dilution curves enjoyed marked popularity in the 1960s with the introduction of indocyanine green as an indicator dye.[73] Indocyanine green did not discolor the patient. It also has a peak absorption at 805 NM where the light absorption of reduced and oxyhemoglobin are the same so that indocyanine green (which was also known as Fox green) was not affected by changes in saturation. In the 1970s the use of indocyanine green began to diminish, and now it is essentially used only for detecting right-to-left shunts. However, to understand the technique of how dilution works as an indicator we will now demonstrate some of the methods used in measuring cardiac output with green dye.

A green dye cardiac output determination can be compared to putting any material, such as a pollutant, into a river and measuring its concentration downstream. (This example is used because it demonstrates how a dye dilution curve works; it is not intended

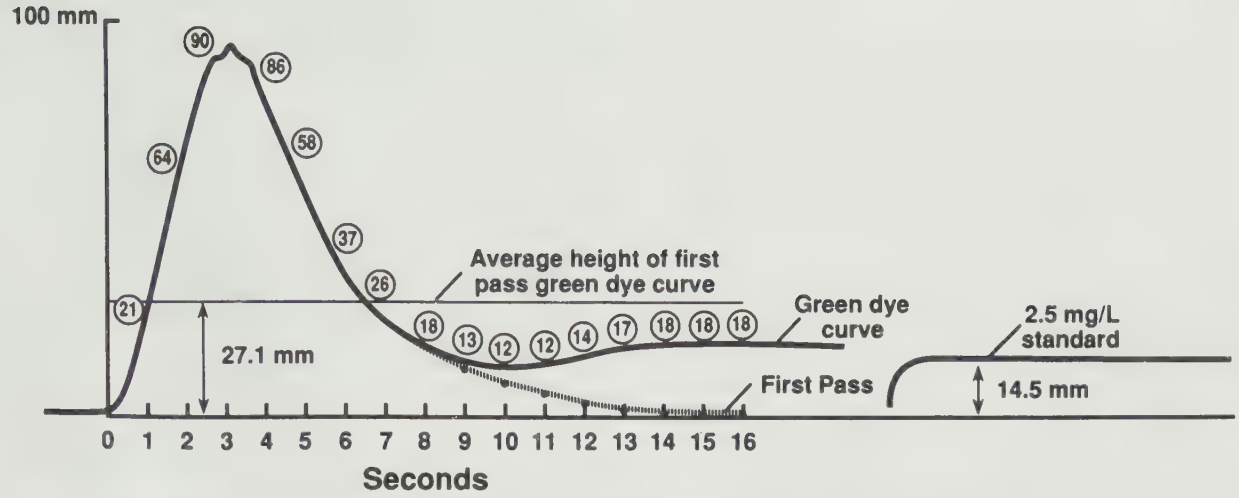


Fig. 54–13. Measurement of cardiac output with an indocyanine green dye curve: 5 mg of green dye was injected into the venous system and at time 0 it is detected by a densitometer. At about 3½ seconds the green dye curve peaks at a maximum of 93 mm (the numbers inside the circles are the height of the dye—in mm—each second). At 9 seconds the curve begins to rise a second time, due to recirculation of the dye. The dashed line is the curve that would have been inscribed if there were no recirculation; this is also known as the "first pass" of the green dye. Note that the standard, which was 2.5 mg of green dye per liter of blood, gave a standard curve height of 14.5 mm. Thus, the average height of the first pass of the green dye curve is 27.1 mm as discussed in Figure 54–14.

as a political statement, and does not necessarily represent the views of the publisher, editors, authors' institutions, or authors.) For example, let us assume that 2000 lb (16 oz per lb) of a toxic waste is dumped into a river and after complete mixing there is found to be exactly 1 oz of toxic waste in every gallon of water downstream. Thus, the 2000 lb of toxic waste had to have been diluted in 32,000 gallons of water. And if this bolus of toxic waste, which averaged 1 oz per gallon of water, completely passed by a measuring station in exactly 3 minutes and 12 seconds (3.2 minutes), then the river is flowing a rate of 10,000 gallons per minute. Measuring cardiac output is similar. A known amount of green dye is injected into the bloodstream, the concentration is measured downstream, and the time the green dye passes is also calculated.

However, in using the river analogy there is one major difference. This is due to the recirculation of blood, which is analogous to a city taking the polluted water at a point downstream, using it for drinking water, and then dumping it back into the river upstream. Now one could not determine how much of the toxic waste was due to the initial contamination and how much was due to the recycling. In measuring green dye curves, the same thing happens, some of the blood with green dye recirculates through the entire body and gets back to the measuring point (usually the femoral artery in children) before the initial bolus of green dye has passed downstream. Thus, in determining the cardiac output from a green dye curve, one must first determine which part of the curve is due to the first pass of the green dye and how much is due to recirculation. Because of the exponential decay of the disappearance of the first pass of green dye this can be determined by plotting the disappearance curve on semilog paper. Figure 54–13 shows a typical green dye curve and Figure 54–14 shows the semilog plot of the dye curve.

The technique of measuring the cardiac output by doing a green dye curve is to inject a known amount of dye, usually 5 mg, into the pulmonary artery, though it can be injected anywhere in the venous system. Then one continuously withdraws a constant flow of blood from the femoral artery into a densitometer cuvette capable of measuring the concentration of green dye in the blood. A green dye curve is inscribed as shown in Figure 54–13.

A calibration factor is then determined by diluting a known amount of green dye into a sample of the patient's blood. This is done by using a microliter syringe to inject the green dye solution into a 10-mL volumetric flask of blood (drawn before any dye is injected into the patient) so that the final concentration will be 2.5 or 5.0 mg of green dye per liter of blood. This sample is then withdrawn through the same densitometer cuvette and the height of the calibration line displaced from the baseline will be equal to 2.5 or 5.0 mg/L.

Green dye cardiac outputs are classically done by using the Stewart Hamilton equation which is[75,76]

$$CO = \frac{60 \times i}{\bar{c} \times t}$$

Using the values in Figures 54–13 and 54–14 we can see that over 16 seconds (t) the sum of all the measured heights in the initial pass of green dye came to 434 mm. Thus, the average height of the green dye curve during those 16 seconds was 27.1 mm. Because the calibration factor contains a height of 14.5 mm deflection for 2.5 mg/L, the average concentration of the green dye curve is 4.7 mg/L ($\bar{c}$). Since 5 mg of green dye was injected (i), the cardiac output comes to 4.0 L/min as shown in Table 54–14.

There are multiple formulas for calculating cardiac output from green dye curves.[1] All of them are based on calculating the area of the curve to determine the denominator in sec·mg/L. The most common other formula is

$$CO = \frac{60 \times i}{A \times CF}$$

As shown in Table 54–15 this is really identical to

$$\frac{60 \times i}{\bar{c} \times t}$$

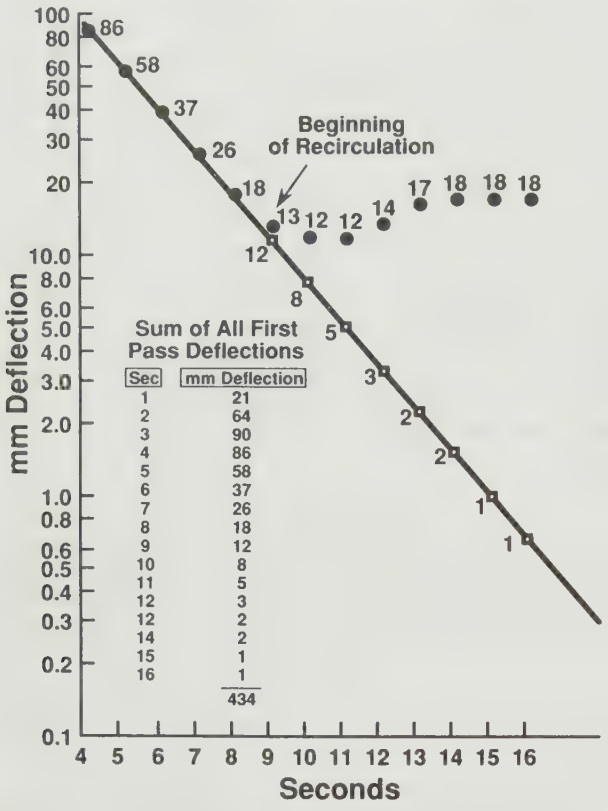

Fig. 54–14. Exponential decay of an indocyanine green dye curve: the disappearance of green dye from the circulation of the bloodstream decreases in an exponential fashion. If no recirculation occurred, the green dye disapperance curve would be a straight line on semilog paper. However, in most children about 10 seconds after the initial appearance of the first amount of green dye at the arterial sampling site, recirculation of blood (and hence the green dye) will occur. Thus, one plots the level of green dye on three cycle semilog paper. Where the straight line "breaks" is the beginning of recirculation. The straight line is then extrapolated to 1% of the peak concentration of green dye. The first pass of green dye is assumed to be completed when less than 1% of the initial first pass persists (which is in this case would be 0.93 mm, as the peak concentration was 93 mm). Next, one determines the average concentration of the green dye during the entire first-pass green dye curve. This is done by summing up the amount of green dye present during the first pass. In this example from Figure 54–13, during 16 seconds the sum of all of the first-pass deflections was 434 mm, which comes to an average height of 27.1 mm. The standard of 2.5 mg/L caused 14.5 mm of deflection. Since the first-pass green dye curve had an average height of 27.1 mm, the average concentration of the first-pass green dye curve would be 4.7 mg/L. Reference 74 and the previous page include further explanations of how to determine cardiac output.

There are also formulae where one can assume that the area of the initial portion of the curve is proportional to the total area of the curve. For example, in the forward triangle method of Hetzel, the initial portion of the curve corresponds to 35% of the total area of the curve following a peripheral injection of green dye, and 37% if a central injection is used.[77] The forward triangle method is the most common formula used for determining green dye cardiac outputs, because it is relatively easy to do and does not require determining the recirculation phase. See Figure 54–15 for an example of a cardiac output done using the forward triangle method.

With left-to-right shunts, low cardiac output, and valvular insufficiency; the cardiac output frequently cannot be determined by the usual formulae because in these conditions one often cannot determine where the recirculation phase begins. In these situations the forward triangle method is an alternative method that can be used for calculating cardiac output; with left-to-right shunts, it is debatable how accurate these alternative methods are.

There are potential errors in measuring the cardiac output from green dye curves. One main problem is no matter how accurately one tries, the amount injected through a syringe and catheter usually will not be exactly the amount thought to be injected. We use a stopcock system where the green dye is injected first and this is followed by a saline flush. We believe this method is as accurate as any of the multiple ways we have used to try to deliver accurate volumes of green dye. Another potential error is that the flow in the withdrawal syringe has to be constant, and, therefore must be

Table 54–14. Standard Formula for Calculating Cardiac Output by Indicator Dilution Curve

The formula for calculating cardiac output is

$$CO = \frac{60 \times i}{c \times t}$$

Abbreviations: CO = cardiac output in L/min, 60 = sec per min, i = mg green dye injected, c = mean concentration of green dye in mg/L, and t = seconds.

Therefore with the example in the text, the cardiac output is

$$CO = \frac{60 \text{ sec/min} \times 5 \text{ mg}}{4.7 \text{ mg/L} \times 16 \text{ sec}} = 4.0 \text{ L/min}$$

It can be seen that seconds and milligrams of green dye will cancel out so that the final units are L/min (liters of blood flowing per minute).

Table 54–15. Alternative Cardiac Output Formula (Denominator)

$$CO = \frac{60 \times i}{A \times CF}$$

Where A = area of first pass of green dye curve measured in mm deflection multiplied by duration of first pass in seconds; and CF = calibration factor of standard measured in mg green dye per L/per mm deflection.

Since "mm deflection" cancels out, A × CF have the same units in the denominator as $\bar{c} \times t$ which are mg/L × sec.

Using the data in Figures 54–13 and 54–14, and Table 54–14; the area of the curve is 434 mm deflection × sec during the first pass, and the calibration factor is 2.5 mg/L/14.5 mm deflection.

Thus, the formulae are

$$CO = \frac{60 \times i}{\bar{c} \times t} \text{ or } \frac{60 \times i}{60 \times CF}$$

and the calculations are $\frac{60 \times 5}{4.7 \times 16} = \frac{300}{75.2}$ or

$$\frac{60 \times 5}{434 \times \frac{2.5}{14.5}} = \frac{300}{74.8}$$

The differences are due to "rounding off," a more precise figure for "$\bar{c}$" is 4.677, which also gives 74.8 mg/L × sec in the denominator.

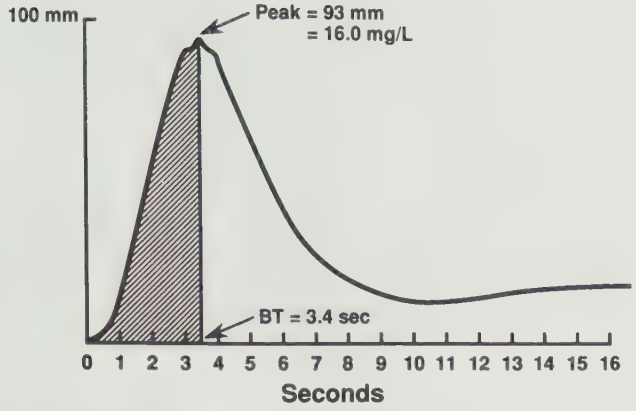

Fig. 54–15. Forward triangle method of Hetzel and associates:

$$CO = \frac{i \times 60 \times K}{\frac{PC}{2} \times BT}$$

where: CO = cardiac output in L/min

i = amount injected in mg

60 = 60 sec/min

K = constant of 0.37 or 0.35

PC = peak concentration in mg/L

BT = time in sec to reach peak concentration

This curve is the duplicate of the curve in Figure 54–13. It took 3.4 seconds to reach a peak deflection of 93 mm. 93 mm deflection is equivalent to 16.0 mg/L as 14.5 mm deflection = 2.5 mg/L. Therefore, using the forward triangle method, the cardiac output is 4.1 L/min.

$$CO = \frac{5 \times 60 \times 0.37}{\frac{16.0}{2} \times 3.4} = 4.1 \text{ L/min}$$

done by a constant infusion pump. The cardiac output has to stay constant during the measurement or the result will be incorrect. There has to be complete mixing of the dye and the blood, which usually means that the dye must pass through at least one ventricular chamber. The delayed curves that occur with valve insufficiency and low cardiac outputs cause inaccurate readings.

In general, the Fick principle is better for accurate determination of reduced cardiac outputs, and the green dye method is better when the cardiac output is increased. When the cardiac output is high there usually is a small difference between the arterial and venous oxygen content, so that any errors in measurement of AVO_2 difference will cause a proportionally large error in the calculated cardiac output when using the Fick principle. On the other hand, a low cardiac output will result in a significant portion of the initial bolus of the green dye recirculating before the first circulation is complete.

Approximately 10 years ago the thermodilution technique replaced green dye curves for measuring cardiac output. While green dye curves are still occasionally used for measuring shunt fractions, presently the only major remaining role of green dye curves is detecting small right-to-left shunts. For example, a patient may have a oxygen saturation of 93% in the femoral artery and two pulmonary venous samples could be 93% and 96%. In this case one could not tell by oximetry if a small intracardiac right-to-left shunt was present or not. Injection of green dye into the IVC with sampling in the femoral artery will reveal if there is early appearance of the dye in the femoral artery. If early appearance does occur with the green dye curve, then some of the mild desaturation of the femoral artery in this case was due to an intracardiac right-to-left shunt. Injection of green dye into the IVC with sampling in a systemic artery is one of the most sensitive methods available for the detection of a small right-to-left shunt. This is because fetal patterns of preferential blood flow from the IVC across the foramen ovale often persist in the child, even when there is no other right-to-left shunt present. A Valsalva maneuver will increase the right-to-left shunt across the foramen ovale.[78] Figure 54–16 shows examples of right-to-left shunts.

Green dye curves are essentially no longer used for detecting intracardiac left-to-right shunts or minor amounts of valvular regurgitation, because of the development of cineangiography and echocardiography. However, prior to the 1970s it was almost impossible by angiography to visualize mild amounts of valvular regurgitation when the angiograms were taken at only 6 frames per second. Also if atrioventricular valvular regurgitation was seen, one often could not determine whether this was due to "true" valvular regurgitation or to ventricular ectopy which usually occurred with ventricular angiograms. However, if injection of green dye into the left ventricle revealed early appearance of the dye in the left atrium, one could conclude that mitral regurgitation was present. First, these intracardiac curves (injecting dye in the heart

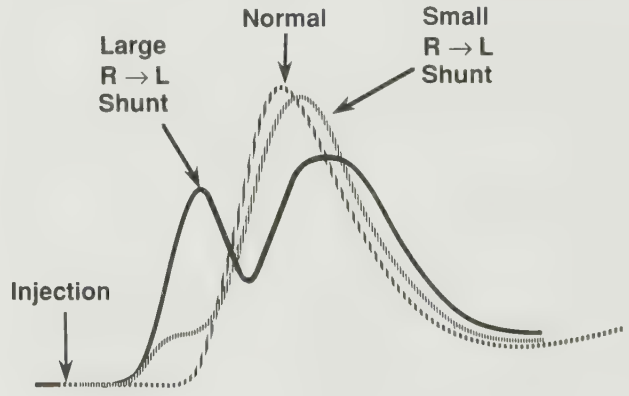

Fig. 54–16. Examples of right-to-left shunts: by injecting in the "right side" of the circulation and sampling in a systemic artery, one can detect a right-to-left shunt if there is early appearance of the green dye. Also, the contour of the curve with the early peak suggests that there is a right-to-left shunt. The greater the magnitude of the early peak, the greater the magnitude of the shunt. The site of a right-to-left shunt can be detected by injecting in two different right-sided chambers, with one of the chambers being distal to the shunt. For example, in a patient with right-to-left shunting at the atrial level, injection in the right atrium and sampling in the femoral artery would show an early peak to the dye curve, while injecting in the right ventricle and sampling in the pulmonary artery would show a normal curve without an early peak, thus confirming that the right-to-left shunting was at the atrial level.

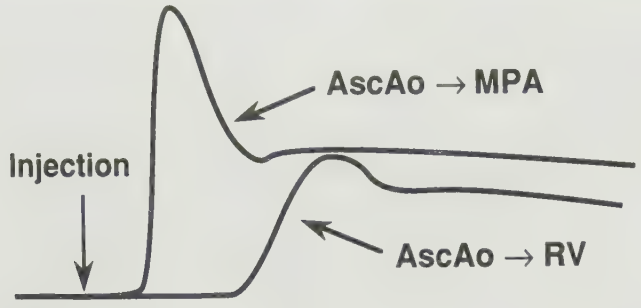

Fig. 54–17. Example of an intracardiac curve: "intracardiac curves" refers to using two catheters in the heart, injecting in one and sampling in the other. In this example, a patient with a patent ductus arteriosus (PDA), green dye is injected into the ascending aorta (Asc Ao) in both examples, but the sample is withdrawn from the main pulmonary artery (MPA) in one and from the right ventricle (RV) in the other. Note that there is an early appearing tall peak in the sample withdrawn from the MPA because relatively undiluted green dye is diverted directly from the Asc Ao to the MPA by way of the PDA. However, the green dye, which has to circulate through the body before it reaches the RV, is relatively diluted, so that the concentration of the green dye is much less.

with one catheter and sampling in the heart with another catheter) were very sensitive as essentially undiluted green dye would go directly from the left ventricle to the left atrium. Second, small injections of green dye rarely caused ectopy.

Intracardiac curves are also sensitive for finding small left-to-right shunts. For example, if one injects green dye in the left ventricle and finds early appearance of the dye in the pulmonary artery, but injecting in the left ventricle and sampling in the right ventricle does not show early appearance, then one could assume that the patient has a patent ductus arteriosus or some other type of left-to-right shunt at the great artery level. Figure 54–17 shows an example of an intracardiac curve.

Figure 54–18 shows examples of left-to-right shunts. Left-to-right shunts will have a lower peak than normal curves because some of the indicator recirculates through the lungs instead of going directly to the sampling point. There will not be as steep of a downslope, because the left-to-right shunt that recirculated through the lungs arrives at the sampling point later than the green dye that goes directly to the femoral artery.

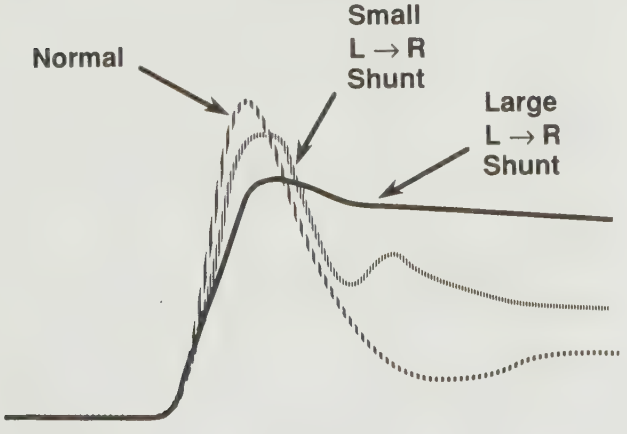

Fig. 54–18. Examples of left-to-right shunts: a large left-to-right shunt, compared to a normal curve, will have a slow decay of disappearance of the green dye at the sampling site. A small left-to-right shunt will have a curve similar to a normal shunt but will usually have a distinct early recirculation "bump." These examples are typical of injecting in the "right side" of the heart and sampling in a systemic artery.

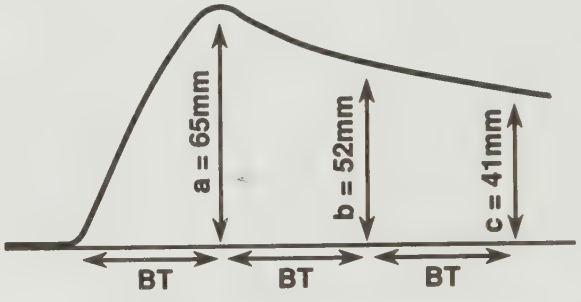
Carter's formula has been developed for determining the amount of left-to-right shunting.[79] The Carter formula is best used when there is a smooth downstroke. If there is not a smooth downstroke, then the formulas of Victorica and Gessner should be used.[80] Left-to-right shunts by this method of green dye curve have a threshold of detection of about a 25 to 30% shunt.[81] Figures 54–19 and 54–20 show examples of left-to-right shunts and how to calculate the shunt fraction.

Figure 54–21 shows an example of calculating the percentage of a right-to-left shunt from a green dye curve where the dye is injected into the IVC and sampled in the aorta. As can be deduced, if blood or green dye passes directly from the IVC to the right atrium to the left atrium, it will arrive at the systemic artery much more rapidly than the normal blood flow would because it has to go from the right atrium to the right ventricle to the pulmonary artery to the lungs to the pulmonary veins and then back to the left atrium. Thus the early peak is due to the right-to-left shunt, and the magnitude of the early peak is proportional to the amount of right-to-left shunting. The formulas for calculating right-to-left



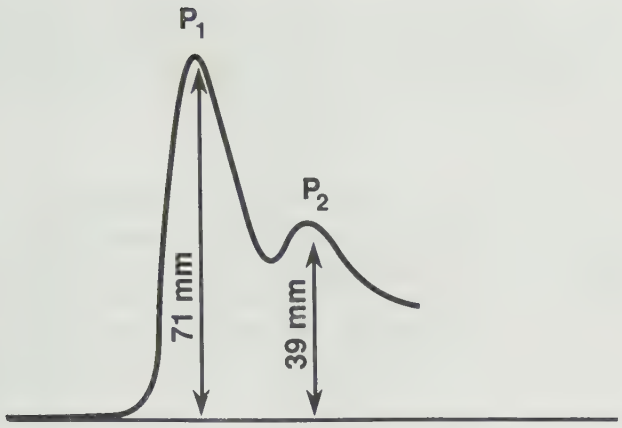
BT = time to reach peak concentration (build up time)
a = height of peak concentration in either mm or mg/l
b = height of dye curve at 2 BT
c = height of dye curve at 3 BT
%Qp = percent of pulmonary blood flow due to left to right shunt

formulae:

A. % Qp = 141 $(\frac{b}{a})$ -42

B. % Qp = 135 $(\frac{c}{a})$ -14

Fig. 54–19. Calculation of the amount of left-to-right shunting using the Carter formula: Carter and associates (reference 79) used arterial dilution curves to estimate the amount of a left-to-right shunt. "a," "b," and "c" can be measured in either peak concentration of milligrams of green dye per liter of blood or in millimeters deflection. In this example "a" is 65 mm tall (prior to being reduced in size for the text), "b" 52 mm tall, and "c" 41 mm tall. Thus for formula A, %Qp = 141 × (52/65) − 42 = 71%. For formula B, %Qp = 135 × (41/65) − 14, which also = 71%.



formula:

$$\text{A. \% Qp} = \left(\frac{P_2}{P_1}\right) \times 100$$

where:

%Qp = percent of pulmonary blood flow due to left to right shunt
P_1 = first peak
P_2 = second peak

Fig. 54–20. Two-peak method of calculating the amount of left-to-right shunting: Victorica and Gessner found that they could reliably estimate the magnitude of a left-to-right shunt if two peaks were present on the arterial dilution curve. They were usually able to show two discrete peaks if the indocyanine green was injected centrally and the blood was withdrawn rapidly from either the aorta or other central systemic artery. We have not generally found this to be true, but have not performed many green dye curves for determining left-to-right shunts since their article was published in 1975. The first peak (P1) is believed to be due to pulmonary blood flow. The second peak (P2) is believed to be due to the left to right shunt. In this figure the height of P1 is 71 mm and the height of P2 is 39 mm so that the percent of the pulmonary blood flow (%Qp) due to the left to right shunting is (39/71) × 100 which is 55%.

formula:

$$\text{\% Qs} = \frac{(BT_1)(PC_1)}{(BT_1)(PC_1) + (0.44)(T_2)(PC_2)} \times 100$$

where:

%Qs = percent of systemic blood flow due to R→L shunt
PC_1 = height of first peak
BT_1 = build up time from appearance time to PC_1
PC_2 = height of second peak
T_2 = time from injection to PC_2
0.44 = constant

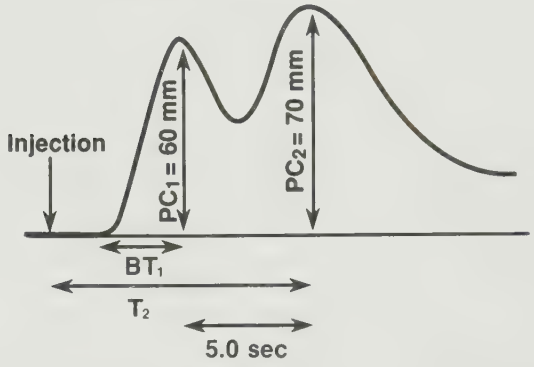


Fig. 54–21. Formula for calculating the amount of right-to-left shunting: using the above formula where PC_1 equals 60 mm deflection, PC_2 equals 70 mm deflection, BT_1 equals 3.3 seconds, and T_2 equals 10.5 seconds, the percent of the systemic blood flow which is due to right to left shunting is 38%. As shown by the calculation:

$$\%Qs = \frac{(3.3 \times 60)}{(3.3 \times 60) + (0.44)(10.5)(70)} = 38\%$$

shunts are modifications of the forward triangle method.[82] These methods will detect right-to-left shunts as low as 2.5 to 5% of the total cardiac output.[81] This increased accuracy probably reflects the fact that with right-to-left shunts the dye goes relatively undiluted (compared to the dye that must circulate through the lungs) and directly to the densitometer which is connected to the systemic artery.

THERMODILUTION

In the last decade, thermodilution has replaced indocyanine green as the main method of determining cardiac output. The advantages of thermodilution are 1) there is no recirculation phase because the cold water used for measuring the cardiac output is quickly dissipated by body temperature, 2) no blood needs to be withdrawn, 3) water is an inexpensive, inert, easily available indicator, 4) no arterial puncture is required (though we believe almost all children having cardiac catheterization performed should have an arterial line in place), 5) one can do rapid sequence determinations to obtain successive measurements, 6) cold water "mixes" somewhat better than green dye, 7) thermodilution is simple and easy to perform compared to the green dye technique, 8) because there is no recirculation, relatively simple computers can be used to measure the cardiac output rapidly, and 9) the amount of injectate used can vary and the computer will take this into account.

The technique of measuring cardiac output by thermodilution is to inject cold water in a proximal cardiac chamber and measure the temperature downstream. The method of using thermodilution catheters to measure cardiac output is first to position a specially constructed thermistor-tipped balloon-flotation catheter into the pulmonary artery or a PA branch. The thermistor is very sensitive to changes in temperature. The catheter has a proximal port for injection of cold water. The orifice of the proximal port will usually be in the right atrium or one of the vena cavae; this allows enough distance for complete mixing of the cold injectate with the blood. One then injects a known amount of iced or room-temperature water (or saline or dextrose solution) through the proximal port. As the cold injectate passes the thermistor, a computer that is connected to the catheter will calculate the cardiac output. In essence, the cooler the temperature of the blood as it passes the thermistor, the lower the cardiac output will be (i.e., when blood flow is low, then the cool injectate will not be diluted as much by the warm [body temperature] blood). It is also possible to "float"

the catheter out the aorta and measure the left ventricular output by sampling in the aorta after injecting in the left ventricle.

Either iced water or room-temperature water can be used for the injectate. We prefer using water at room temperature rather than ice water because it is easier to use. With iced water one can use smaller amounts. For measuring cardiac output, thermodilution is as accurate as using either the green dye method[83] or the Fick principle for determining cardiac output.[84] The thermodilution technique is also accurate for measuring cardiac output in children.[85]

Initially double thermistors were used for measuring cardiac output with one thermistor in the SVC to measure the temperature of the injectate and another thermistor in the pulmonary artery.[86] Now only a distal thermistor is used as the computers used calculate the injectate temperature. Use of a single thermistor requires the assumption that the temperature of the injectate is warmed a measurable amount during the injection. About 18% of the heat is lost in the handling process. Thus, the correction factor is 0.82,[87] for the difference between the temperature of the solution before it is injected and what the temperature is when it leaves the proximal port. This factor may be off depending upon the length of time that the physician holds the syringe in his/her hand and the time between injections. For infants we usually use 3 cc of injectate when measuring cardiac output, 5 cc for children up to 25 kg, and 10 cc for older children.

Cardiac output measurements should be done as rapidly as possible until three successive readings are within 15% of each other. In our experience they are usually within 5 to 10% of each other.

Thermodilution cardiac outputs are less reliable whenever there is a very low cardiac output.[88] This is probably due to heat loss during the prolonged time that it takes the cold water and blood to go from the injectate port to the pulmonary artery. Thus, the thermodilution method can overestimate the actual cardiac output whenever there is low flow.

Another possible error in the thermodilution technique can theoretically occur if the catheter thermistor happens to be against the pulmonary arterial vessel wall. In this case the temperature of the cold water bolus may be warmed by the temperature of the wall. This can give a falsely high cardiac output, but does not appear to happen very often if the catheter is not wedged. Thermodilution cardiac outputs are also unreliable if there is an intracardiac shunt. Though if the shunt (either right-to-left or left-to-right) is less than 10% of the total cardiac output, the error is usually insignificant.[89]

In both small and large left-to-right shunts, thermodilution measurements with the catheter tip in the pulmonary artery underestimate the cardiac output (Qs). If the left-to-right shunt is greater than 10%, one should use a different method for measuring the cardiac output. In a small right-to-left shunt, underestimation occurs because the thermistor, in essence, measures only the pulmonary blood flow and does not record that portion of the Qs that includes the right-to-left shunt. Because of the algorithm used in calculating the cardiac output, whenever there is a large right-to-left shunt, Qs can be highly overestimated.

With thermodilution, it is possible to measure bidirectional intracardiac shunts.[90] There is also a relatively simple method of measuring Qp/Qs in patients with a left-to-right shunt, and is calculated by a method similar to the way one measures left-to-right shunts from green dye curves.[91]

As long as blood flows freely, it does not appear to materially change the cardiac output whether one injects in the RA, adjacent IVC, or SVC; nor does it appear to matter if the thermistor is in the PA or its proximal branches (Fig. 54–22).

CALCULATION OF STENOTIC VALVE AREAS

The orifice size (cross sectional area) of a stenotic valve is calculated by using the Gorlin formula, which states that the pressure difference across a valve is directly proportional to the flow across the valve and inversely proportional to the area of the valve.[92] Obviously, the narrower the valve the greater the pressure gradient across it; similarly, the greater the flow across a narrowed valve, the greater the pressure gradient will be. The valve orifice of each cardiac valve is approximately 2.5 cm^2/M^2.

All one needs to calculate a valve area is 1) the cardiac output,

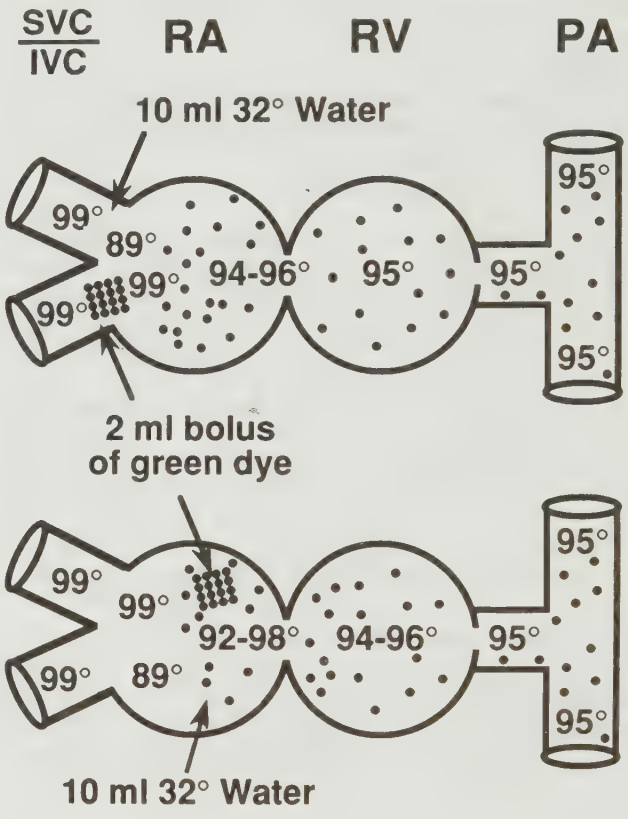

Fig. 54–22. "Mixing" of cold water, or green dye, in the "right heart": Abbreviations: SVC/IVC = superior and inferior vena cava, RA = right atrium, RV = right ventricle, PA = pulmonary artery and its branches. The numbers are the degrees in temperature Fahrenheit. The dots are particles of indocyanine green dye. In both panels the same amount of cold water (or green dye) is rapidly injected into the vena cava (upper panel) or right atrium (in lower panel). While there may be some temperature variation in the cardiac chamber distal to where the cold water was injected, by the time the cold water reaches the next chamber it should be essentially completely mixed. Essentially, the same principles apply to cardiac outputs obtained with injections of green dye. Note that for illustrative purposes the temperature changes by 4 degrees from the vena cavae to the PA; in actuality, the change in temperatures with thermodilution curves is much less than this (reference 83).

Table 54–16. Calculation of Aortic Valve Area by Gorlin Formula

$$AVA = \frac{\frac{CO}{SEP}}{C \times 44.3 \sqrt{LVP - AOP}}$$

Abbreviations: AVA = aortic valve area, CO = cardiac output, SEP = systolic ejection period. The SEP is the systolic ejection time (SET) multiplied by the heart rate (HR). C = correction factor, 44.3 = $\sqrt{2g}$. LVP = mean left ventricular systolic pressure, AOP = mean aortic systolic pressure.

See text for details. Note that the square root of the difference in the mean systolic pressures is multiplied by 44.3. This number is derived from the square root of the gravity acceleration factor (980 cm/sec/sec) multiplied by two.

2) the heart rate, and 3) the pressure curves from each side of the stenotic valve (along with the usual time lines and pressure calibration). In this section we will demonstrate how to measure the *aortic valve area,* as in pediatric patients this is the valve area most often measured, as the calculated valve area often provides information that is helpful in the decision regarding surgery. The Gorlin formula is shown in Table 54–16.

The first step in calculating the area of the aortic valve is to determine the mean gradient between the two pressure curves. This is done by measuring the area between the two pressure curves and converting this to a mean gradient in mm Hg. While the most accurate measurements are obtained by recording simultaneous pressures with high fidelity catheters in the left ventricle and in the aorta (and the average pressure gradient measured for three consecutive beats), in children this is frequently impractical or impossible. Most commonly, the left ventricular systolic pressure is measured using a large bore angiographic catheter. The femoral arterial pressure is measured simultaneously with the left ventricular pressure, however, there is a problem with pulse amplification and delay of the femoral pressure. In other cases the gradient is obtained by withdrawing the angiographic catheter across the stenotic valve; this makes it necessary to trace the aortic pressure curve and superimpose it over the left ventricular pressure.

The area between the aortic and left ventricular pressure is measured in mm² by planimetry. This area is then divided by its base in mm, to give a mean height of the area. The mean height difference in mm between the left ventricular systolic and aortic systolic pressures is then converted to a mean difference in mm Hg. This is shown in Figure 54–23.

Figure 54–24 shows two ways of estimating the average gradient. One way is to measure the difference in the pressure curves at 7 to 8 equidistant points along the curve. The sum of these pressures are added up and divided by the total number of lines as is shown on the right hand side of Figure 54–24. One can also estimate the mean pressure difference between the aortic and left ventricular tracings by estimating the mean of each pressure during ejection. Usually this estimate is within a few mm Hg of the actual planimeterized mean value and is demonstrated on the left hand side of this figure. The calculation of the pulmonic valve gradient is identical to the aortic valve gradient.

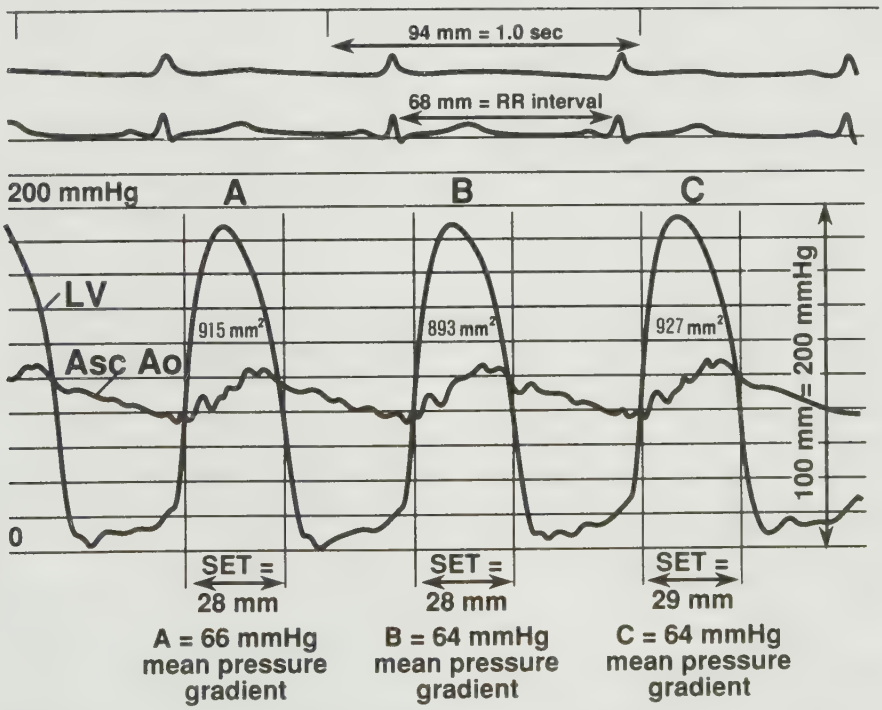

Fig. 54–23. Determination of aortic valve gradient using planimetry: in order to obtain an aortic valve area, one must first determine the mean pressure gradient between the left ventricle (LV) and ascending aorta (Asc Ao) during systole. This is done by using a planimeter to measure the area between the LV and Asc Ao pressure curve. The areas for curves "A," "B," and "C" are 915 mm², 893 mm², and 927 mm², respectively. The mean height difference between the two pressure curves is determined by dividing the area by the duration of the systolic ejection time (SET). This results in a mean height of 33 mm for "A," 32 mm for "B" and 32 mm for "C." Since 1 mm = 2 mm Hg the mean systolic pressure gradient from LV to Asc Ao is 66 mm Hg for "A," 64 mm Hg for "B," and 64 mm Hg for "C."

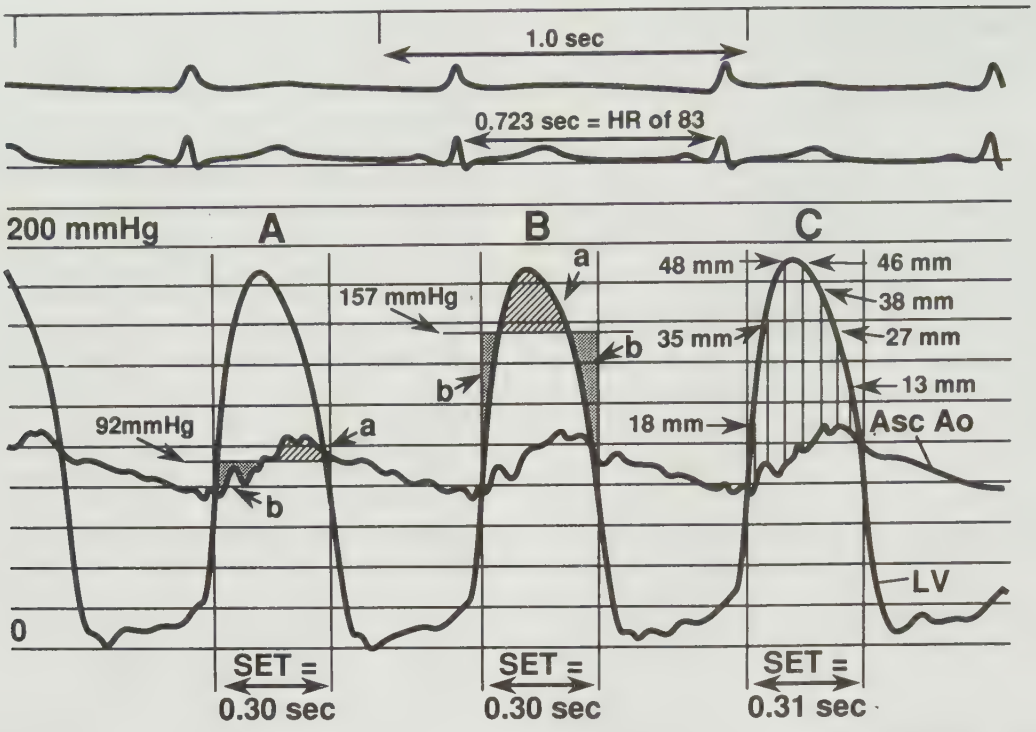

Fig. 54–24. This figure shows two ways of estimating the mean systolic pressure gradients between the LV and Asc Ao: these are the same pressure curves as shown in Figure 54–23. On the right hand side in "C," 7 equidistant lines are plotted and measured. The sum of the 7 lines is 225 mm. Therefore, the average of these lines is 32 mm. Since 1 mm = 2 mm Hg, the mean systolic pressure gradient is 64 mm Hg. Another way of estimating the difference in the pressure curves is to draw a line between both the Asc Ao and LV pressure curves *during ejection only* so that the area above the line ("a") is equal to the area(s) below the line ("b"). This is demonstrated in "A" and "B" and in this example does approximate the mean systolic pressure gradient very well (157 mm Hg − 92 mm Hg = 65 mm Hg). Also note that the heart rate (HR) and SET have been calculated in this diagram.

Table 54–17. Calculation of Aortic Flow (ml/sec)

$$Q = \frac{CO}{SEP} \text{ or } \frac{CO}{(SET) \times (HR)}$$

Q = flow (mL) each second the heart valve is open
CO = cardiac output in mL/min
SEP = systolic ejection period which is the number of seconds the valve is open each minute
SET = systolic ejection time which is the number of seconds that the aortic valve is open each heart beat
HR = heart rate which is the number of heart beats per minute

Therefore, the calculation of units is as follows:

1. $Q = \frac{CO}{SET \times HR} = \frac{mL/min}{(sec/heart\ beat) \times (heart\ beat/min)}$
2. "heart beat" cancels out and therefore:

$$Q = \frac{CO}{SEP} = \frac{mL/min}{sec/min}$$

3. "minutes" cancels out and therefore:

$Q = mL/sec$

Table 54–18. Calculation of Aortic Valve Area

Values for calculation are those in Figures 54–23 and 54–24, with the assumption for illustrative purposes that the cardiac output is 3000 mL/min:

Cardiac output (CO) = 3000 ml/min
Heart rate (HR) = 83 beats per minute
Systolic ejection time (SET) = 0.30 seconds per heart beat
Systolic ejection period (SEP) = HR × SET = 83 × 0.30 = 24.9 sec/min

$$Q = \frac{CO}{SEP} = \frac{3000}{24.9} = 120.5 \text{ mL/sec}$$

Mean gradient = 64 mm Hg

$$\text{Therefore, Cardiac output} = \frac{\frac{3000}{83 \times 0.30}}{1 \times 44.3\sqrt{64}} = \frac{120.5}{354.4} = 0.34 \text{ cm}^2$$

Note that the values used in this example are very similar to the text except that in the figures the heart rate was 83 instead of 80. Therefore the SEP was slightly more than in the text (24.9 vs. 24 sec/min) while the flow *each second* was slightly less than in the text (120.5 vs. 125 mL/min).

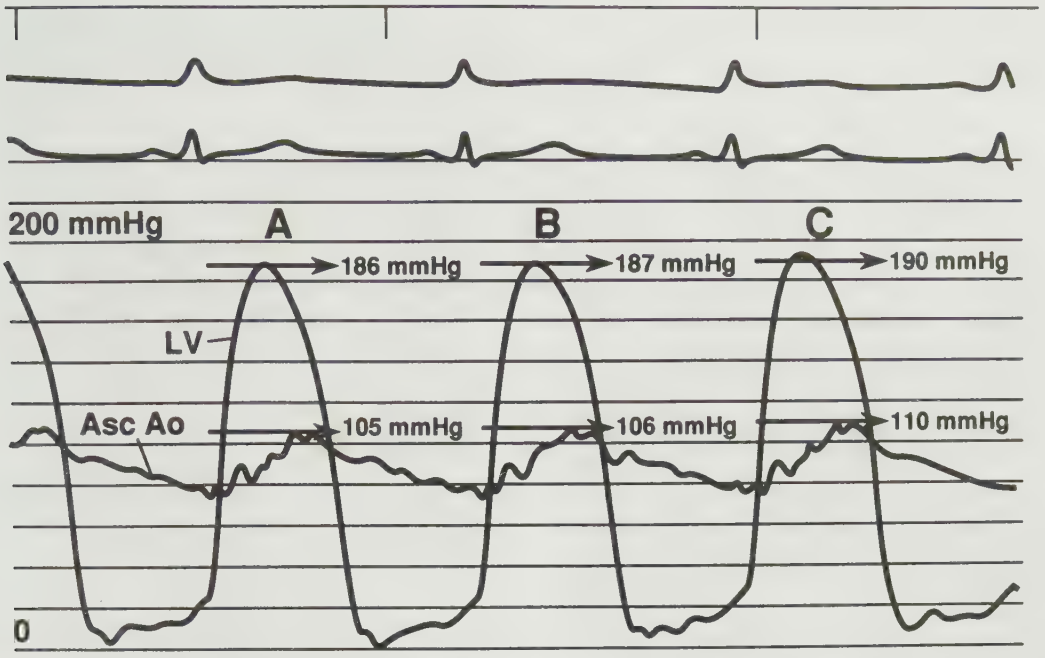

Fig. 54–25. Determination of the aortic valve area using the Bache method: the peak-to-peak systolic gradient is determined by subtracting the peak Asc Ao systolic pressure from the peak LV systolic pressure. The arrows represent the peak LV and Asc Ao systolic pressures for tracings "A," "B," and "C." Note that the differences for each of these three tracings is 81, 81, and 80 mm Hg; respectively. See Table 54–20 for the full calculation of the aortic valve area using the Bache formula.

After the gradient has been calculated, the flow across the aortic valve must be determined. In calculating valve areas one must use the flow that occurs when the valve is open. This is a different number than the cardiac output, and is determined by dividing the cardiac output by the time the aortic valve is open during systole.

Depending upon the heart rate and ejection time, systole occurs only about 40% of the cardiac cycle. Obviously, the aortic systolic gradient occurs only during the time that blood is flowing across the aortic valve. For example, if a patient had a cardiac output of 3000 cc/min, and had a systolic ejection time that was only 40% of the cardiac cycle, then the total of 3000 cc would be ejected only during 24 seconds of each minute. Thus, the flow across the aortic valve would be 125 cc each second the valve is open. This would correspond to someone who has a heart rate of 80 beats per minute with a systolic ejection time (SET) of 0.30 seconds. The systolic ejection period (SEP) is the heart rate multiplied by the SET; in the above example it was 24 seconds each minute. The SET is from the opening of the aortic valve during systole to its dicrotic notch. Table 54–17 shows how to determine the amount of blood flowing across the aortic valve each second which is the CO divided by the SEP.

For measuring diastolic flow across mitral and tricuspid valves, the diastolic flow period (DFP) is the diastolic flow time multiplied by the heart rate. As with aortic flow, mitral and triscupid flow is calculated by dividing the CO by the DFP. The diastolic flow time is from the opening of the atrioventricular valve to end-diastole. The gradient across the mitral valve is calculated similar to the aortic valve gradient, except that it is, obviously, measured in diastole.

The correction factor (C) is 1.0 for the aortic, pulmonic and tricuspid valves. In the initial report by Gorlin and Gorlin, 0.7 was used as the correction factor for the mitral valve. However, they did not measure the true diastolic time from actual pressure curves, but assumed them from systolic curves. Later on the correction factor for the mitral valve was changed to 0.85.[93]

Table 54–18 shows a calculation of an aortic valve area.

After reviewing the previous methods of measuring mean aortic valve gradients during systole, there is a shortened empiric formula for measuring the aortic valve valve area which requires using

Table 54–19. Example of Bache Formula for Aortic Valve Area (AVA)

$$AVA = \frac{Q}{37.8\sqrt{PSPG + 10}}$$

Q is the same as in Table 54–18 while the value for PSPG is from Figure 54–25, therefore:

$$AVA = \frac{120.5}{37.8\sqrt{81 + 10}} = \frac{120.5}{360.6} = 0.33\ cm^2$$

Table 54–20. Importance of Accurately Measuring Cardiac Output in Calculating Aortic Valve Area

A. $\frac{120.5}{44.3\sqrt{64}} = 0.34 = \frac{241}{44.3\sqrt{256}}$

B. $\frac{120.5}{44.3\sqrt{64}} = 0.34 = \frac{150.6}{44.3\sqrt{100}}$

only the peak-to-peak systolic gradient.[94] The formula is known as the Bache formula and is

$$AVA = \frac{\frac{CO}{SEP}}{37.8\sqrt{\text{Peak systolic gradient} + 10}}$$

An example is shown in Figure 54–25, and the calculations in Table 54–19.

Table 54–20 shows the importance of measuring the cardiac output accurately. The Gorlin formula states that if the flow is doubled, the gradient quadruples, assuming that the heart rate and systolic ejection time remain constant (which is not necessarily true). The example in Table 54–20 does reveal that a patient with an aortic valve area of 0.34 cm^2 will have a mean systolic gradient of 64 mm Hg with a flow of 120.5 mL/sec, but a gradient of 256 mm Hg with a flow of 241 mL/sec (almost an impossibility—but does show that doubling the CO will quadruple the gradient). Table 54–20 also shows that a 25% increase in CO (a definite possibility) will change the calculated gradient by more than 50%, from 64 mm Hg to 100 mm Hg.

There are errors in estimating the aortic valve area. In children probably the most important one is measuring the cardiac output simultaneously with the pressure measurements. This is usually not practical in pediatric patients as there is only so much time to do the study and only so many catheters that can be put inside a child's heart. There are also the inherent errors in measuring the cardiac output. When there is aortic regurgitation one also underestimates the area of the aortic valve because the measured cardiac output is less than the volume of blood that flows across the aortic valve.

Another error is using peripheral arterial pressures for the aortic pressure. The pressure curves do not line up with the aortic pressure because of delay in transmission of the pressure wave to the distal artery. Folland has shown that without realignment of the pressure curves, the left ventricular to femoral artery gradient overestimates the actual aortic valve gradient by about 9 mm Hg.[95] With realignment of the left ventricular and femoral artery tracings, the measured gradient underestimates the actual left ventricular to aortic gradient by about 10 mm Hg. Thus, the measured aortic valve gradient, the cardiac output, and hence the flow across the valve can be markedly different because they are recorded at different times, and under different physiological circumstances. This is especially true in pediatric patients when multiple sedatives frequently need to be given during the catheterization study.

How accurate are these valve gradients even if done as correctly and accurately as possible? The Gorlin formula is meant for rigid tubes without changes of the rate of flow. Flow across a stenotic valve is not uniform, and the stenotic valve may not be circular. With stenotic valves the opening of the valve may change in contour during systole. Furthermore, recent data suggests that the Gorlin correction factor (C) varies with the area of the valve, plus that the calculated valve area increases as the cardiac output increases.[96,97]

Despite these drawbacks, calculation of the aortic valve area is one more factor that can be used to decide whether or not the stenosis is severe enough to recommend surgery. In general, cardiac surgery is recommended when the aortic valve area is less than 0.5 to 0.7 cm^2/M^2.[98] This corresponds more or less to a peak systolic aortic pressure gradient of 50 to 75 mm Hg.

CHAPTER 55

Catheterization and Angiography

Michael R Nihill

The role of cardiac catheterization in the management of cardiovascular disease has changed considerably over the past 20 yr, particularly in the past 5 to 10 yr in patients with congenital cardiovascular disease. These changes have been brought about by the development of new invasive and noninvasive diagnostic and therapeutic techniques.

Cardiac catheterization is no longer a "set piece" fishing expedition to make an anatomic and physiologic diagnosis. An experienced operator using high-resolution two-dimensional and Doppler echocardiography will be able to define most of the cardiovascular anatomy accurately in 95% of the patients with congenital cardiovascular defects.[1–3] Catheterization and angiography will be necessary only for patients with unusual anatomy, unusual presentation of common defects, or inadequate echo windows. The resolution of echocardiography does not yet approach that of angiocardiography; the need to obtain surgically important detailed anatomic studies will be decided by the cardiologists and surgeons treating a patient. The indications for cardiac catheterization in the management of some defects has decreased, while in others it has become the means for specific treatment (see Chapter 130).

At present, cardiac catheterization is the most reliable way to obtain data about the physiologic derangements caused by congenital cardiovascular defects. As the techniques for anatomic and physiologic correction of congenital heart defects continues to expand, there will be an increased need to evaluate the results as thoroughly as possible on a longterm basis; cardiac catheterization and angiography will continue to play an important part in ongoing evaluation of these surgical and medical treatments.

HISTORICAL BACKGROUND

Since its inception, cardiac catheterization has been used as an investigative and diagnostic tool by various disciplines in medicine and physiology. J.R. Dieffenbach[4] has been credited with the first use of a cardiac catheter in a human while treating a patient with cholera. Physiologist Claude Bernard[5] measured intracardiac temperature in animals, and in 1860 Pavy[6] coined the term "cardiac catheterism" to describe his experiences in passing a catheter into the right ventricle in humans and animals. A double-lumen catheter was used by physiologists Chauveau and Marey in 1861[7] to measure simultaneous pressures in the right ventricle and right atrium.

Werner Forssmann, using himself as the subject,[8] was the first to undertake a systematic study of the technique of cardiac catheterization and angiography. His early experiments were published in 1929 and 1931.[9] The first published works on central and peripheral angiography in children were published by Castellanos and his colleagues in Havana.[10–12] By the early 1940s, angiography of congenital cardiac defects was a well-established procedure.

The methodology and techniques of cardiac catheterization were standardized and extensively used by Cournand et al.[13] and others[14–17] in New York in the 1940s. There soon followed several papers and monographs[18–22] on the use of cardiac catheterization to diagnose congenital heart defects in children and infants. Catheterization of neonates was sporadic and little was published until the late 1950s[23,24] and 1960s when Adams and Lind,[25] Emmanouilides et al.,[26] and others[23,27] catheterized normal and sick infants to establish the foundations of our knowledge of fetal and neonatal cardiovascular physiology.

As surgical techniques for the repair and palliation of congenital

heart defects developed in the 1950s[28] and 1960s there were rapid developments and refinements of catheterization techniques, especially in younger children, infants, and newborns.[29–34]

Changes and improvements in surgical, imaging, and catheterization techniques have mandated a constantly evolving approach to the management of the infant and child with cardiovascular and pulmonary disease.[2,35] The application of these techniques will continue to change to supply the information needed for medical and surgical management of patients with congenital heart disease.

INDICATIONS FOR CARDIAC CATHETERIZATION

Table 55–1 lists the various diagnostic procedures and data that may be obtained during a cardiac catheterization. One should carefully evaluate the data that may be obtained by such procedures and whether it is applicable to the treatment of the patient. Not all of the procedures are a required part of a cardiac catheterization in a particular patient; one must formulate a protocol and design the catheterization procedure to obtain the most useful information in the least traumatic manner.

Cardiovascular Anatomy

The anatomy of the various parts of the heart and great vessels are demonstrated at cardiac catheterization using angiography and the course of the catheter through the heart and great vessels.[36] Before catheterization, a thorough two-dimensional echocardiographic study with Doppler will help plan the various angiographic studies (see Chapters 35 to 37). Two-dimensional echocardiography will provide accurate diagnoses of most of the above anatomic features under ideal conditions.[3] Echocardiography, however, is still an art, and the echocardiographer must be experienced in order to demonstrate, and more importantly to recognize, intracardiac and extracardiac anatomy. Demonstration of intrathoracic anatomy may be especially difficult in sick newborns with severe pulmonary disease, particularly those with emphysematous lungs, in whom an adequate echocardiographic window is difficult to find. In infants with severe hyaline membrane disease, anomalous connection of the pulmonary veins may be especially difficult to rule out,[35] and catheterization may be required for this single piece of information.

Table 55–1. Indications for Cardiac Catheterization

Define cardiovascular anatomy—The morphology, position, relations and connections of the
Systemic and pulmonary veins
Atria
Atrioventricular valves
Ventricles and outflow tracts
Proximal pulmonary and systemic arteries
Peripheral pulmonary and systemic arteries
Measure and calculate central and peripheral hemodynamics
Blood pressure in the systemic and pulmonary arteries and veins
Blood flow in the systemic and pulmonary circulation
Calculate shunts
Calculate vascular resistance in the pulmonary and systemic beds
Calculate valve areas
Evaluate cardiac pump function
Evaluate cardiac muscle function
Monitor changes in hemodynamics and cardiac function in response to drug, respirator, or surgical interventions
Electrophysiologic studies and therapy
Myocardial biopsy

Hemodynamics

Blood Pressures in the Central Aorta and Pulmonary Artery

The principles of data acquisition and wave-form analysis during cardiac catheterization have been well established and standardized for a number of years (see Chapter 29). Dynamic changes in the pulmonary and systemic circulations up to and for several months after birth[26,37] will determine what is interpreted as normal in a particular infant (Chapter 43).

In order to obtain accurate and reproducible blood pressure measurements, one should have a well-balanced and optimally damped transducer, which is matched to the catheter size and length of the connection tubing if a fluid-filled measuring system is used.[38–40] Catheters with side and end holes are preferable, with the widest, shortest path possible to the transducer. Great care should be taken when using small, balloon-directed Swan-Ganz catheters,[41,42] which have only an end hole; the small lumen size and relatively long length of these multilumen catheters usually produce over-damped pressure tracings. Other factors that may influence the accuracy and reproducibility of the pressure recordings are severe airway obstruction with marked inspiratory and expiratory swings in intrathoracic pressure and high mean airway pressure produced by respirator settings necessary for adequate oxygenation.

Physiologic Recordings

A minimum of four channels of simultaneous records should be available to record two electrocardiograms, and at least two simultaneous pressures. The pressure measuring and recording system should be evaluated before catheterization to optimize pressure signal recording. Small-caliber catheters will produce over-damped pressures in a fluid-filled system. Tubing length, caliber, and rigidity should be tested before the catheterization to minimize over- or under-damping.

Pressure wave forms are displayed and recorded at a gain to show the points of interest of the wave form in the middle of the screen. Each pressure recording is marked on the recording paper and in the handwritten log, and a calibration signal is recorded for each pressure.

The recording device may produce an instantaneous record for immediate viewing, but if photographic paper is used, it must be available for review immediately after the catheterization.

PRECATHETERIZATION ASSESSMENT

One of the most important parts of a catheterization is the prior assessment of the patient's clinical problems in order to decide which catheterization procedure is to be used. Catheterization procedures should be goal-oriented and be planned to elucidate further the nature of the patient's problem, as well as to set the background for future therapeutic maneuvers.

A complete physical examination and assessment of the patient's condition and stability is essential. A physical examination will identify the overall clinical condition of the patient, state of hy-

dration, cyanosis, respiratory distress, and adequacy of the peripheral circulation. Physical examination together with complementary laboratory investigations will determine whether the patient needs endotracheal intubation before the catheterization and whether other therapy such as inotropic support, diuretics, or prostaglandins should be started before catheterization.

An electrocardiogram is useful in evaluating arrhythmias, which may need to be controlled before the catheterization. The electrocardiogram can also reflect disturbances of electrolytes, pH, and blood sugar.[43]

Arterial blood gases indicate whether the pH should be corrected and if a trial of increased oxygen concentration will change the arterial pO_2. Any abnormalities of acid–base balance or electrolytes should be corrected as far as possible before the catheterization, as progressive acidemia and hypoglycemia often develops during catheterization of sick infants.[44] Hemoglobin and hematocrit should be measured before the catheterization, and blood volume or hemoglobin should be corrected as necessary using the arterial oxygen saturation value. The hemoglobin should be adjusted to produce an oxygen content of at least 15 mL of oxygen per 100 mL of blood (content = Hb g/dL × 1.36 mL O_2/g Hb × O_2 saturation). At least 20/mL/kg of blood should be typed and cross matched and available before the start of the catheterization.

A current two-dimensional echocardiogram is reviewed before the catheterization to evaluate the basic anatomy of the heart so that excessive use of contrast material is avoided. Anomalies of systemic venous return should be noted in planning the venous access route.[45–47] Echocardiography can define the basic anatomy of the heart and great arteries and help determine the need for further anatomic studies such as angiography. An echocardiogram is also useful in evaluating the contractility of the myocardium prior to the catheterization. The patency of the ductus arteriosus can be determined and can be monitored in response to prostaglandin administration.[47,48]

A written outline or plan of the catheterization procedures should be made so that none are omitted during the course of the catheterization and the laboratory staff can prepare for the various procedures.

PREMEDICATION

Most neonates do not require sedatives or narcotics before cardiac catheterization. Infants are particularly susceptible to the central nervous system depressant effects of narcotics; morphine, in particular, may destabilize the hemodynamics of an infant with low cardiac output by producing vagotonic bradycardia and venous dilation. Sedation of seriously ill patients should be administered under the direct supervision of the attending physician in the catheterization laboratory.

Meperidine (Demerol, 1.5 to 2.0 mg/kg), promethazine (Phenergan, 1.0 mg/kg), and chlorpromazine (Thorazine, 1.0 mg/kg) are commonly used in combination as an intramuscular "lytic cocktail" and given 30 to 45 min before catheterization. Chlorpromazine is a potent vasodilator, especially when given intravenously, and should be avoided in patients with ventricular outflow-tract obstruction, tetralogy of Fallot, and those with pulmonary vascular disease. Intramuscular injection of promethazine can be quite painful and oral administration of this drug or another antihistamine may be preferable. Diazepam alone given before catheterization to infants and small children does not provide enough sedation; it is a useful relaxant for older, more cooperative children.

Ketamine is a rapidly acting dissociative anesthetic and analgesic.[49] A dose of 2.0 mg/kg intramuscularly will sedate a child within 2 min. When given intravenously (0.5 to 1.0 mg/kg) over 30 to 60 sec there is no significant change in systemic or pulmonary hemodynamics. Moreover, it does not lower systemic resistance and therefore is an excellent sedative for patients with tetralogy of Fallot, who are likely to have a hypercyanotic spell. Slow administration into the pulmonary circulation does not produce vasoconstriction. Ketamine does not depress pharyngeal or laryngeal reflexes, and promotes salivation in patients who have not been given drying agents such as atropine or an antihistamine and in whom suctioning of the hypopharynx may produce glottic spasm. We recommend that ketamine be used only as an adjuvant sedative in combination with an antihistamine premedication.

TRANSPORT OF NEONATES TO THE CATHETERIZATION LABORATORY

The basic principles of neonatal transport as they are used in extramural transport should be applied to intrahospital transport.

The patient's hemodynamics should be as stable as possible and blood volume replacement should be completed before transport. Inotropic or other cardiovascular support drugs should be given at a stable infusion rate, with no adjustments required during the time of transport.

Intravenous lines should be secured and intravenous infusion pumps stabilized for safe transport. Prostaglandin infusions should be via a dedicated intravenous line; flushing of this line should be avoided because bolus injections of prostaglandins will cause apnea and hypotension.[50]

Body temperature control. An infant should be transported in a stable thermal environment such as an incubator or warming stand, as rapid heat loss can occur in an uncovered infant during transport through cold hospital corridors. Insulated wrappers are excellent for neonatal transport and are also radiolucent; the infant can be kept wrapped in this bunting during the catheterization with no degradation of x-ray quality.

Ventilator support. An intubated or ventilated patient is transported to the catheterization laboratory with hand-bagging by one operator. The patient's respirator or another respirator should be set up in the catheterization laboratory before transport so that it is ready to receive the patient on arrival.

Monitoring during transport. Electrocardiogram monitoring is all that is necessary during transport. An arterial line should be secured with a three-way stopcock and flush syringes during transport.

Arrival in the Catheterization Laboratory

Before the infant arrives the catheterization laboratory should be warmed to an ambient temperature of 80 to 85°F. An infant should be placed on some form of warming device. The warming device and the bunting, together with an infrared heating lamp, should be enough to keep the infant warm until being draped for the catheterization. Newer warming devices are not as radiopaque as older rubber heating pads; if heat loss is persistent the baby can

be sandwiched between two of the newer pads without significant loss of x-ray quality.

If a patient is ventilated a respirator must be easily accessible. Catheterization laboratory personnel should be drilled in a resuscitation routine so that obstructing x-ray equipment can be moved rapidly for access to the patient's head for respirator management and/or cardiopulmonary resuscitation.

Restraints are placed on the patient's arms and legs, even if paralyzing agents have been used, so that there will be no movement of the limbs or body after draping. The quality of respiration is assessed with a stethoscope after placing the patient on the catheterization table and the respirator connected. Adjustments to endotracheal tube position, with or without the use of fluoroscopy, are performed before the patient is draped, while there is adequate access to the head. Previously placed arterial lines are connected to the catheterization laboratory transducers and blood pressure and electrocardiogram evaluated for stability prior to starting any procedure.

Intravenous infusion sites should be inspected and should be available for visual monitoring during catheterization to guard against extravasation of fluid and drugs, particularly those containing calcium.

Monitoring During Catheterization

The heart rate, electrocardiogram, blood pressure, temperature, respiratory rate, respirator settings, chest movement, and air entry and infusion sites are monitored during the catheterization. Soon after the arterial line is placed, arterial blood gases are drawn to make sure that there has been no significant deviation from the previous values.

A respiratory therapist or physician is assigned to monitor the respirator, endotracheal tube, chest movement, and air entry during the catheterization. The position of the endotracheal tube, diaphragm movement and the presence of pneumothorax can be checked by fluoroscopy.

Central temperature is monitored via rectal probe with the monitor visible at all times. Excessive withdrawal of blood for blood gas measurements can be avoided by the use of a pulse oximeter placed over the toe, palm of the hand, or ear lobe for constant monitoring during catheterization. Blood sampling should be carefully monitored and excessive loss should be replaced with fresh packed red cells during the catheterization.

Two electrocardiographic leads are displayed, one for monitoring heart rate and one for diagnostic interpretation to observe the P waves and ST segments.

Monitoring urine output is important in patients with prerenal azotemia. A bladder catheter can be inserted or the diaper weighed prior to the catheterization.

Blood pressure can be monitored via an umbilical artery catheter, radial line, or femoral artery line. Marked fluctuations of blood pressure can occur during the catheterization due to infusions of drugs such as prostaglandin or after injection of hyperosmolar contrast material.

RIGHT HEART CATHETERIZATION TECHNIQUES

Catheter Insertion

The percutaneous femoral route is the preferred approach for diagnostic catheterization in patients with congenital heart disease. Percutaneous insertion of a sheath into the femoral vein is now a standard procedure and allows multiple catheter exchanges with minimal trauma to the vein.[51–55] Relatively large sheaths can be used even in small infants; for example, a No. 7 French sheath can be used to insert a balloon septostomy catheter in infants as light as 1.5 kg.

Both groins are infiltrated with 2% lidocaine over the site of needle entry and deeper over the site of vessel entry; convulsions may occur if the total dose of lidocaine exceeds 5 mg/kg.

Special short-bevel 21-gauge needles are used for easy insertion of guide wires. Longer-bevel needles tend to lacerate the vessels; blood return can be obtained with these needles even if the lumen of the needle is not completely within the blood vessel lumen. Guide wires of 0.018-in. diameter should be used for the initial insertion of a small No. 5 French sheath. If a larger sheath (No. 7 French) is to be used, a larger diameter guide wire (0.025 in.) is used for a better fit of the guide wire and dilator and greater stability of the dilator as it enters the vein at the pelvic brim. Short-bevel 19-gauge needles and 0.021- to 0.025-in. guide wires are used in patients heavier than 10 kg.

The femoral vascular sheath is approximately at the midpoint between the superior iliac crest and the pubic tubercle at the symphysis pubis in infants and children and at the medial one third of this line in adolescents and adults. Vessel entry is just below the inguinal ligament in infants and about 1 to 2 cm below this in larger children. The femoral vein and artery are impaled by the needle on the superior ramus of the pubic bone, where their position is relatively fixed and more superficial. The needle enters the skin at a 30- to 45-degree angle and is advanced a few millimeters at a time until blood appears in the hub or the pubic ramus is reached; if blood return is not obtained, the needle is withdrawn in 2- to 3-mm steps, with rotation of the hub at each step until blood is seen in the needle hub. If the vessel is not entered, the needle should be withdrawn and flushed to remove clots or tissue. Once blood return is observed, the soft end of the guide wire is advanced to the end of the needle and gently advanced into the vessel. If the wire does not advance immediately, the needle is advanced or withdrawn 1 to 2 mm and rotated while probing with the wire. Arterial entry of the wire should be very smooth; forceful entry will result in dissection, spasm, or clotting.

If the venous guide wire enters the femoral vein and does not advance beyond the pelvis, the needle is withdrawn over the wire and replaced with a plastic cannula. The wire can then be manipulated or withdrawn and curved. A guide wire should not be withdrawn from the needle once it has passed beyond the needle tip, as the soft floppy end of the wire may be shorn off.

When the guide wire has been advanced well into the inferior vena cava near the right atrium, the needle is withdrawn and pressure is applied to the puncture site; a small shallow nick is made in the skin with a number 11 scalpel and a 21- or 18-gauge tapered plastic cannula is passed over the wire to dilate the skin puncture and vein. This is particularly important during arterial puncture to facilitate smooth entry of the arterial dilator and sheath. The sheath is threaded over the guide wire and advanced into the vessel with a drilling motion, while slight tension is applied to the wire to avoid kinking in the subcutaneous tissue or vessel. A hemostasis valve can be placed on the end of the sheath to minimize blood loss during catheter exchanges.

The umbilical vein can usually be quickly cannulated and is often patent up to a week after birth.[56] To avoid prolonged probing

of the umbilical vein and the portal veins, a small injection of contrast material after insertion of the catheter will demonstrate whether the ductus venosus is still patent. A No. 5 French sheath and dilator can be passed over a guide wire through the ductus venosus in a similar fashion to femoral vein cannulation. The sheath prevents spasm of the ductus venosus if catheter changes are necessary. Intracardiac manipulation of the catheter from the umbilical vein is more difficult as the catheter lies posteriorly in the right atrium, and it is often difficult to enter the tricuspid valve and right ventricle from this approach. It is relatively easy to enter the left atrium and left ventricle from the umbilical vein, and this is a useful route from which to perform balloon atrial septostomy fairly quickly.

The brachial or axillary approach can be used if the femoral veins are not accessible.[57] The axillary vein can be punctured percutaneously about 0.5 to 1.0 cm below the distal axillary crease. The vein usually lies medial to the axillary artery, but the position can be variable. There is a greater risk of damaging the brachial plexus or axillary artery with a percutaneous approach because of lack of supporting subcutaneous tissue. If the axillary approach is necessary, it may be more expedient and safer to perform a cutdown just distal to the distal axillary crease. The vein or artery can be cannulated with a needle and guide wire under direct vision to avoid incising these small vessels.

The anterior brachial vein can be entered percutaneously or by cutdown, but in small neonates and premature babies this is usually too small to accommodate even a No. 5 French catheter, and there is a greater risk of spasm of the brachial vein; it is more difficult to manipulate the catheter through the long course from the arm to the superior vena cava.

The right internal jugular vein can be entered percutaneously[58] and a relatively large sheath can be placed into the superior vena cava. This approach requires a very cooperative or heavily sedated patient. Catheter manipulation from the jugular vein may be more difficult for operators accustomed to the femoral approach. A flow-guided balloon catheter is useful for this approach.

Vascular Cutdown

Incisional exposure of vessels for catheter entry has virtually disappeared from pediatric catheterization laboratories. This approach may be necessary after prolonged fruitless puncturing in a sick patient. The saphenous vein lies 1 cm medial and superficial to the femoral vein until it turns laterally through the deep fascia to enter the femoral bulb. In infants the incision is made through the femoral crease to expose the bulb, while in older children the incision is made 1 to 2 cm below the crease. The saphenous vein lies in the subcutaneous fat and can be traced cephalad to find the femoral bulb if femoral vein entry is desired. The femoral vein proximal and distal to the bulb should be freed with blunt dissection and looped with thick catgut or silk sutures for stability and hemostasis. The femoral artery lies immediately lateral to the vein, has a thicker pale wall, and may pulsate; the artery should be identified before the vein is entered. The artery and vein can be punctured with a short-bevel needle and a guide wire and sheath advanced in a manner similar to percutaneous entry. To incise the vein, a cut is made transversely with fine-pointed scissors and a second incision is made perpendicular to the transverse incision for 3 to 4 mm to make an inverted T. Large catheters or sheaths can be inserted through such an incision (Bargeron, L.M., personal communication, 1972). Incision of the vessel requires repair or ligation; after needle and wire entry, compression of the femoral sheath after skin closure will secure hemostasis.

Cutdown to the axillary vein is made through the distal axillary crease. The vessels and brachial plexus are below the superficial fascia, just medial to the long head of the biceps. Once again, one should identify both the vein and the artery before any vessel incision.

Catheter Types

Woven Dacron catheters are optimal for catheterizing patients with congenital cardiac defects because they are easier to control and direct. Softer, flow-guided balloon catheters are less traumatic but have much less torque control; in small babies the balloon size itself can be obstructive and limit catheter manipulation. While the balloon usually travels with the blood flow, this is not always where one wants the catheter to go. Small catheters such as a No. 4 French Dacron catheter or a No. 4 French balloon-guided catheter have very small fluid lumens, and pressure tracings are usually over-damped and the catheters can clot very quickly. Recent improvements in small catheter design have improved the usefulness of No. 4 French catheters for angiography.[59,60]

Catheter manipulation should be performed very carefully, conceiving the catheter as an extension of the finger with tactile feedback from the catheter tip. In newborn and premature babies, the myocardium is very soft, without much tactile feedback through the catheter. The myocardium is easily perforated, especially the medial wall of the right atrial appendage, which is very thin with little muscle. Perforation of the ventricle is especially likely with a dilated right ventricular outflow tract. There is often a diverticulum-like pouch just proximal to the pulmonary annulus, which appears to be more cranial than the pulmonary artery itself in the posteroanterior projection; forcible manipulation of the catheter in this position can result in perforation of the right ventricular outflow tract. When the anatomy of the heart is uncertain, small injections of 0.5 to 1 mL of contrast material will outline the anatomy enough for safer catheter manipulation and advancement.

Hemodynamic measurements are performed with an end-and-side-hole catheter for higher-fidelity pressure recordings and also to reduce the likelihood of clotting. After blood sampling and hemodynamic measurements are made, a fresh, clean angiographic side-hole catheter is used to perform angiograms.

In small hearts, manipulation of a catheter by itself, even with a balloon, can be difficult and traumatic. Guide wires may be used to help manipulate or bend the catheter,[52,53] especially to gain access to the left ventricle from the left atrium. Prolonged use of guide wires, even polytef (Teflon)-coated guide wires, can result in thrombosis of the catheter lumen[61]; wires should be used sparingly and catheters carefully aspirated and flushed after the use of guide wires. Guide wires with preformed tight curves are difficult to pass through small catheters and may result in loss of the curve. The use of a deflector wire and handle is helpful, and avoids the passage of a tightly curved wire into a relatively straight catheter. The deflector wires are manufactured with a tight 5-mm or larger 10-mm curve. They are particularly useful in entering the left ventricle from the left atrium in infants.

LEFT HEART CATHETERIZATION AND ARTERIAL CANNULATION

Arterial Cannulation

Systemic blood pressure is monitored through an 18- or 21-gauge polyethylene femoral artery catheter. Retrograde catheterization is performed at the end of the procedure to minimize the time that a catheter is in the artery.

When the arterial pulse is impalpable, arterial access can be facilitated by the use of a small Doppler probe over the groin to locate the site of the artery.[62] Continuous Doppler monitoring of the arterial pulse can be used as an early warning of arterial compromise.[63]

The umbilical artery can usually be cannulated in an infant less than 5 days of age.[56] In small infants, or when there is spasm of the artery, a small No. 3.5 French umbilical artery catheter can be used initially. The umbilical artery can be further dilated with a No. 5 French feeding tube or catheter to allow passage of a larger angiographic catheter. We have used the umbilical artery to insert a 5-mm balloon catheter for dilation of a coarctation. If the umbilical artery or vein is not accessible from the umbilical stump, a cutdown can be made at the base of the umbilicus to locate the vein or artery.[64]

Left Ventricle

We prefer the transseptal puncture with a long sheath technique[65,66] to enter the left atrium and left ventricle when the atrial septum is intact, even in small infants, of whom 12% may have an intact interatrial septum at under 1 yr of age.[67] This technique is used in preference to retrograde arterial catheterization to enter the left ventricle, as it avoids traumatizing small arteries and allows use of a larger, shorter catheter for left ventriculography. The long sheath can also be used to place other catheters and bioptomes into the left ventricle. Transseptal left atrial catheterization has been performed in infants as light as 1.5 kg.

Transseptal Left Heart Catheterization

The Mullins long transseptal sheath, dilator, and Brockenbrough needle are flushed with heparinized saline solution and assembled. The small 21-gauge needle tip should protrude 3 to 4 mm from the beveled dilator tip; the sheath is advanced to the end of the dilator and a note is made of the distance separating the hubs of the sheath and dilator, usually 3.5 to 4.0 cm. A 0.025-in. guide wire is passed through the femoral venous sheath to the high superior vena cava or innominate vein. The right femoral vein is the preferred approach for better apposition of the curved Brockenbrough needle and the atrial septum. If the left femoral vein is used, the patient may have to be rotated from left to right to tilt the atrial septum toward the laterally displaced needle. The dilator and sheath assembly are exchanged for the regular venous sheath over the guide wire and advanced to the superior vena cava. After withdrawing the wire and aspirating the dilator, the Brockenbrough needle is advanced to within 5 mm of the dilator tip. The needle is connected to the pressure monitoring tubing and the monitor gain is set to see the anticipated left atrial pressure in the middle of the screen. The directional arrow on the needle hub is directed posteromedially about 30 degrees below the horizontal plane, and the whole assembly is withdrawn as a unit until the dilator tip drops into the right atrium. A few premature atrial contractions may be noted. Continued withdrawal of the transseptal set may result in the tip dropping into the fossa ovalis; if this is not observed, the dilator tip is positioned low in the right atrium, about one vertebral body above the right hemidiaphragm, pointing toward the left and slightly posterior about 15 degrees.

The right atrial pressure wave may disappear when the dilator tip rests against the septum. When the position of the dilator is felt to be satisfactory after viewing the posteroanterior and lateral projections, the needle is advanced into the septal wall. Firm, steady pressure is applied to the assembly and the needle is usually felt to "pop" into the left atrium. If a left atrial pressure wave form is not immediately seen, a small injection of contrast material through the needle will outline the left atrial roof and posterior wall; incomplete entry is identified by a small plaque or "tag" in the atrial septum. Aspiration of the small-bore Brockenbrough needle is difficult and will cause clotting and loss of the pressure wave.

When the needle tip is free in the left atrium, the needle, dilator, and sheath are advanced as a unit toward the left shoulder until the dilator and sheath move across the septum. Some resistance may be felt as the sheath bevel encounters the septum, with bowing of the needle and dilator and lifting of the atrial septum toward the atrial roof. The presence of an undamped left atrial pressure wave form indicates that the needle tip has not reached the atrial wall and further pressure may be applied to advance the sheath through the septum. When the sheath has passed through the septum, it is pushed forward over the dilator 3 to 4 cm, where the almost radiolucent sheath tip is level with the more radiopaque dilator tip. Loss of the left atrial pressure wave indicates that the needle or sheath has reached the atrial roof.

With the sheath well in the left atrium, the needle is withdrawn from the dilator and the dilator is withdrawn from the sheath while aspirating blood to fill the sheath and exclude any air. The sheath is flushed and is ready to accept a catheter.

Retrograde Left Heart Catheterization

Retrograde arterial catheters are generally smaller and longer than venous catheters, which limits the amount and speed of contrast injections. Improvements in catheter design and material have resulted in smaller (No. 3.2 and No. 4 French) catheters,[59,60] which deliver sufficient amounts of contrast material at a fast enough rate for adequate opacification of the heart chambers and great vessels in infants with a rapid heart rate and high cardiac output. These catheters have less torque control than larger catheters. Newer formulations of catheter material have resulted in less kinking of these catheters during manipulation but they should be inserted and advanced with a guide wire. They are best used for retrograde aortic and left ventricular angiography where little catheter manipulation is required.

If it is anticipated that a retrograde catheter will be in place for longer than 20 to 30 min[68] systemic heparinization at 50 units/kg should be instituted. Routine heparinization for all retrograde catheterizations has been recommended by some authors.[69,70]

IMAGING

Biplane fluoroscopy and cineangiography are essential for optimal catheterization of infants and children with congenital cardiovascular defects. Magnification fluoroscopy in the 5- or 6-in.

mode is necessary for small infants; a small focal spot of at least 0.6 mm is required for optimal resolution. A high-quality videotape or disk recorder is necessary to immediately review angiograms to avoid unnecessary repeat angiography. Cineangiograms should be developed and viewed immediately after the catheterization, as the resolution of cineangiograms is higher than most currently available video-recording systems. Small details not visualized on the video recorder may become apparent when the developed film is viewed.

Two-dimensional echocardiography with Doppler facility is a useful adjunct to imaging in the catheterization laboratory. Contrast echocardiograms can localize shunting in any direction and have virtually replaced green-dye curves for shunt detection in my laboratory.

ANGIOGRAPHY

Angiocardiography is used to define the anatomy of the heart chambers and great vessels of the thorax. It is also used to visualize peripheral vessels in the systemic and pulmonary circulations to define the anatomy of the blood supply to various organs as well as the internal architecture. Blood flow between vessels (shunts) can also be demonstrated and ventriculography is used to assess regional and global function of the right and left ventricles. Because of the as yet unsurpassed detail and resolution that can be obtained by angiocardiography, this method of cardiac imaging is still the gold standard by which all other imaging techniques are judged.

The details of x-ray generation, dosage, image acquisition, processing, storage, and viewing will not be discussed here because of the constantly changing technology and equipment in these fields. These subjects are covered adequately in other sources with special reference to pediatric radiology.[71–75] The radiographic requirements for suitable imaging of pediatric patients with congenital heart defects are different from those required to image coronary arteries and the adult ventricle.

For angiography of the heart, one should try to fill the image-intensifier field with the heart or tissue of similar density. A fine focal spot of 0.6 mm or less is used for sharp definition; high kilovoltage and low milliamperage are used for maximal penetration and a wide grade scale. For viewing blood vessels, lower kilovoltage and higher milliamperage are used for sharper contrast and edge definition. The standard cine film format in pediatric laboratories is 35-mm film exposed at 30 to 90 frames per second using a fine-grain, wide-latitude film. Whenever possible one should use matched components along the whole imaging chain from the electrical generator to the x-ray tube, image intensifier, the cine camera, and video viewing system. Video-recording equipment should be of high resolution and allow storage of two to three cine runs, and have stop-frame viewing and flicker-free forward and reverse controls so that cineangiographs can be reviewed immediately after the injection is completed.

ANGIOGRAPHIC CONTRAST MATERIAL

Contrast material is radiopaque by reason of its iodine content, which ranges from 260 to 480 mg/mL in commonly used formulations. These materials are water soluble, iodinated salts of benzoic acid, while the cation is sodium or methylglucamine in various combinations[75] (Table 55–2). Sodium salts have a lower osmolarity and are less viscous but produce more toxicity and irritation, possibly in relation to its effect on ionized calcium.[76] The methylglucamine salts are more viscous, and the hyperosmolarity produces most of the cardiovascular side effects. Newly developed nonionic contrast materials have lower osmolarity and toxicity while producing opacification equivalent to the standard ionic contrast materials. Another ionic contrast material that has recently been developed is a dimeric benzoic acid derivative with increased iodine concentration at a low osmolarity and toxicity.[74]

Cardiovascular Effects of Contrast Material

The cardiovascular effects of contrast agents are related to the osmolarity, sodium content, and effects on serum calcium. In pediatric ventriculography, the usual dose of contrast material is between 1 and 2 mL/kg injected over two to three cardiac cycles, or about 1 to 2 sec (Table 55–3). This produces a slight immediate increase in ventricular end diastolic volume equivalent to about 50 to 60% of the normal stroke volume. If the injection is of a relatively large volume in a short period of time, there is an immediate increase in end diastolic volume and pressure with a Starling reflex increase in stroke volume, dP/dT, and ejection fraction, with a resulting rise in systolic pressure during the first two to five beats after the injection. However, with slower ventricular injections, during the first two to six beats, there is essentially no change in left ventricular dynamics and volume so that calculations of ventricular volume and function are comparable to the resting or preinjection state.[77–82] The pressure generated by the injector pump is not transmitted to the ventricular cavity and plays no part in the rise in end diastolic pressure during the injection of contrast material; the pressure from the pump is dissipated by the length and diameter of the catheter and the viscosity of the contrast material. Measurements of ventricular pressure with high-fidelity pressure transducers in the ventricle during injection show no change in systolic pressure during the injection.

When contrast material reaches the coronary circulation, there is coronary vasodilation and chelation of calcium from the blood

Table 55–2. Angiographic Contrast Agents

Name	*Type*	*Example*	*Iodine, mg/mL*	*Sodium, mg/mL*	*Osmolality*	*Viscosity at 37°C*
Diatrizoates	Ionic	Hypaque 75	385	9.0	2108	8.3
Ioxaglate	Ionic dimer	Hexabrix	320	3.48	600	7.5
Iohexol	Nonionic	Omnipaque	350		844	10.4
Iopamidol	Nonionic	Isovue	400		796	9.4
Metrizamide	Nonionic	Amipaque	300		484	6.2

Table 55–3. Dose of Contrast Agents

Site of Injection	*Dose (mL/kg)*	*Rate of Injection (mg/kg/sec)*
Ventricle, normal size	1.0–1.25	0.5–1.0
Ventricle, large, increased flow	1.5–2.0	1.0
Ascending aorta, MPA, normal flow	0.8–1.0	1.0–1.5
Ascending aorta, MPA, increased flow	1.5–2.0	1.5–3.0
Descending aorta, RPA, LPA	0.75–1.0	1.0
Pulmonary arterial wedge	0.5–1.0 (total)	0.25 mL/sec
Pulmonary venous wedge	0.3–0.6	0.5 mL/sec

MPA = Main pulmonary artery; RPA = right pulmonary artery; LPA = left pulmonary artery

and probably the intracellular fluid.[83,84] There is a drop in the coronary hematocrit due to an increase in intravascular water from the tissues. These effects result in decreased myocardial contractility with a rise in end diastolic volume and pressure and a decrease in stroke volume, depending upon the initial contractile state of the ventricular myocardium. Patients with coronary artery disease, chronic congestive heart failure, or decreased myocardial reserve will have a more profound fall in ventricular function and systolic blood pressure than those with a normal myocardium. This negative inotropic action of contrast material occurs earlier and more profoundly after aortic root or coronary artery injections; after ventriculography the effect occurs about 13 to 16 beats after the injection.[77]

When hyperosmolar contrast material reaches the peripheral circulation, there is vasodilation in response to the rise in serum osmolality[85]; this results in a reduced afterload faced by the ventricle producing an increase in stroke volume and ejection fraction, which in turn causes a temporary decrease in end diastolic volume that is soon restored and even increased by the expansion of circulating blood volume and hemodilution caused by hyperosmolar contrast. The hypotensive effect after ventriculography lasts for 15 to 30 sec; with an increase in venous return there is an increase in cardiac output and systolic blood pressure and a rise in end diastolic volume and pressure, which in normal hearts is accompanied by an increase in dP/dT. There may also be some peripheral sympathetic stimulation due to the acute vasodilation, which promotes an increase in myocardial contractility and cardiac output. The hemodynamics return to base-line values after 5 to 15 min, depending upon the amount of the injection and the number of previous injections. The effects of contrast injections are cumulative and are more pronounced in patients with poor myocardial function, hypotension, and a low serum calcium. The effects are attenuated by the use of lower-osmolality agents[86] and nonionic contrast material[87] and by the addition of calcium to the contrast material[88] or administered intravenously before contrast injection. These effects are particularly important in neonates, infants, and patients who have been taking diuretics chronically, who may have a low serum calcium.[89,90] The administration of furosemide before angiography hastens the elimination of iodine and sodium from the circulation and shortens the duration of the cardiovascular effects.[91]

Injection of contrast material into the pulmonary circulation causes an abrupt rise in pulmonary artery, right ventricular, and right atrial pressures during the first five beats after the injection due to the speed and volume of the injection.[92] Injection of a large volume of contrast into the main pulmonary artery in patients with pulmonary hypertension may produce a stretch reflex vasoconstriction,[93] which may be particularly disastrous in patients with Eisenmenger's syndrome or primary pulmonary hypertension. However, the major effect of hyperosmolar contrast injection into the pulmonary arteries is that of vasodilation and a reduction in pulmonary vascular resistance; any persistent rise in pulmonary artery pressure is due to an increase in cardiac output and pulmonary blood flow. Patients with elevated pulmonary resistance will have a greater increase in pulmonary artery pressure due to the reduced compliance of the pulmonary vascular bed.

Toxic Reactions

Allergic reactions are rare without a previous exposure to contrast agents, especially in the pediatric population.[74] If there has been a history of previous allergy, reactions can be minimized by the administration of an antihistamine before angiography. Renal damage has been reported after angiography and probably results from hyperosmolar tubular damage with resulting hematuria and proteinuria with casts.

It has been recommended that the dose of contrast material not exceed 4 mL/kg in infants and children. However, careful timing of injections, administration of fluid and diuretics, and supplemental calcium doses will reduce the toxicity and cumulative hemodynamic effects, allowing up to 6 mL/kg of contrast material to be given over a period of 2 to 3 hr.

DOSE OF CONTRAST MATERIAL

To visualize anatomic detail in a normal-sized ventricle optimally, my colleagues and I use 1.0 to 1.25 mL/kg of contrast material injected at a rate of 0.5 to 1.0 mL/kg/sec. For smaller ventricles, such as a hypertrophied right ventricle in a patient with tetralogy of Fallot, we use a lesser dose of 1.0 mL/kg at an injection rate of 1.0 mL/kg/sec. This same dose is used to opacify normal pulmonary arteries and the ascending aorta. A slightly smaller dose of 0.7 to 0.8 mL/kg is used in the descending thoracic aorta.

For a dilated ventricle with large flow, such as the left ventricle with a large left-to-right shunt, a dose of 1.5 to 2.0 mL/kg at a flow rate of 1.0 to 3.0 mL/kg/sec is used. For example, in an infant with truncus arteriosus and a heart rate of 150 beats/min, a volume of 2.0 mL/kg at flow rate of 3.0 mL/kg/sec will be needed to opacify the truncus and pulmonary arteries adequately. When studying ventricular function, a slower rate of injection over three to five cardiac cycles will reduce the incidence of premature

ventricular contractions and allow several cardiac cycles to be studied for ventricular volume and wall-motion analysis. For slow injections, a slightly larger amount of contrast material is used than that for a normal-sized ventricle.

As a general principle, the shortest, widest catheter with multiple side holes should be used for ventriculography. The rate of contrast delivery into the chamber varies inversely with the viscosity of the contrast material, the catheter length, and directly with the lumen diameter. When long, small-lumen catheters are used, high-pressure injections will cause straightening of the catheter, which may recoil into the proximal chamber or against the ventricular wall and cause staining of the myocardium. The more curved the catheter inside the heart, the greater the rise time should be for the injection.

ANGIOGRAPHIC DEMONSTRATION OF CARDIOVASCULAR ANATOMY

Angiographic definition of cardiovascular anatomy should show the morphology, position, relations, connections, and function of the cardiac chambers, valves, and vessels entering and leaving the heart. Consideration must be given to the spatial orientation of a particular structure and whether it is best seen en face or in profile to a particular image intensifier.

Biplane video fluoroscopy and cineangiography are essential in pediatric cardiac catheterization laboratories. Because of the greater exposition of intracardiac anatomy obtained by angled angiographic views, various configurations of C or U arms carrying the x-ray tubes and image intensifier are employed to obtain biplane, angled projections of specific areas of the heart.

Radiologic Nomenclature

The direction of the x-ray beam determines the order of names when describing a particular x-ray projection. For example, if the x-ray tube is below the examination table and the image intensifier directly above the patient, the projection is called posteroanterior (PA) (Fig. 55–1).

When the image intensifier is tilted sagittally toward the patient's head, the x-ray beam travels caudocranially (Fig. 55–2); this is often called cranial angulation. When the image intensifier is tilted toward the patient's feet, the x-ray beam travels in a craniocaudal direction, but is often referred to as caudal angulation.

When the image intensifier is tilted to the right or left of the

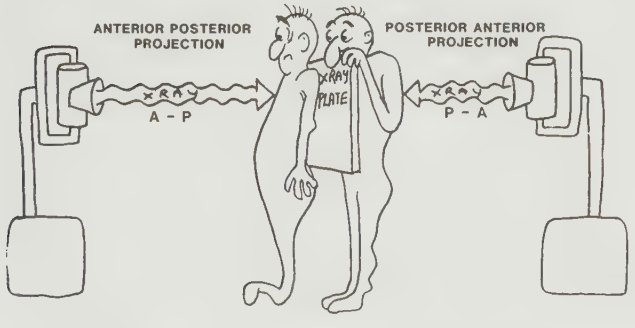

Fig. 55–1. Nomenclature of x-ray projections. The direction of the x-rays from the x-ray tube to the image intensifier or x-ray film determines the order of the names.

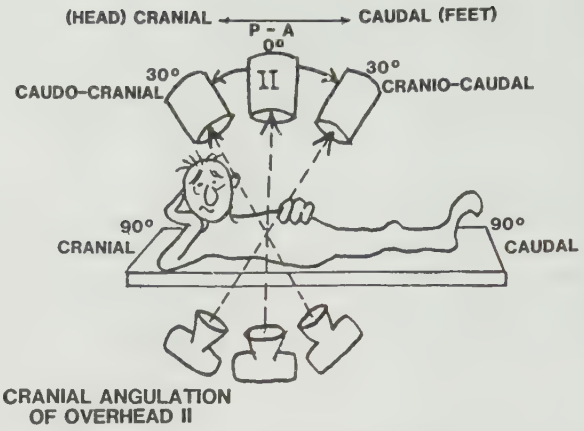

Fig. 55–2. Nomenclature of x-ray projections–sagittal angulation. Cranial angulation of the overhead image intensifier (I.I.) causes the x-ray to travel in a caudocranial direction.

patient, the part of the body nearest the image intensifier determines the name. For example, if the lateral image intensifier is to the left side of the patient, the projection is called left lateral; when the vertical image intensifier is tilted 30 degrees toward the patient's left, the view is called left anterior oblique (LAO) (Fig. 55–3A and 55–3B). If the image intensifier is below the horizontal plane on the left side, the position is left posterior oblique (LPO).

Standard x-ray projections for angiocardiography have usually been in the PA and lateral projections; some early experiments with angled angiography in the 1950s were unsatisfactory because of distortion produced by the x-ray equipment.[94] However, further experiments revealed that tilted or angled angiography (later known as "axial angiography") produced much more information than the standard views.[95,96] While certain congenital cardiac malformations have a constant number and form of defects, the variation in morphology, position, and a degree of deformity varies considerably among individual patients. The angiographer must have a thorough knowledge of normal and abnormal cardiac anatomy; with precatheterization echocardiography and the information obtained from the catheter course through the heart, one should be able to "previsualize" the internal anatomy of a given heart before angiography. The x-ray tubes and/or the patient are positioned to visualize specific parts of the intracardiac anatomy optimally. Several injections will be required to image all of the defects completely in a particular heart and more than one injection may be required to image one particular anomaly completely.

Being mindful of the constraints of the amount of contrast material that can be given to a particular patient, the first injection is made in the chamber or vessel that provides the most information for the immediate medical or surgical management of that patient, in case this is the only injection that can be performed.

Many anomalies in a heart with multiple defects can be well visualized by echocardiography or other noninvasive means; angiocardiography should be confined to lesions or defects that have not been previously clearly defined.

Common X-Ray Projections

Different manufacturers of x-ray equipment have their own systems and nomenclature for the positions of the image intensifiers and x-ray tubes. Some laboratories have fixed PA and lateral tubes;

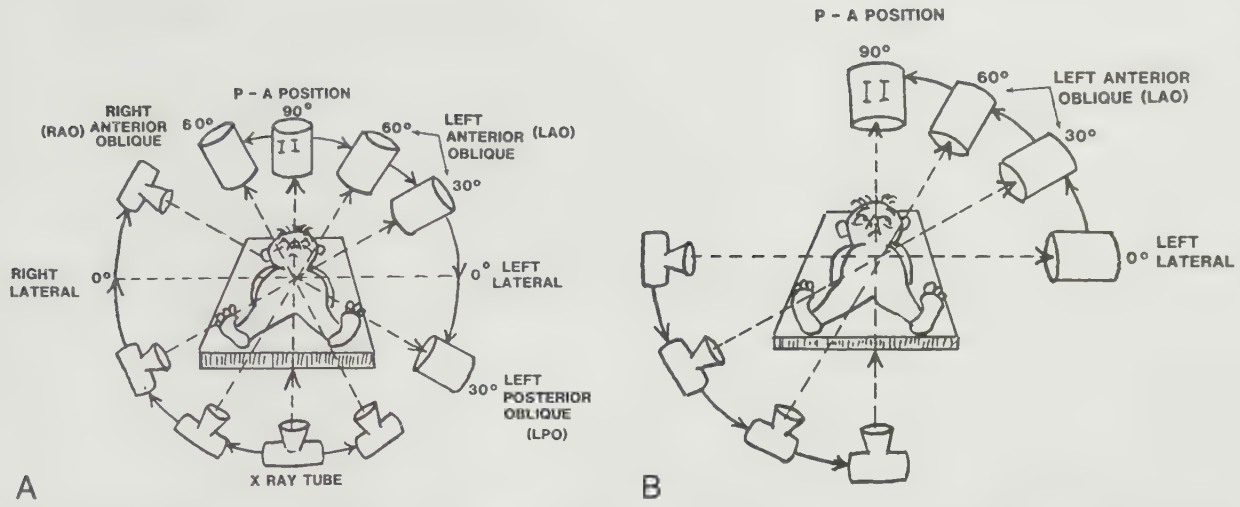

Fig. 55–3. Axial angiography nomenclature: The part of the body nearest the image intensifier determines the name of the projection (see text). (A) Positions of the vertical image intensifier. (B) Positions of the horizontal image intensifier.

to obtain axial views of the heart, one has to move the patient. Other systems have either C arms or U arms, which allow motion of the tubes and intensifiers around three axes.

By convention, the position of the vertical PA image intensifier, when positioned directly above the patient, is considered to be at 0 degrees, while the orthogonally positioned horizontal or lateral image intensifier is at 90 degrees. This convention may vary among laboratories, some designating the lateral tube to be at 0 degrees and the PA tube to be at 90 degrees (Table 55–4).

When imaging congenital heart defects, the principles of axial angiography are 1) place the long axis of the heart perpendicular to an x-ray beam (Fig. 55–4) and 2) rotate the heart or x-ray beam so as to profile the areas of the heart that are to be imaged (Fig. 55–5) (Table 55–5).

Standard Projections

Posteroanterior and Lateral Views

The vertical image intensifier is at 0 degrees directly above the patient, while the horizontal intensifier is at 90 degrees on the left side of the patient.

Right Anterior Oblique (RAO) and Left Anterior Oblique (LAO) Projections

Moveable X-Ray Tubes and Intensifiers. The vertical image intensifier is tilted 30 to 45 degrees toward the patient's right (RAO projection) and the horizontal image intensifier is elevated 30 to 45 degrees from the horizontal position (LAO projection). The x-ray tube-intensifier axes do not have to be orthogonal and each

Table 55–4. X-Ray Projections

	Image Intensifier Position

intensifier may be tilted to different positions to display best the diagnostic information available from its aspect of the heart.

Fixed X-Ray Tubes. The patient's right shoulder is elevated 30 to 45 degrees from the table top and rested on a foam wedge. This presents the RAO projection to the vertical image intensifier and the LAO projection to the lateral intensifier.

Long Axial Projection (Tilted Left Anterior Oblique)

In one view, after positioning the image intensifiers in the RAO and LAO positions, the horizontal image intensifier is tilted 20 to 30 degrees toward the patient's head (cranial) so that the horizontal x-ray beam is perpendicular to the elongated long axis of the heart. The LAO elevation places the left ventricular outflow tract and septum in profile to the x-ray beam. The long axial projection has been used for right ventricular injections but the trabecular septum wraps around the left ventricle and the septal profile is not as sharp as that seen from a left ventricular injection. The vertical image intensifier can be tilted caudally 20 to 30 degrees to produce an elongated right anterior oblique projection.

In another view, the patient is twisted from the hips toward the horizontal image intensifier to align the long axis of the heart parallel to the table and perpendicular to the horizontal x-ray beam.

The right shoulder is then elevated 30 degrees to profile the left ventricular outflow tract and septum to the horizontal x-ray beam.

Four-Chamber View (Hepatoclavicular)

This projection is used to look at the crux of the heart with both atria and ventricles en face to the image intensifier with the atrioventricular valves in profile. Either the vertical or horizontal image intensifiers can be used for this projection.

In one view, the vertical image intensifier is tilted 30 degrees LAO and 20 to 30 degrees cranial. The horizontal tube can remain in the left lateral position. Alternatively, the horizontal intensifier can be elevated 60 degrees LAO from the horizontal position and then tilted 20 to 30 degrees cranially. The vertical image intensifier can be rotated 30 to 45 degrees RAO with or without a caudal tilt of 20 to 30 degrees to show an elongated RAO view of the left ventricle.

In another view, the patient's chest is elevated 30 degrees from the table top using a foam wedge; the right shoulder is elevated 20 to 30 degrees to present a four-chamber view to the vertical image intensifier and a long axial view to the horizontal image intensifier.

Cranial Angulation (Sitting-up View)

In one view, the vertical image intensifier is rotated 30 degrees in a cranial direction (caudocranial x-ray projection) and the patient's head rotated to one side. This elongates the right ventricular outflow tract, main pulmonary artery, and bifurcation. When the main pulmonary artery is dilated, the origin of right and left branches may not be well seen from this straight cranial angulation. Therefore one should use cranial angulation of both the vertical and horizontal image intensifiers in a 30-degree RAO and LAO projection to see the origin of the right and left pulmonary arteries.

In another view, the patient's chest is raised 30 degrees from the table top and the head allowed to drop back over the foam wedge. The horizontal intensifier is moved to obtain a left lateral projection.

Aortic Orifice View

With normal origin of the aorta from the left ventricle, the horizontal intensifier is lowered 10 to 15 degrees left posterior oblique (LPO) and tilted caudally 10 to 30 degrees.[97] The position of the horizontal image intensifier will depend upon the orientation of the aortic annulus, which may be almost vertical in some patients and almost horizontal in others.

The patient may also be twisted to the right from the hips with the left shoulder elevated 10 to 15 degrees so that the aortic orifice faces the horizontal image intensifier. The injection is made as close as possible to the aortic valve to fill both coronary arteries without producing aortic regurgitation. This projection outlines the sinuses of Valsalva, the aortic annulus, and valve cusps and has been used to look at the origin of the coronary arteries and the morphology of the aortic valve, and to measure aortic valve area.

Right Ventricular Outflow Tract (Orifice) View

This is useful for looking at the pulmonary annulus while injecting in the main pulmonary artery or the aortic annulus in transposition of the great arteries. The vertical image intensifier is tilted 30 to 45 degrees in a caudal direction with a variable degree of LAO rotation depending upon the sagittal orientation of the main pulmonary artery or ascending aorta. The origin of the coronary arteries is well seen in transposition of the great arteries and the morphology of the pulmonary valve in pulmonary stenosis.

Pulmonary Artery Wedge Angiography

In order to evaluate the morphology of the peripheral pulmonary circulation in the primary pulmonary lobule, pulmonary arterial wedge angiograms are taken in a high magnification mode to assess the lobar architecture and microcirculation in the primary pulmonary lobule; the morphology of the muscular pulmonary arteries and supernumerary arteries; the background blush that constitutes the arterioles, capillaries, and venules; communications between pulmonary arteries and veins; and the pulmonary venous return.[98]

Low kilovoltage and high milliamperage are used to maximize contrast for sharp edge definition of the small pulmonary arteries. A focal spot of 0.3 to 0.6 mm is used and a film rate of 30 frames per second with an exposure of 4 msec. An end-hole catheter is wedged into a distal pulmonary artery in the periphery of the lung, preferably at the costophrenic angle or chest wall. A small test injection of 0.2 to 0.5 mL is made to evaluate the alignment of the pulmonary lobule with the vertical image intensifier. If there is foreshortening of the central pulmonary artery in the PA projection the lateral projection or biplane filming should be used. The image intensifier is raised as high as possible from the table top to increase magnification without loss of edge definition. The field is then adjusted to visualize the peripheral arterial tree as well as the venous return to the left atrial border. One should try to center the x-ray field over tissue of uniform density such as the lung without any liver or heart shadow present.

A very slow hand injection of 0.5 to 1.0 mL of contrast material is made to outline the central pulmonary artery and small branches. As soon as the vein starts to fill, the catheter is flushed with 2 to 5 mL of flush solution to wash the contrast material through the lobule and visualize the capillary background blush and venous return.

If it is not possible to wedge an end-hole catheter into the peripheral pulmonary arteries, an end-hole balloon catheter can be inflated in a sublobar artery and 1 to 5 mL of contrast can be injected to fill the peripheral pulmonary arteries. The balloon is then deflated and the pulmonary blood flow will wash out the contrast into the capillaries and pulmonary veins. If the injection is made too proximally, too many vessels will be filled and will obscure the terminal branches and supernumerary vessels and not enough contrast will be available to opacify the smaller pulmonary lobules.

Wedge angiography can identify morphologic patterns associated with high pulmonary blood flow with low resistance, high pulmonary blood flow with elevated pulmonary artery pressure, and elevated pulmonary resistance and obstructed pulmonary vascular disease (Heath and Edwards Grade IV). Anomalies of pulmonary venous connection can also be demonstrated with very small amounts of contrast. Pulmonary venous varices and pulmonary venous obstruction can be identified more readily by this technique than by main pulmonary artery injections.

Pulmonary Venous Wedge Angiography

When an injection is made into an end-hole catheter wedged in a pulmonary vein, there is retrograde filling of the pulmonary

arteries if the pulmonary artery pressure is low or the blood flow in the pulmonary arteries is less than normal.[99] This technique is used in patients with pulmonary atresia to visualize the central pulmonary arteries and the connections of the lobar blood supply when there are several systemic collateral vessels.

An end-hole catheter is wedged into a pulmonary vein and a very slow hand injection of 0.3 to 0.6 mL/kg is made at a rate of 0.5 mL/sec. This amount of contrast will load several pulmonary lobules with contrast material. The catheter is then flushed by hand injection with 5 to 10 mL of flush solution at a flow rate of 1.0 mL/sec.

The fields are set to visualize the tip of the catheter and, more importantly, the hilar and mediastinal regions. The filming rate is 30 frames/sec to allow for the slow injection through the capillary bed and retrograde flow to the proximal pulmonary arteries. If more than one blood vessel supplies the lung, several injections may have to be made to define the small central pulmonary arteries and confluence. Injection into a lobe supplied by a systemic collateral vessel may result in washout of the contrast and no central filling of the collateral or true pulmonary artery confluence.

Pulmonary venous wedge angiograms are never performed with a power injector because the force of the injection will extravasate contrast material into the lung parenchyma and bronchi.[100] Coughing during an injection is quite common but no serious complications or hemoptysis have occurred in over 300 studies.

An alternative technique is to inflate an end-hole balloon catheter in a more proximal pulmonary vein and inject a larger amount of contrast material into several peripheral pulmonary veins. This contrast is then flushed with a larger amount of flush solution to fill the pulmonary arteries in retrograde fashion.

Aortic Occlusion Angiography

Injections of contrast in the ascending or descending aorta may not provide good visualization of small aortic branches such as the coronary arteries or systemic collateral vessels because of the fast runoff down the aorta. Using an angiographic balloon catheter with side holes proximal to the inflated balloon, one can inflate the balloon just distal to the point of interest.[101,102] A power injection is then made, forcing the contrast to fill the proximal aorta and small side branches. The balloon is then deflated quickly after the injection. With the balloon inflated just proximal to the brachiocephalic arteries, an injection in the proximal ascending aorta will visualize the coronary arteries in transposition of the great arteries, especially when the vertical intensifier is tilted caudally (see above). Angiography with balloon occlusion of the descending aorta just above the diaphragm will provide excellent visualization of systemic collateral vessels arising from the descending aorta in pulmonary artery atresia. When a catheter is passed through a patent ductus arteriosus and a balloon inflated just distal to the ductus, contrast injection will show the ductus as well as the aortic isthmus and coarctation and often the ascending aorta.[103]

HEMOSTASIS AND ANTICOAGULANTS

Precatheterization clotting studies are drawn on all newborns and patients with a hematocrit over 60%; some newborns require the administration of vitamin K before catheterization. Some patients may have disorders of blood clotting or platelets due to infection or shock; fresh frozen plasma and fresh platelets should be administered if clotting disorders are identified. One unit of fresh packed red cells, or at least 20 mL/kg, should also be available during all catheterizations of infants of less than 5 kg because of the relatively large blood loss when exchanging catheters or sheaths in infants as compared with other children.

The use of hemostasis or bleed-back valves on percutaneous sheaths will minimize blood loss during catheter exchanges or when there is poor size tolerance between the catheter and sheath size. When using a small catheter in a larger sheath, back flow of blood into the sheath around the catheter may result in thrombosis inside the sheath; this clot could be flushed into the circulation during catheter exchanges or flushing of the side arm of the hemostasis valve. In my laboratory we have used a constant slow infusion of heparinized saline through a bleed-back valve in patients who have required prolonged catheter manipulation.

If a femoral or saphenous cutdown is performed, the distal vessel is ligated or secured with a heavy ligature if later repair is planned. A temporary hemostasis suture is placed around the proximal part of the common femoral vein while the catheter is in the heart. This prevents back bleeding during the catheterization and also helps in repairing the vein after the catheterization.

Anticoagulants are not routinely used during a venous catheterization. If a retrograde arterial catheterization is likely to take longer than 30 min systemic heparinization at 50 U/kg should be instituted. Patients with marked polycythemia may have accelerated clotting and a consumptive coagulopathy if the hematocrit is over 60%[104,105]; phlebotomy with plasma replacement will reduce this tendency.

POLYCYTHEMIA AND ANEMIA

Patients who are markedly polycythemic have a marked elevation of blood viscosity when the hematocrit is above 65%. If the precatheterization hemoglobin is above 20 g/dL, a centrifuged hematocrit is obtained using venous blood to measure the true packed cell volume. An oxygen-carrying capacity of 17 to 19 mL of oxygen/100 mL of blood is desirable (assuming 95% saturation in a normal patient with 10 to 15 g of hemoglobin). If the hematocrit is 65% or greater, we recommend erythropheresis before angiography to reduce the centrifuged hematocrit to 60%.[106] The amount of blood withdrawn is replaced with fresh plasma or 5% albumin solution, which has the same osmolality as plasma. Patients with secondary polycythemia have an elevated blood volume on the order of 90 to 110 mL/kg (average, 100) due to the increased red cell mass.[107]

$$\text{Blood volume to withdraw} = \text{wt (kg)} \times 100 \times \frac{\text{observed hematocrit} - \text{desired hematocrit}}{\text{observed hematocrit}}$$

A similar calculation can be used to increase the patient's oxygen-carrying capacity if there is systemic hypoxemia and low oxygen-carrying capacity.

Reduction of the oxygen-carrying capacity and blood viscosity is performed cautiously in patients with obstruction to pulmonary blood flow, such as tetralogy of Fallot, or those with high pulmonary resistance. A reduction in blood viscosity will result in a greater fall in systemic resistance than in pulmonary resistance, which may induce more right-to-left shunting and systemic hypoxemia. On the other hand, patients with transposition physiology

tend to improve their systemic saturation with a reduction in hematocrit to 60%.[106]

DRUGS

Intravenous drug infusions are maintained on arrival at the catheterization laboratory. Once monitoring catheters have been inserted, the infusion rate of these drugs may be changed and the effects recorded. Maintenance fluid in infants and premature babies is 10% glucose with one-quarter to one-fifth normal saline. Regular checks of the blood glucose are made during the catheterization as the stress of the illness or catheterization may cause hypoglycemia even with 10% glucose administration. Bolus doses of glucose are given intravenously at a concentration of 25%; more-concentrated solutions may cause hypotension due to hyperosmolality.

Half the calculated dose of a drug is administered initially and the effect on the patient observed to make sure that no idiosyncratic or untoward reactions occur. The rest of the calculated dose may then be administered in small aliquots with interval flushing until the desired effect is achieved.

Infants are more susceptible to the central nervous system depressing effects of narcotics and drugs such as ketamine. We have found that a total dose of 0.1 mg of morphine is adequate for sedation in infants under 6 mo of age rather than the usually recommended dose of 0.1 mg/kg.

A bolus intravenous flush of ketamine of 0.5 to 1 mg/kg may result in apnea or extrapyramidal seizures in infants. This dose causes few problems or changes in hemodynamics when infused over 30 to 60 sec.[49]

The dose of lidocaine used for local anesthesia infiltration is carefully monitored, and no more than 5 mg/kg should be given subcutaneously.

Antibiotics are not routinely given before catheterization as the risk of bacterial endocarditis in an otherwise noninfected child is rare after cardiac catheterization. If indicated, cardiac catheterization can be safely carried out in a child who has other signs of sepsis, such as endocarditis, while the usual therapeutic antibiotics are being administered.

If a cutdown is needed for venous access, topical antibiotics can be applied to the wound at closure.

We have found an increased incidence of wound and systemic infections in children who have prostaglandin E_1 infusions for ductal-dependent congenital heart defects. We recommend the routine administration of broad-spectrum antibiotics in all children receiving prostaglandin E_1 and also recommend that the use of this drug be limited to as short a time as possible with as low a dose as possible.

Emergency medications should be drawn up in administration syringes and available during the catheterization. Table 55–6 lists emergency drugs that should be available during a cardiac catheterization and their doses.

COMPLICATIONS OF CARDIAC CATHETERIZATION

The mortality and morbidity associated with cardiac catheterization is directly related to the underlying cardiopulmonary defect and the general condition of the patient rather than to age and size.[108] The moribund, acidotic, hypoxic neonate with poor perfusion, who has not responded to precatheterization medications and management, has a poor chance of survival with or without cardiac catheterization. Such infants are likely to have complex or inoperable cardiopulmonary defects and usually die in spite of, rather than because of, the catheterization.

The incidence of complications and the number of deaths from cardiac catheterization have decreased sharply over the past 20 yr. Cardiac catheterization techniques, vascular access, catheter design and materials, the quality and type of imaging, and the type of contrast materials used for imaging have undergone considerable refinements and have improved the quality and safety of cardiac catheterization and angiography over the past 20 yr. The indications for a cardiac catheterization have also changed with the introduction of other imaging modalities, such as two-dimensional echocardiography.

Mortality

A cooperative study on cardiac catheterization[109] gathered data on the incidence and type of complications that occurred during 12,367 cardiac catheterizations carried out over a 2-year period from 1963 to 1965. There were 4050 children less than 14 yr of age included in this study and 1161 were under 1 year of age. A total of 55 deaths (4%) occurred within 24 hours of the catheterization and 40 of these (72%) were in children. Twenty-nine (72%) of the pediatric deaths were in infants less than 2 months of age, who had a total mortality rate of 6%. The mortality rate for the 2-to-11-months age group was 1.2% and thereafter was 0.3 to 0.05%, comparable to all other age groups, including adults.

Perforation of the heart by a catheter or after angiocardiography occurred in 24 patients less than 15 years of age and resulted in nine deaths in patients aged 4 days to 4 months. Bradycardia and complete heart block was poorly tolerated in infants and resulted in seven deaths in severely ill patients age 36 hours to 6 weeks. Ventricular tachycardia precipitated the death of a 2-month-old infant with mitral atresia, while supraventricular tachycardia preceded the death of a 7-month-old child with congestive cardiomyopathy.

Progressive deterioration and death ensued in eight patients who were critically ill or moribund from severe congestive heart failure, cyanosis, or uncorrectable cardiac defects.

Twelve patients died within 24 hours of the catheterization after being transferred to the ward and it was argued that "after catheterization, critically ill infants should be observed and monitored in an environment resembling an intensive care or coronary care unit."[109]

Of the 55 patients who died, 27 (49%) were in New York Heart Association Class IV, 11 (20%) in Class III, 5 (9%) in Class II, and 1 (1.8%) in Class I. Twenty-three of these deaths occurred during the catheterization, while 19 occurred within 24 hours and 13 died more than 24 hours after the catheterization.

Since that initial collaborative study, many changes have taken place in the methods of catheterization and angiography, medical management, operative techniques, and the type of patients undergoing cardiac catheterization for the investigation of congenital heart disease.

Several later studies of cardiac catheterization complications from the early and late 1970s[108,110,111] showed that the causes of death were similar to those described in the first collaborative study but the incidence was remarkably lower. In all of these later

Table 55–6. Emergency Drugs

Drug	*Intravenous Dose*	*Comment*
Albumin	1.0 g/kg	Volume replacement
Aminophylline	Bolus: 3.0 mg/kg Infusion: 0.7 mg/kg/hr	Hypotension, tachycardia
Atropine	0.01–0.04 mg/kg	Tachycardia, spells in tetralogy of Fallot
Bretylium	5.0 mg/kg, up to 20 mg/kg	
Calcium chloride	50–100 mg/kg	Vagal stimulation
Chloral hydrate	Rectal, by mouth: 25–80 mg/kg	
Chlorpromazine	I.M.: 1.0 mg/kg I.V.: 0.25 mg/kg	Hypotension, hypothermia
Cryoprecipitate	1 unit (bag) = 250 ml FFP	
Dextrose 25%	2.0 ml/kg	
Diazepam	0.10 mg/g	Vasoconstriction in pulmonary hypertension
Digoxin	I.V. digitalizing dose: 20–30 μg/kg	
Diphenhydramine	2.0–5.0 mg/kg	
Dobutamine	1–40 μg/kg/min	
Dopamine	1–30 μg/kg/min Renal dose: 2–5 μg/kg/min	Tachycardia, arrhythmias
Epinephrine 1:10,000	Infusion: 0.10 μg/kg/min Bolus: 0.10 ml/kg	
Fresh plasma	10–15 ml/kg	Hypotension. Ca++ reverses
Furosemide	1–5 mg/kg/dose	
Hydralazine	0.20–1.2 mg/kg	Hypotension
Isoproterenol	0.10 μg/kg/min	Tachycardia, hypotension
Ketamine	0.5–1.0 mg/kg	Apnea, seizures
Lidocaine	Bolus: 1–5 mg/kg Infusion: 20–40 μg/kg/min	Seizures
Mannitol	0.5–1.0 g/kg	
Meperidine HCl	1–2 mg/kg	Hypoventilation
Methoxamine	0.05–0.1 mg/kg	Vasoconstriction
Methylprednisolone	30 mg/kg	
Morphine	0.01–0.1 mg/kg	Hypoventilation, apnoea
Nalorphine	0.1–0.2 mg/kg	
Naloxone	0.01 mg/kg	
Neostigmine	0.025–0.05 mg/kg	
Nitroglycerine	0.1–1.0 μg/kg/mg	Hypotension
Nitroprusside	0.5–10 μg/kg/min	Hypotension, cyanide
Pancuronium	0.1 mg/kg	
Pentothal	10–30 mg/kg	Apnea
Phenobarbital	1–5 mg/kg	Apnea
Phenylephrine	0.01–0.10 mg/kg	Vasoconstriction
Procainamide	10–15 mg/kg over 40 min	Hypotension
Propranolol	0.01–0.025 mg/kg	Bradycardia, hypotension
Succinyl choline	1.0 mg/kg	
Tolazoline	1–2 mg/kg	Hypotension, gastric hyper-acid
Verapamil	0.10 mg/kg	Bradycardia, hypotension

studies, the mortality was highest in infants less than 2 mo of age who were rated as critically ill and had a noncardiac illness or uncorrectable cardiovascular defects. The incidence of deaths related the catheterization procedure itself ranged from 0.26 to 1.6%, and they were due to cardiac perforation, arrhythmias (particularly bradyarrhythmias), and hypotension. Progressive deterioration due to inoperable cardiovascular defects, failed medical treatment, or pulmonary disease with no congenital heart defects resulted in a total pericatheterization mortality rate of 1.6 to 5% in infants less than 12 mo of age.

Patients with the highest mortality were those classified as "critically ill" or "at high risk" and were characterized as being acidemic (PH <7.1), hypoxemic (pO_2 <25 mm Hg), with poor peripheral perfusion and requiring ventilation. These patients comprised 12 to 20% of the infants catheterized, and they had a mortality rate of 30 to 36%. Those considered to be at low risk (30 to 66% of infants catheterized) had a mortality rate of 1.2 to 3.4%.

Stanger et al.[110] studied the complications of cardiac catheterizations in neonates, infants, and children for a 36-mo period from January 1970 to December 1972. There were 218 neonates among this group with 20 deaths (9.2%) within 24 hours of catheterization. Forty-seven patients were severely ill prior to the catheterization with profound hypoxemia (pO_2 less than 25 mm Hg), acidemia (pH less than 7.1) with poor peripheral perfusion or were ventilated during catheterization. Two of these patients died during the catheterization (one with hypoplastic left heart syndrome and one with pulmonary disease) and 15 others died within 24 hours of the catheterization, for a mortality rate of 36.2%. Only two of these patients had remedial cardiac defects. The authors felt that only one patient died as a direct result of the procedure itself and in another patient the relation was not clear.

A similar study of 194 neonates catheterized at less than one week of age was conducted at Texas Children's Hospital between January 1971 and July 1976.[111] There were 10 deaths (5%), 3 (1.6%) of which were related to the catheterization procedure itself, resulting from perforation of the right ventricular outflow tract, right atrium, and umbilical artery. Three patients with pulmonary disease and pulmonary hypertension died within 24 hr of catheterization, and one patient with hypoxic cardiomyopathy died during catheterization. Three patients in critical condition from their congenital heart defects (truncus arteriosus with interrupted arch; coarctation, ventricular septal defect, atrial septal defect, patent ductus arteriosus; ventricular septal defect and atrial septal defect) died within 48 hr of catheterization. Nonfatal complications occurred in 31 patients.

The most recent prospective study was from January to December of 1978 and included 155 neonates less than 28 days of age from the New England Regional Infant Cardiac Program.[108] Thirty-eight of the infants weighed less than 2 kg. Among the neonates, there were 10 deaths within 24 hr of the catheterization and a further nine of the survivors (6.2%) died within 48 hr of the catheterization. Death was attributed to the catheterization in only one patient who had transposition of the great arteries and who died after an embolus lodged in his left anterior descending coronary artery. The other deaths were due to inoperable lesions such as hypoplastic left heart, pulmonary disease, failed medical therapy, or postcatheterization surgical complications. Patients who were judged to be in the high-risk group had 10 times greater mortality than the patients in the low-risk group.

A prospective study performed in the last five years would probably show very few catheterizations of patients with inoperable cardiac lesions and few diagnostic catheterizations of patients with pure pulmonary problems.

However, the major risks of cardiac catheterization are probably the same now as they were in the earlier studies: cardiac perforation and tamponade; blood loss; failure to improve progressive hypoxemia, hypoxia, hypotension, acidemia, or depressed myocardial function; and thrombotic or traumatic occlusion of iliofemoral and brachiocephalic arteries.

Perforation of the heart has become less frequent; this may be due to the use of balloon-tipped catheters. It should be noted that manipulation of these catheters with the balloon deflated is more hazardous since the catheter tip is sharply tapered when the balloon is deflated.

Blood loss represents a more significant problem in neonates and small premature infants than in older infants and children. Blood withdrawal for arterial blood-gas measurement and oxygen saturations for green-dye curves present a cumulative blood loss that may have to be replaced. Using a percutaneous sheath with a bleed-back or hemostasis valve reduces blood loss during catheter exchanges.

Hypotension is common after angiography with ionic contrast material.[76] The degree and incidence of hypotension has been reduced with the introduction of nonionic contrast material in the past few years.[90] Subclinical dehydration may be present in neonates and premature babies because of diuretic administration, nonhumidified respirators, and blood sampling during the catheterization. The first angiogram may produce profound and progressive hypotension and bradycardia in an infant who is barely compensated for preexisting low blood volume. Atrial filling pressures should be checked before angiography; calcium chloride may have to be administered in infants who have had large doses of diuretics prior to the catheterization.

Arterial Complications

Since the introduction of the percutaneous sheath technique, major arterial complications have virtually disappeared.[73,112,113] Minor complications involving decreased femoral or peripheral pulses with pallor and coolness of the limb still occur, but this incidence has also been reduced by systemic heparinization during arterial catheterization.[112] Most of the problems from arterial cannulation improve within 24 hr and rarely does the patient need surgical embolectomy or arterioplasty. Recent reports have shown that the use of streptokinase or urokinase might be helpful in opening up occluded femoral arteries if 24 hr of systemic heparinization does not improve the circulation.[113] Femoral pulses may also be compromised if relatively large catheters are introduced via the umbilical artery. Trauma to the umbilical artery–iliac artery junction may occur or thrombi may accumulate at this junction when the catheter is passed into the descending aorta.

Embolic phenomena are rare and may occur at the same frequency in neonates as in older infants and children. There is a higher risk in children with right-to-left intracardiac shunts or those who are polycythemic. The overall incidence may be as high as 1 to 2%.

Other Complications

Arrhythmias

Transient supraventricular tachycardia, atrial flutter or fibrillation, ventricular tachycardia/fibrillation, and second- and third-degree heart block are the most common major and minor complications occurring during cardiac catheterization. Arrhythmias are usually transient and resolve spontaneously after withdrawal of the catheter stimulation. Fast ventricular rates are usually tolerated well by neonates and infants, except those with tetralogy of Fallot physiology, who become more cyanotic with tachycardia. Bradycardia on the other hand is less well tolerated by infants who rely on increasing heart rate to increase cardiac output. Recent digitalis administration is a risk factor for the development of atrial or ventricular tachycardia as well as third-degree heart block. Catheter manipulation is the usual precipitating cause.

Infections

Systemic infections are rare after cardiac catheterization, and bacterial endocarditis prophylaxis is not recommended in patients undergoing catheterization. Localized wound infections have virtually disappeared since the introduction of the percutaneous sheath technique. I recommend the administration of systemic broad-spectrum antibiotics in children being administered prostaglandin E_1 for as long as this drug is being administered.

SUMMARY

The indications for cardiac catheterization must be assessed in the context of the patient's problems and the information that is necessary to treat these problems. When clear information is not available from one source, other procedures should be used to obtain data pertinent to the clinical situation.

Cardiac catheterization should be used after taking into consideration the patient's problems, available equipment, the skills of the investigating physician and technicians, and the availability of positive therapy.

CHAPTER 56

Selective Coronary Arteriography in Children with Heart Disease

G Ali Massumi
Robert J Hall

IMPORTANCE OF SELECTIVE CORONARY ARTERIOGRAPHY IN CHILDREN AND ADOLESCENTS WITH HEART DISEASE

Selective coronary arteriography has been recognized as a major diagnostic tool in cardiology since its advent some three decades ago. In the past 20 years, this technique has found increasing application in pediatric cardiology. Selective coronary arteriography serves as a guide to identification of congenital heart disease[1] and identifies anomalies and disease processes of the coronary arteries in children and young adults. Advances in cardiac surgery and an increase in the incidence of Kawasaki disease are other factors leading to broader application of this diagnostic procedure. Preoperative knowledge of the coronary anatomy serves as a guide to appropriate surgical approach, especially when right ventriculotomy is anticipated. This is particularly important since intraoperative recognition and diagnosis of anomalous coronary arteries can be quite difficult. The presence of pericardial adhesions as a result of previous palliative intrapericardial procedures or intramyocardial course and distribution of a coronary artery makes such a distinction virtually impossible. Even when recognized, an anomalous coronary artery may limit the scope of ventricular incision, thus hindering the surgeon. Major complications with fatal consequences have been reported as a result of inadvertent severing of a vital coronary artery branch.[2]

Aortic root angiography is frequently inadequate in providing accurate diagnosis.[3] This becomes particularly important when the proximal left coronary artery is the focus of interest. Dense opacity caused by contrast material in the aorta and sinuses of Valsalva obscures the anatomy in this area, especially when left anterior oblique views are taken. The right coronary artery, however, may be adequately visualized by aortography.[4]

Selective coronary arteriography in children including various techniques and approaches has been reported. In 1969, G. Formanek[5] presented five patients between the ages of 6 and 11 years who were studied by selective coronary arteriography. Between 1974 and 1979, 238 patients were studied by Parenzan[6] with the youngest patient being 5 months old. In 1980, Dabizzi[7] reported selective coronary arteriography in 119 patients from 5 months to 26 years in age with tetralogy of Fallot. A. Formanek's[3] series of 12 patients between 3 weeks to 16 years in age was published in 1980. Takahashi[4] described his technique of selective coronary arteriography in 1983. He reported on 34 cases in patients aged 7 months to 18 years. Reported series from France appeared in 1975 by Chaumont,[8] and in 1985 by A.M. Worms,[9] who reported selective coronary arteriography in 47 children performed between 1977 and 1983 with the age range of 1 to 13 years.

INDICATIONS FOR SELECTIVE CORONARY ARTERIOGRAPHY

Definition of the coronary artery anatomy in congenital heart disease may establish precise identification and diagnosis of specific conditions. Selective coronary arteriography helps in recognition of atrioventricular connections (concordance or discordance), as well as positions of cardiac chambers and interventricular septum.[1]

Diagnosis of congenital coronary artery anomalies and malformations depends on proper anatomic information obtained by selective coronary arteriography. These coronary artery anomalies

include anomalies of origin, course, or both.[1–7,9] These anomalies vary from major malformations with very significant clinical implications, including anomalous origin of the left coronary from the pulmonary artery,[10,11] to minor anomalies with little or no clinical importance.

Preoperative selective coronary arteriography serves as an important guide for the cardiac surgeon in the design and safety of a planned procedure. Preoperative assessment and knowledge of the coronary artery anatomy is particularly important when the goal is surgical repair and correction of specific conditions such as tetralogy of Fallot, double outlet right ventricle, and complete transposition of the great vessels.[1–7,9]

Various acquired diseases of the coronary arteries constitute another indication for the performance of selective coronary angiography.[9] These conditions include Kawasaki disease,[12] especially in view of its increased incidence; hypercholesterolemia of the familial homozygous type; various forms of inflammatory arteritis; and others.

Evaluation of myocardial ischemia[9] in the presence of chest pain or an abnormal exercise-test response will require selective coronary arteriography. This diagnostic tool may be part of a complete evaluation of dysrhythmias with significant clinical implications. Assessment of cardiac tumors[9] and cardiomyopathies includes selective coronary arteriography.

Postoperative selective coronary arteriography is indicated in many clinical situations,[9] for instance, following surgical treatment of anomalous origin of the left coronary artery from the pulmonary artery. Various techniques have been employed in treating this coronary anomaly in patients who have survived the early period of their life.[13,14] Patency and results of direct implantation of the left coronary on the aorta when feasible or saphenous vein bypass grafting of the left coronary artery with ligation of the proximal coronary artery should be assessed by selective coronary or graft injection. Selective coronary arteriography will show that the marked increase in size of the right coronary artery and the extensive collateralization from the right coronary artery to the left coronary artery will be reduced substantially following successful surgery.[13] Table 56–1 summarizes the indication for selective coronary arteriography in this age group.

TECHNIQUE OF SELECTIVE CORONARY ARTERIOGRAPHY

The technique of selective coronary arteriography varies according to the age of the patient. Although selective coronary arteriography has been performed in patients as young as 3 weeks, it is rarely performed in those under 1 or 2 years of age in whom aortic root injection is used. Different approaches[6] have been used, including femoral, axillary, humeral, and brachial, utilizing either percutaneous or cutdown techniques. For smaller children under age 5, size 4 or 5 French catheters with or without tapered tip are used. Catheter tips are usually formed just before the procedure.[3] The diameter of the terminal curve of the catheter should correspond to the width of the ascending aorta.[5] For the left coronary artery, an Amplatz-like catheter with a short tip (less than 5 mm) is appropriate.[4] The curvature of the catheter must approximate that of the aortic root. The short tapered tip is utilized to avoid wedging or subselective injection. For the right coronary artery, an "L" configuration is used.[4] The length of the ascending aorta and the diameter of the patient's aortic root are important factors in the selection of catheters.[4] These dimensions were found to be related to the height, body surface area, and age of the patients. In larger patients, Sones or Judkins catheters sizes 5 to 7 French with appropriate tip sizes can be used.[9]

Table 56–1. Indication for Selective Coronary Arteriography in Children and Adolescents

1. Precise definition of coronary artery anatomy for the diagnosis of congenital heart disease.
2. Precise diagnosis of congenital coronary artery anomalies and malformations.
3. Preoperative definition of the coronary artery anatomy, especially in specific conditions such as tetralogy of Fallot.
4. Acquired diseases of the coronary arteries.
5. Evaluation of myocardial ischemia.
6. Evaluation of cardiac tumors.
7. Evaluation of cardiomyopathies.
8. Evaluation of major ventricular dysrhythmias.
9. Postoperative evaluation of the coronary anatomy.

Safe performance of selective coronary arteriography in children requires adequate sedation. Various agents including promethazine (Phenergan), meperidine (Demerol), chlorpromazine (Thorazine), and fentanyl (Innovar) have been used in smaller children. In older patients, diazepam (Valium) or midazolam HCl (Versed) may be used.[4,9]

The use of anticoagulation in the form of heparin at a dose of 100 IU/kg is recommended.[9] Heparin can be administered either intra-arterially or intravenously. Following completion of the study, anticoagulation may be reversed by the use of protamine sulfate. Although atropine and lidocaine are not used routinely in adult selective coronary arteriography, their use in children undergoing this test is probably appropriate. Atropine is recommended at a dose of 0.01 mg/kg.[4]

If percutaneous technique is employed, arterial entry is made in the usual manner. The arterial needle must accommodate at least a 0.25-in. wire. A Teflon-coated "J" tipped wire is recommended. The wire must be flushed before and after each use to reduce potential clot formation. Once the wire has reached the abdominal aorta, appropriate size sheath and dilator are introduced into the artery. Heparin at the recommended dose is administered. The catheter is then introduced over the wire into the ascending aorta. The wire must not meet any resistance as it is traveling into the aorta. The operator should make every effort to minimize the time that a wire is in the arterial system. Following removal of the wire, blood is aspirated, and the catheter is connected to the manifold system. Arterial blood pressure is checked to confirm that the catheter tip is in the true lumen of the artery. A small test dose injection of the contrast material also will demonstrate that the catheter has not created a false channel. The closed manifold system is maintained at all times to obviate the need for removing the syringe and to decrease the inadvertent introduction of air emboli. The operator should not allow the catheter tip to engage into the aortic arch vessels as it is being advanced into the ascending aorta.

The catheter should be moved slowly and cautiously with constant monitoring of the blood pressure curve. For the left coronary artery cannulation, the LAO view provides easier recognition of the ostium of the coronary artery. The catheter is gently maneuvered into the left coronary sinus. The tip is guided upward toward

the left coronary ostium. Once the catheter is felt to be in the proper position, a very small test dose is given. This not only demonstrates proper catheter position, but also shows free flow and rapid clearance of the contrast material, proving that the catheter is not "wedged" and that injection can be made safely. The lumen of the catheter should be filled with contrast material at all times. Blood must not be allowed to back up into the catheter or the manifold. Once appropriate positioning of the catheter and free flow of the contrast material are ensured, injection is made, using adequate pressure to deliver the contrast material in a uniform fashion. Interrupted or weak injections are to be avoided. The duration and amount of injection depend on the size of the artery and the patient. An adequate injection spans three or four cardiac cycles. The right coronary artery is then approached, using a proper size catheter. The LAO view is a suitable view to start. If the catheter is moving freely, a gentle clockwise rotation will facilitate entry into the right coronary artery.

Careful monitoring of cardiac rhythm and hemodynamics is essential for the performance of safe selective coronary arteriography. Continuous pressure monitoring through the tip of the catheter except during injection of contrast material is mandatory. Such pressure monitoring will allow the operator to be aware of any "wedging" of the catheter into the coronary artery due to either mismatch of catheter size and coronary artery diameter or the presence of ostial narrowing. Frequently, subselective engagement of the catheter tip into a branch other than the main orifice of the coronary artery may be the cause of a pressure drop, as recorded by the catheter tip. This could prove to be a cause of potentially serious complications. The operator should ensure the presence of an air-free system, utilizing all precautions and proper procedure to avoid introduction of air emboli into the arterial system.

The dosage of contrast material injection and the number of injections[4] must be kept to a minimum without sacrificing the quality of the study. This goal can be achieved by the proper choice of angiographic views. Biplane coronary angiography utilizing appropriate angulations will limit the number of injections. Choice of a contrast agent depends on the operator's preference. Low osmolality ionic (ioxalate) or nonionic (iopamidol or iohexol) contrast media with adequate iodine concentration for better visualization is recommended.

In children, the number of angiographic positions and views used are fewer than in adults. Two LAO views (40 to 70°) of the left coronary artery, one of these in a cranial angulation, and a 30° RAO will be sufficient in most cases. The right coronary artery is imaged in LAO and RAO views.

PROBLEMS AND COMPLICATIONS

Difficulties and problems that may be encountered during the course of or following selective coronary arteriography are variable and secondary to a number of factors.[3–5,9] Arterial spasm, either in the brachial-axillary artery or the femoral artery, may lead to difficulty in manipulating the catheter and is uncomfortable for the patient. Once the catheter is in the ascending aorta, improper catheter size, configuration, or length of the catheter tip will impose difficulty in selectively engaging the coronary artery ostium. Caliber of the vessel in relation to the caliber of the catheter should be carefully noted. A catheter that is too large in diameter compared to the artery that is being cannulated will not only result in "wedging" of the catheter tip, but may prevent selective engagement altogether. A common pitfall that must be avoided while performing selective coronary arteriography is that of overlooking separate ostia. A conus branch occasionally has a separate ostium from that of the right coronary artery. In tetralogy of Fallot, the coronary ostia may not be where expected and are located in a more anterior-posterior position.

Complications associated with selective coronary arteriography in children and adolescents range from relatively minor to fatal.[3–5,9] The occurrence of a localized hematoma or bleeding is the same as with any arterial catheterization and should be minimized by using proper techniques. Arterial complications including occlusive thrombosis or dissection may require surgical intervention. Hypotension, which is usually transient, can be corrected with infusion of fluids, and will rarely require use of vasopressors. Arrhythmias including ventricular fibrillation or bradyarrhythmias may be noted, and appropriate forms of treatment must be readily available. A most serious complication is dissection or laceration of a coronary artery. This could happen as a result of inadvertent advancing of the catheter tip, resulting in injection of contrast material into the wall of the artery or one of the smaller branches. If a catheter has wedged into a branch and injection is made forcefully, dissection will easily develop. Abrupt movement by the patient is another factor that may lead to dissection. The operator must avoid excessive penetration of the catheter into the coronary arteries and should not allow the tip of the catheter to reach bifurcating or dividing positions. When retracting a catheter, especially if Amplatz-type curve is used, cautious practice requires this to be done under fluoroscopy, since the catheter tip tends to advance for a distance with the tip "scratching" the intima of the coronary artery as the catheter is being withdrawn. Death has been reported[3] due to a major coronary artery dissection.

CONGENITAL ANOMALIES OF THE CORONARY ARTERIES IN SPECIFIC CONDITIONS

Selective coronary arteriography is particularly indicated when surgical correction is planned. The results of surgery not only depend on the functional abnormalities involved, but also on the presence of certain unfavorable anatomic and coronary features. The course and distribution of the coronary arteries should be known prior to surgery to prevent division of an aberrant vessel. Since anomalous and aberrant coronary arteries are frequently undetectable during surgery, the inadvertent division of a large coronary branch during right ventriculotomy often results in major problems and even death. A vessel may be obscured by epicardial fat or by pericardial-epicardial adhesions from previous surgery, or by assuming an intramyocardial course. The possibility of serious complications is reduced when the preoperative coronary anatomy is known. Even with such information, the surgical approach cannot always be free of hazards. The distribution of the coronary arteries over the anterior surface of the right ventricle is of particular importance when surgery is anticipated.

Selective Coronary Arteriography in Patients with Tetralogy of Fallot and Double Outlet Right Ventricle

The true incidence of coronary anomalies in tetralogy of Fallot is not firmly established. Reported frequency of coronary anomalies varies according to the method of study. Four different meth-

ods have been used to assess the incidence of coronary anomalies in tetralogy of Fallot: 1) intraoperative inspection,[15] 2) necropsy examination,[16,17] 3) aortography or ventriculography,[18] and 4) selective coronary angiography.[7]

Various series[15,19–22] including a large series of 1,400 cases[15] are reported from 1959 to 1975. The incidence of a coronary anomaly detected at the time of surgery varied between 2 and 19%. When the anterior descending coronary artery originated from the right coronary artery, a 30% mortality due to myocardial infarction was reported in the series by Berry.[15] His series showed a 2% incidence of coronary anomaly detected intraoperatively.

Incidence of coronary artery anomaly at necropsy was found to be between 4 and 9%.[16,17]

A 6 to 12% incidence of coronary anomalies has been found when angiographic data have been utilized.[7,18]

In 1980, Dabizzi[7] reported on 119 patients with tetralogy of Fallot. All patients had selective coronary arteriography. A 9% incidence of major anomalies and a 19.3% incidence of a large conus branch were found. McManus et al.[23] looked at the combination of all methods and found a 3% overall incidence of anomalous coronary arteries.

The most important coronary artery anomalies in tetralogy of Fallot, as determined by various methods of detection,[15,23] are listed in Table 56–2.

In double outlet right ventricle, the origin of the anterior descending coronary artery may be from the right coronary artery.[24]

Complete Transposition of the Great Arteries

Anomalies of the coronary arteries in complete transposition have been described by several authors.[25,26] Coronary artery anatomy in complete transposition has multiple patterns.[27] The most common variations are

1. Origin of the left coronary artery from the left sinus and the right coronary artery from the posterior sinus.
2. Origin of the right coronary artery and the left circumflex from the posterior sinus and the anterior descending from the left sinus.
3. Single coronary artery from the posterior or left sinus.

In congenitally "corrected" transposition, the coronary arteries are inverted compared to normal. Accurate knowledge of the coronary arterial tree is important when a Mustard, Rastelli, or any other procedure is planned. Various surgical injuries to a major coronary artery branch have been described.[28] The presence of pericardial fibrosis from previous surgery may further obscure the anatomy, especially if an incision has to be made in the anterior surface of the right ventricle. Inadvertent ligation, occlusion or division of a major coronary artery can happen during a Rastelli procedure. Lesions of the sinus node artery in complete transposition undergoing Mustard procedure have been noted, resulting in sinus node dysfunction. Preoperative selective coronary arteriography is recommended to decrease the incidence of surgical trauma to a major coronary artery branch.

Table 56–2. Coronary Artery Anomalies in Tetralogy of Fallot

1. The anterior descending artery originating from the right coronary artery or the right sinus of Valsalva.
2. Single coronary ostium, either single left coronary or single right coronary.
3. The left circumflex origin from the right coronary artery.
4. The presence of a large conus branch, which should be differentiated from the anterior descending artery. This is a frequent finding in tetralogy of Fallot, probably as a response to right ventricular hypertrophy.
5. Fistulas between the coronary arteries and the pulmonary artery or the right atrium.
6. Connections between coronary and bronchial arteries.
7. Right coronary artery from the pulmonary trunk.
8. Hypoplastic coronary arteries.
9. Separate origin of the conus artery from the aorta.
10. Complete intramyocardial course of the anterior descending artery (7% of all cases).

Anomalous Origin of the Left Coronary Artery from the Pulmonary Artery

The anomalous origin of the left coronary artery from the pulmonary artery was first described in 1908.[29] The clinical course of this anomaly depends on the presence and development of collateral circulation. In the majority of patients, symptoms appear in the first few months of infancy and result in myocardial infarction, congestive heart failure, or death.[13] However, patients with extensive collateral circulation will reach adulthood and may even lead an asymptomatic, normal life. Selective coronary arteriography reveals the presence of a large right coronary artery, which supplies extensive collateral circulation to the left coronary artery (Figs. 56–1 and 56–2).

The left coronary artery, which drains into the pulmonary artery, is visualized with the injection of contrast material into the right coronary artery. Corrective surgery, whether direct implantation

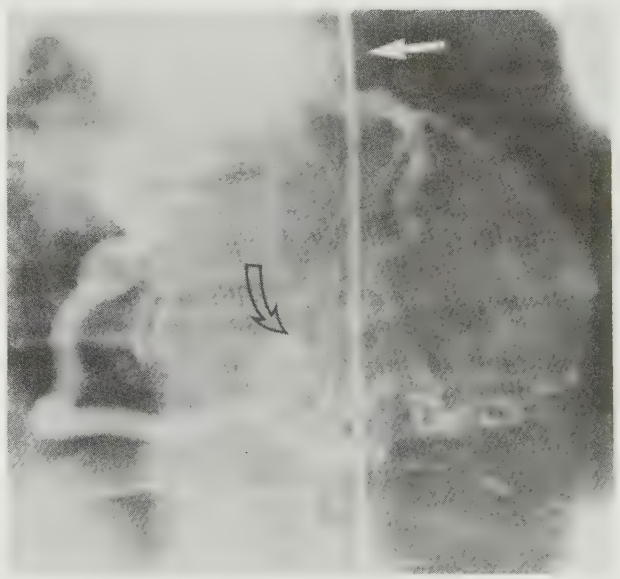

Fig. 56–1. Selective injection of contrast material into the right coronary artery showing a very large and redundant vessel opacifying the left coronary artery through collaterals (black arrow). White arrow visualizes the attachment of the left coronary artery to the pulmonary artery.

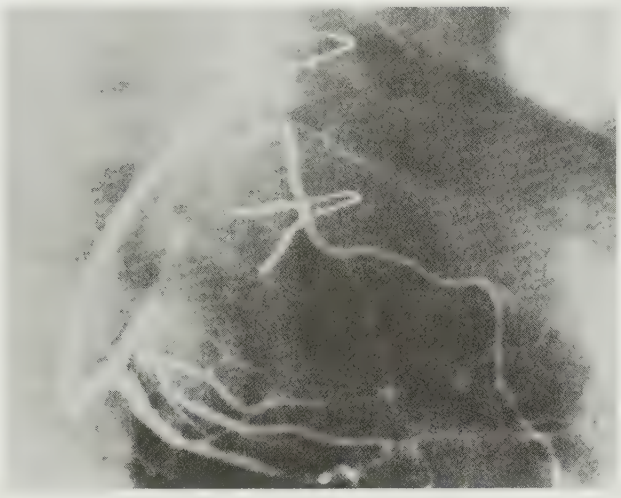

Fig. 56–2. Selective right coronary arteriography reveals marked decrease in size and redundancy of this vessel. No collaterals to the left coronary artery are visualized.

of the left coronary artery on the aorta or bypass grafting, will result in gradual normalization of the right coronary artery size and angiographic disappearance of the collateral vessels (Fig. 56–3).

ACKNOWLEDGMENT

We would like to thank Carol J. Latta, M.A., for her assistance in the preparation of this manuscript.

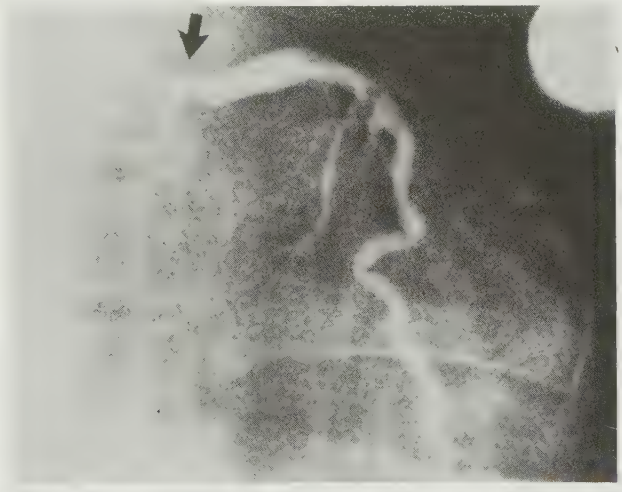

Fig. 56–3. Selective coronary arteriography shows patent and smooth implantation site (arrow) with normal left anterior descending and circumflex arteries.

CHAPTER 57

Peripheral Vascular Angiography

Mark D Skolkin

The first radiographic demonstration of a human blood vessel was obtained in 1896, only months after the discovery of x-ray energy by Wilhelm Conrad Roentgen.[1,2] Since that time, countless evolutionary steps have resulted in the highly sophisticated field of peripheral vascular angiography as we know it today. Perhaps the most significant contribution was the introduction of percutaneous transfemoral catheterization by Seldinger in 1953.[3]

Image-intensified fluoroscopy, mechanical contrast injectors, and high-speed film-screen combinations that allow the acquisition of at least three films per second are basic requirements of the imaging suite. Small-focal-spot x-ray tubes (0.1 to 0.3 mm in diameter) are essential for the performance of high-quality magnification radiography and for imaging small vessels in sharp detail.

Digital subtraction angiography (DSA) is a technique by which images taken prior to contrast injection are electronically subtracted from those acquired after administration of a contrast bolus so that only vascular structures are displayed. The major advantage of DSA in comparison with conventional film angiography is its increased contrast sensitivity. Conventional angiography requires a contrast concentration of approximately 40 to 50% within a blood vessel to obtain a satisfactory image, while DSA requires only 2 to 3%.[4] Major drawbacks to the technique are decreased spatial resolution with resultant loss of image detail and degradation of the image by respiratory, peristaltic, cardiovascular, or voluntary motion.

Intra-arterial DSA is performed in the same manner as conventional film angiography. However, only one-fifth to one-third the amount of contrast material is necessary. Intravenous DSA usually requires the placement of a central venous catheter and injection of approximately 1 mL/kg of body weight of contrast material for each run—a considerable increase over conventional intra-arterial angiography for most studies. Therefore my colleagues and I rarely use intravenous DSA, with notable exceptions being the study of central veins and use in patients in whom arterial access cannot be obtained.

State-of-the-art radiographic equipment can produce excellent images only in relatively motionless subjects. For this reason, we prefer to use general anesthesia in all children less than 10 years of age; older children are evaluated for use of local versus general anesthesia on an individual basis.

In the first 2 weeks of life, the umbilical artery may be recanalized for the performance of peripheral vascular studies, particularly in the investigation of congestive heart failure related to neonatal hepatic masses. Injection of contrast through umbilical artery catheters, which are used to monitor critically ill neonates, is helpful in detecting complications related to their placement, including thrombosis, embolism, or aneurysm formation. Needles and basic guidewires used in femoral artery catheterization are shown in Figures 57–1 and 57–2. My colleagues and I perform the puncture with a 21-gauge Argon needle (Argon Medical Corp., Athens, TX) in children under 4 to 5 years old. This needle will allow introduction of a 0.021-in. Teflon-coated guidewire into the femoral artery, over which graduated dilation of the puncture site with 20- and 18-gauge intravenous cannulae (Argyle Medicutt, Tullamore, Ireland) is performed. In older children, an 18-gauge thin-walled needle (Cook Company, Bloomington, IN) is used, through which a 0.035-in. guidewire is threaded.

Catheter shapes routinely employed in our department are shown

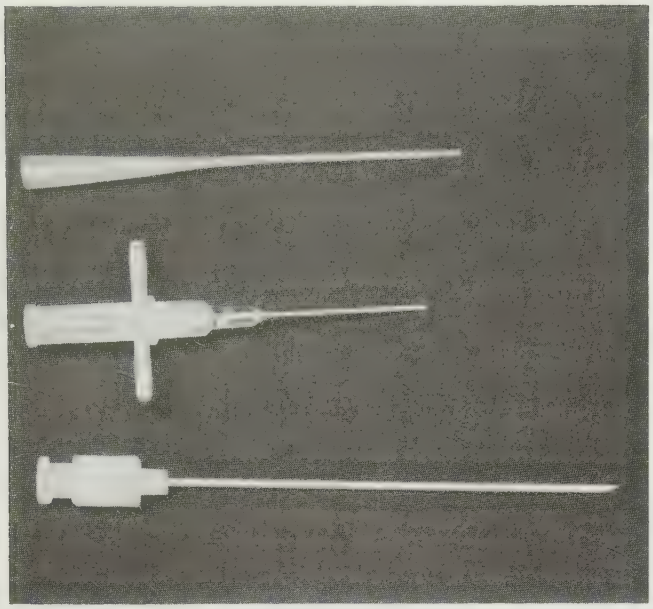

Fig. 57–1. Needles and cannulae used in femoral puncture. Top to bottom: intravenous cannula (18- and/or 20-gauge), 21-gauge Argon needle, 18-gauge thin-walled needle.

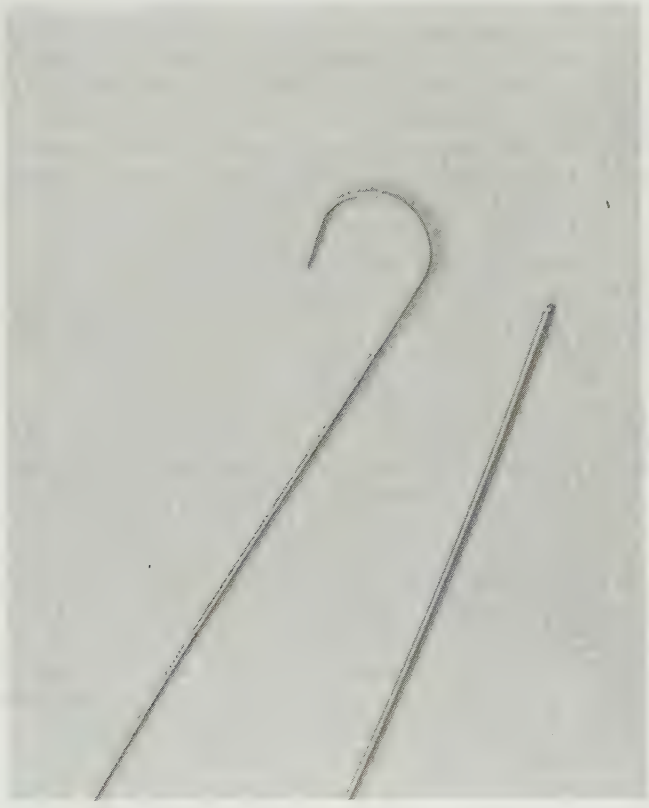

Fig. 57–2. Basic guidewires. Left: J-shaped guide; the radius of curvature is commonly 1.5, 3.0, or 15.0 mm. Right: straight guide.

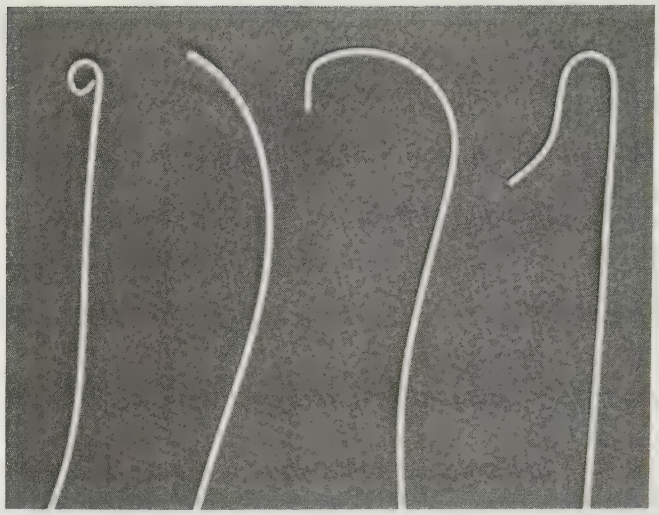

Fig. 57–3. Basic catheter shapes. From left to right: pigtail, simple curve, cobra, reverse curve (shepherd's crook).

in Figure 57–3. The smallest catheter that can accomplish the objectives of the study is chosen. For aortography 4 or 5 French pigtail catheters are appropriate; simple curve, cobra curve, or reverse-curve shapes are suitable for selective catheterization. Approximate contrast injection and filming rates are listed in Table 57–1.[5,6]

Radiographic contrast agents are water-soluble triiodinated benzoic acid derivatives. The recently introduced low-osmolality agents exist in both ionic and nonionic forms; osmolality is approximately one-half that of conventional compounds at the same iodine content (Table 57–2).[7] Theoretically, lower osmolality should decrease fluid shifts and other cardiovascular side effects. However, existing clinical data are unclear on this point as well as on the relative incidence of allergic-type reactions and nephrotoxicity.[8–10] A reported disadvantage of these newer compounds is their poor anticoagulant action, which necessitates frequent flushing of the catheter to prevent the formation of small thrombi.[11,12]

Embolic agents most frequently used in our department are gelfoam, polyvinyl alcohol foam (Ivalon), and stainless steel coils. Gelfoam is supplied in a sheet-like sponge, which may be cut into pledgets approximately the size of the vessel. Occlusion is usually temporary. Permanent occlusion may be achieved with Ivalon (particles and pledgets) or coils. A further discussion on occlusive materials and techniques may be found in Chapter 85.

Angiography is contraindicated in children in whom diagnosis and therapy can be based on information obtained noninvasively. It should be avoided in the ecchymotic subgroup of Ehlers–Danlos syndrome, as arterial rupture may occur from seemingly minor catheter or guidewire trauma.[13,14] Patients in the other four subgroups of this disorder may be approached carefully; up to four arteriographic studies have been reported in a patient with the mild variety without sequelae.[15] Studies in individuals with homocystinuria are relatively contraindicated because of the possibility of arterial thrombosis.[16,17]

The risks of catheterization for the purpose of peripheral vascular studies are small, particularly when performed by an experienced pediatric angiographer. The most common untoward effect is transient spasm at the femoral puncture site, with devel-

Table 57–1. Approximate Contrast Dosages and Filming Rates

	Contrast Dose in ml					
	10 kg	*10 to 20 kg*	*20 to 40 kg*	*40 kg (in ml/kg)*	*Injection Duration (sec)*	*Filming Rates (Films per sec/ no. of sec)*
Aorta, arch	8–15	15–30	25–50	0.8–0.9	2.0	3/2:1/4

Inferior mesenteric	3–7	5–10	10–20	0.4	5.0–6.0	2/5:1/5:0.5/10

*0.5/10 represents one film obtained every other second over a 10-sec period. Adapted from Kirks et al.[5] and Stanley and Miller.[6]

opment of a pale, cool lower extremity; peripheral pulses are usually not palpable. At our institution, children who develop this side effect are approached conservatively. The involved extremity is kept warm, and systemic heparinization is initiated at a dose of 75 to 100 units/kg, which is given as an intravenous (IV) bolus. The partial thromboplastin time is maintained at approximately two times normal, with IV heparin given every 4 to 6 hours, and peripheral circulatory status is monitored with Doppler ultrasound. Surgical exploration of the femoral artery is rarely necessary, as most pulses return to normal within 24 hours.

Thrombosis at the arterial puncture site is less commonly observed since the advent of smaller catheters and refinement of percutaneous catheterization techniques. There may be an association between thrombosis and subsequent growth retardation of the lower extremity, particularly when it occurs at an early age.[18,20]

Children with coagulopathies or severe hypertension are at risk for bleeding from the puncture site. Clotting disorders should be corrected before arteriography is performed. Pharmacologic control of blood pressure is important in hypertensive children, particularly when large catheters are used to perform renal angioplasty.

Adverse effects of contrast injection include renal insufficiency, congestive heart failure, and allergic-type reactions. Contrast-induced renal dysfunction is most likely to occur in the setting of preexisting renal disease or concomitant administration of a nephrotoxic drug. Contrast toxicity can generally be avoided by limiting the volume to a maximum of 4 mL/kg of body weight and ensuring good hydration. Allergic reactions range from mild urticaria to life-threatening cardiovascular collapse and are more common in children with a history of asthma. Individuals with a documented mild reaction to contrast media may be premedicated with diphenhydramine (Benadryl) in a dosage of 5 mg/kg intramuscularly 30 min before the study.[21] If the reaction is severe, every attempt should be made to obtain the desired information noninvasively, using computed tomography, ultrasound, and/or magnetic resonance imaging. As a last resort, angiography with one of the newer low-osmolarity contrast agents and following pretreatment with prednisone (2 mg/kg daily for 3 days) may be performed.

Risks of transcatheter embolization, vasopressin infusion, and balloon dilatation are discussed later in the chapter.

Table 57–2.

Contrast Agent	*Iodine Content (mg/mL)*	*Osmolality (mOsm/kg H_2O)*

THORACIC AORTA—GENERAL CONSIDERATIONS

The thoracic aorta and great vessels are the product of fusions and regressions of the paired dorsal aortae and aortic arches. A detailed embryologic discussion of this process can be found elsewhere.[22] The "normal" aortic arch courses posteriorly and to the left at the level of the fourth thoracic vertebral body, giving rise to the brachiocephalic, left common carotid, and left subclavian arteries. The most prevalent variation is a common origin of the brachiocephalic and left common carotid vessels, which occurs in nearly one of four individuals. Direct origin of the left vertebral artery from the aortic arch rather than from the subclavian artery occurs in up to 6% of the general population.[23] Discussion here of abnormalities of the thoracic vasculature will be limited to Takayasu's arteritis, systemic arteries to the lung (bronchopulmonary sequestration and bronchial arteriography), aortic trauma, and structural diseases that result in aortic aneurysm; thoracic aortic coarctation and complex cardiovascular disorders that involve the aorta are covered in other chapters.

Takayasu's Arteritis

Takayasu's arteritis is a granulomatous giant-cell arteritis of the aorta and its large branches, which contain abundant mural elastic fibers. Pulmonary arterial involvement has been reported in 50 to 80% of cases.[24] Pathologically, there are transmural inflammatory alterations that are most pronounced in the intima, where marked thickening and fibrosis is found.

Takayasu's disease is found worldwide, although it is more prevalent in Southwest Asia, Japan, and Africa. It occurs most frequently in women (80 to 90% of the reported cases) in the second and third decades of life.[25,26] Two clinical phases are recognized. In the acute phase, patients often complain of constitu-

tional symptoms (fever, fatigue, malaise, anorexia) and migratory large-joint arthritis. These symptoms typically diminish over several weeks. The chronic phase is manifest months to years later, with cardiovascular and neurologic symptomatology. Hypertension and decreased carotid and upper extremity pulses and bruits in the neck and abdomen are commonly found on physical examination. Both right- and left-sided heart failure may occur and are related to pulmonary arterial or systemic hypertension, aortic insufficiency, and/or myocarditis.

Cardiomegaly and contour irregularity of the aortic arch and descending thoracic aorta with areas of dilatation or frank aneurysm formation may be found on chest roentgenography.[27] Angiography remains pivotal in establishing the diagnosis of Takayasu's disease. In most individuals, arterial DSA of the aortic arch in the right posterior oblique projection and abdominal aorta in the anteroposterior and lateral projections is performed. Evaluation of the pulmonary circulation should also be performed. In individuals unable to cooperate fully or with large amounts of bowel gas, biplane conventional angiography of the thoracic and abdominal aortae is appropriate.

Stenoses are the most common angiographic feature and vary from smooth, concentric to irregular, eccentric lesions.[28] Prestenotic and poststenotic aneurysms, luminal contour irregularity, and branch artery occlusions are commonly observed (Fig. 57–4). Well-recognized collateral pathways circumvent foci of narrowing or occlusion. The arteries most frequently affected are the left subclavian (in 85 to 95% of cases), renal (75%), abdominal aorta (greater than 50%), pulmonary (greater than 50%), superior mesenteric, thoracic aorta, brachiocephalic, left carotid, and celiac.[26,28] Stenoses of the great vessels and visceral arteries usually occur at or just distal to their origins. Long-segment fusiform stenosis of the descending thoracic and midabdominal aortae rarely progress to total occlusion; the inferior mesenteric artery may become markedly enlarged in the latter instance (see Fig. 57–9).

A firm diagnosis of Takayasu's arteritis can be established in the great majority of cases by integration of the angiographic and clinical pictures. Isolated renal arterial stenoses, however, are difficult to differentiate from those related to neurofibromatosis, fibromuscular dysplasia, and other vasculitides.[27]

Prognosis in this disease is guarded, with a tendency toward chronicity and gradual deterioration.[29] Death is most frequently attributable to heart failure or cerebral complications. The current mainstay of therapy is oral prednisone; intravenous cyclophosphamide has proven beneficial in some cases.[26,30]

Surgical bypass may be performed in individuals in whom severe steno-occlusive lesions result in unacceptable limitation of function or are life threatening. Failure of this procedure may ensue, however, when progressive arteritis produces stenosis at or adjacent to the proximal or distal anastomoses. Recently, percutaneous transluminal dilatation of stenoses has been performed with encouraging results. Renal angioplasty in this disease will be discussed later in this chapter. Carotid, mesenteric, and subclavian lesions have also been successfully dilated.[31] Transluminal dilatation, even if unsuccessful, rarely precludes subsequent operative intervention.

Bronchopulmonary Sequestration

Bronchopulmonary sequestration is a relatively rare developmental abnormality that results in a cystic mass of nonfunctioning lung tissue that lacks normal communication with the tracheo-

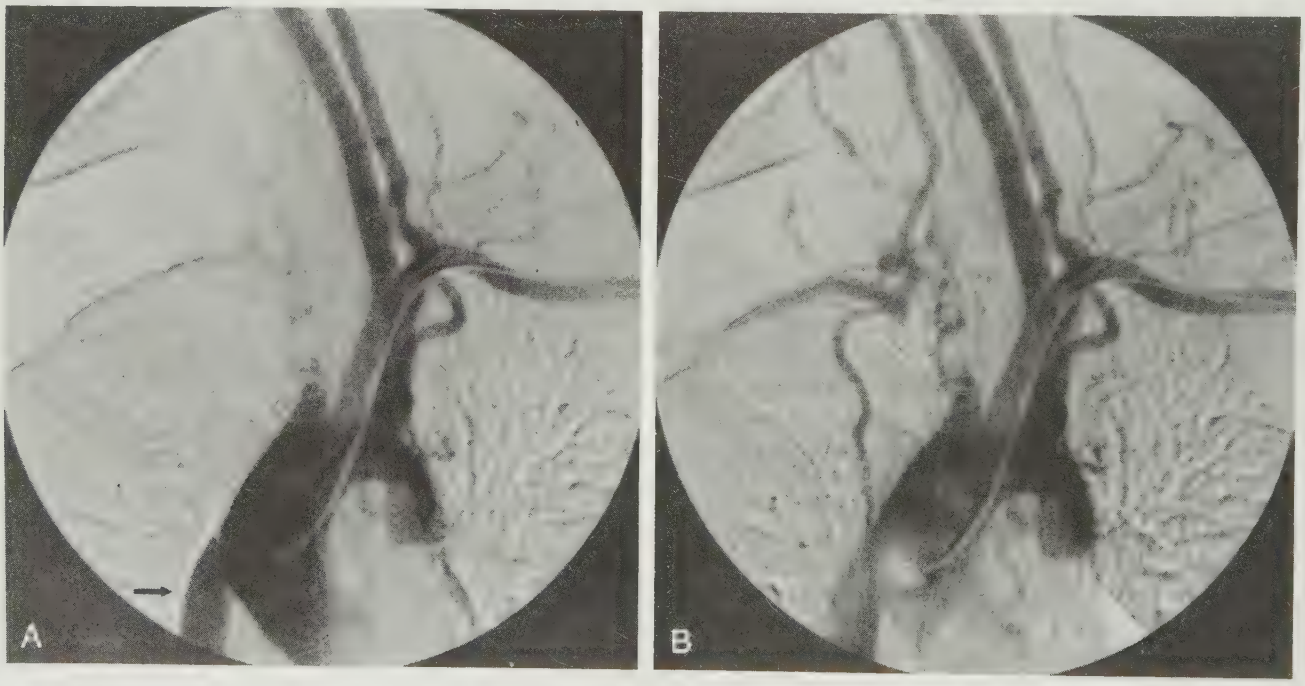

Fig. 57–4. DSA of 16-year-old with Takayasu's disease. (A) Early arterial phase with occlusion of the brachiocephalic artery just distal to its origin and the proximal descending thoracic aorta and marked enlargement of the left vertebral artery. Note graft projected to the right of the ascending aorta (arrow), which is anastomosed distally to the abdominal aorta. (B) Late arterial phase. Retrograde flow down the right vertebral artery has resulted in a "subclavian steal" phenomenon. Enlargement of the internal mammary arteries to supply collateral flow to the lower extremities is also seen.

bronchial tree and receives all or most of its blood supply from anomalous systemic arteries. The more common form of this entity is the intralobar variety, in which the sequestered lung is invested within the visceral pleural lining of the normal adjacent lung. There is a predilection for the lower lobes, although the lesion may be found in the upper lobes[32] or, rarely, bilaterally.[33] It is frequently discovered during the investigation of recurrent pneumonia. In a review of nearly 400 cases, aberrant arteries from the thoracic and abdominal aortae were observed in 74% and 19% of cases, respectively.[34] Pulmonary venous drainage has been reported in more than 95% of cases.[35]

In the extralobar form, the sequestration is contained in a separate pleural envelope, which isolates it from the adjacent lung. Associated complex congenital anomalies are present in up to 50% of cases.[34,35] Descending thoracic (46%) and abdominal (32%) aortic, as well as pulmonary (5%) and intercostal (4%) arterial blood supply was noted in the series of Savic et al.[34] Venous return is usually via systemic veins (particularly, the azygous and hemiazygous systems), although pulmonary or dual pulmonary and systemic venous drainage may be observed infrequently.

Chest roentgenography reveals a solid or cystic-appearing soft-tissue mass. Computed tomographic examination will better define its relation to the mediastinum and surrounding lung; visualization of the anomalous artery on contrast-enhanced studies has been reported.[36,37] Thoracic aortography with subsequent selective injection of the feeding vessel remains the procedure of choice in the presurgical evaluation of these children (Fig. 57–5). Filming is always carried out to the venous phase, which generally occurs quite rapidly, with frank arteriovenous shunting in some cases. The feeding artery averages 6 to 7 mm in diameter; multiple vessels are present in at least 15% of cases.[34] Definitive angiographic distinction between intralobar and extralobar varieties is not possible in some individuals because of the overlap in venous drainage patterns. We do not routinely perform pulmonary arteriography;

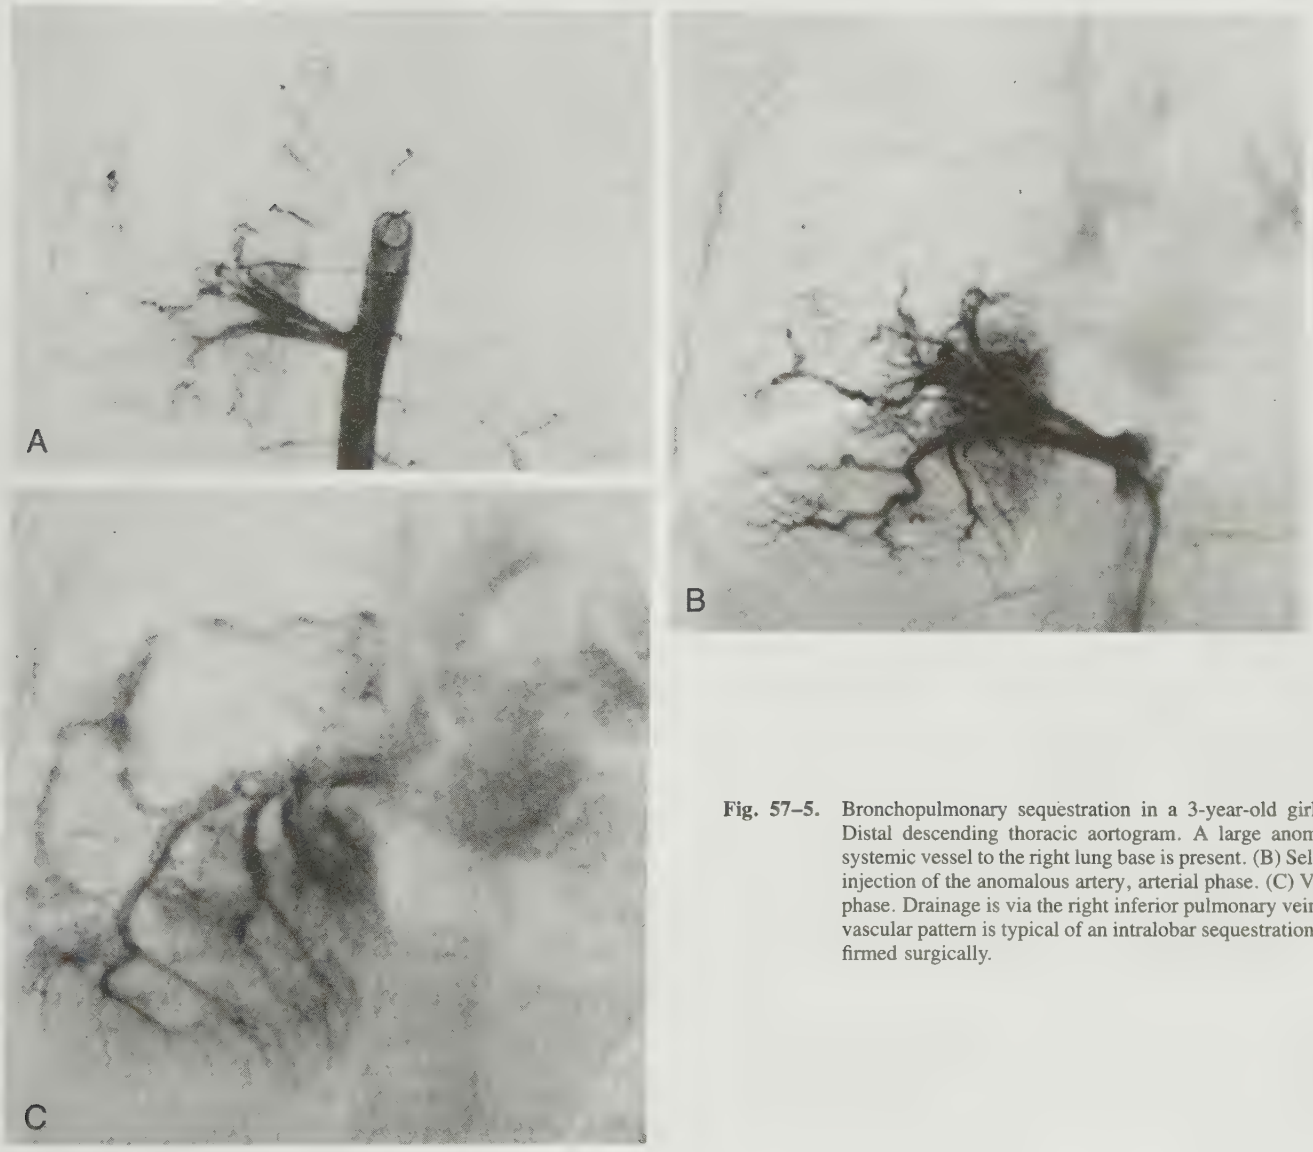

Fig. 57–5. Bronchopulmonary sequestration in a 3-year-old girl. (A) Distal descending thoracic aortogram. A large anomalous systemic vessel to the right lung base is present. (B) Selective injection of the anomalous artery, arterial phase. (C) Venous phase. Drainage is via the right inferior pulmonary vein. The vascular pattern is typical of an intralobar sequestration, confirmed surgically.

however, it is of potential benefit in the few cases in which the systemic vasculature does not appear to supply the entire soft-tissue or cystic mass.

Treatment of this entity is segmental or lobar resection, and prognosis is excellent. Untreated cases run the risk of recurrent pneumonias, hemorrhage, or, rarely, congestive heart failure secondary to arteriovenous shunting.

Bronchial Arteriography and Embolization

Massive hemoptysis (more than 300 mL of blood in a 24-hr period) in patients with advanced pulmonary disease of cystic fibrosis results from erosion of enlarged bronchial arteries found in areas of bronchiectasis and is potentially a life-threatening problem.[38] Resection of the bleeding segment is not optimal in these patients with limited pulmonary reserve, neither is it always possible to localize the bleeding site preoperatively by bronchoscopy or radionuclide studies.[39] Transcatheter embolization offers the advantages of prompt cessation of bleeding and commencement of vigorous pulmonary physical therapy within 24 to 48 hr.[40]

Bronchial arteries are quite variable in number and position but usually arise from the anterior or anterolateral aspects of the descending thoracic aorta just distal to the origin of the left subclavian artery. The most constant vessel is the intercostobronchial trunk to the right upper lobe. Care must be taken in occluding this vessel as it is known occasionally to supply radicles to the anterior spinal artery.[41]

Arterial DSA of the descending thoracic aorta is first performed to localize the enlarged bronchial arteries, which are subsequently selectively catheterized. Use of low-osmolarity contrast agents decreases the urge to cough due to bronchial irritation and limits potential neurotoxicity if arteries to the spinal cord are present.

The most commonly observed angiographic feature is the presence of bronchial-to-pulmonary-artery shunting (Fig. 57–6); it is quite unusual to demonstrate active extravasation.[40] We occlude all enlarged bronchial arteries in which a catheter can be well seated; a reverse-curve shape has been the most effective for this purpose. Injection of small particles of gelatin (e.g., gelfoam) pledgets is terminated when stagnant flow in the vessel is achieved. Ethanol should not be used, as it causes intense pain and carries the risk of bronchial necrosis and injury to the spinal cord.[42] The postembolization syndrome consists of temperature to 101°F for 24 to 72 hr and chest-wall pain, which is probably related to occlusion of small mediastinal and intercostal arteries.[40] Massive hemorrhage is arrested quickly in the vast majority of children. However, the incidence of rebleeding is high, and approaches 50% at our institution within the first year. Repeat embolizations are performed as deemed clinically appropriate; we have followed patients for up to 8 yr with this approach. The nonbronchial systemic arteries of the lung become increasingly important with each procedure, particularly branches of the subclavian, axillary, intercostal, and phrenic arteries.[43,44] Care must be taken to ensure that, if the posterior intercostal arteries and thyrocervical trunk are to be sacrificed, they do not supply the spinal cord.

Aortic Trauma

Survival after blunt trauma to the thoracic aorta and great vessels hinges on an aggressive approach to the diagnosis and treatment of these injuries. Emergent thoracic aortography should be performed on patients who have evidence of a mediastinal hematoma on chest roentgenography after a deceleration injury, severe fall, or crushing blow to the chest.[45]

The examination is performed from a femoral artery approach, with a J-shaped guidewire placed into the ascending aorta, over which a pigtail catheter is threaded. Adverse effects of traversing an aortic injury from below are rare as long as the wire is redirected if it appears to get caught on an intimal flap and if power injection of contrast is never performed at the site of suspected transection.[46] Two views of the aorta, preferably the right posterior oblique and anteroposterior or left posterior oblique projections, are obtained. The pigtail catheter is always straightened with a wire before being retracted through an aortic laceration. High-quality intra-arterial DSA is adequate to rule out an aortic injury[47]; conventional angiography should be performed in patients who are unable to cooperate fully or in clarifying any possible abnormality found on DSA.

Classically, transection occurs at the aortic isthmus, which is located just distal to the left subclavian artery. Injuries of the ascending and descending thoracic aorta and origins of the great vessels are observed infrequently.[45,48] Arteriographically, transection usually manifests as a false aneurysm or intimal flap at the aortic isthmus (Fig. 57–7). Rarely, extravasation is observed. Care must be taken not to confuse a ductus diverticulum with an acute injury; the former is recognized by a smooth transition with the adjacent aorta and no evidence of intimal disruption.

Children with penetrating injuries to the thoracic aorta and brachiocephalic arteries typically are taken directly to surgery, without angiographic evaluation. In the largest series in the literature, only 1% of patients had angiography before surgical exploration.[49]

Aortic Aneurysms

Aortic aneurysms are most frequently related to structural weakness of the aortic wall as in the Marfan or Ehlers–Danlos syndromes, or are inflammatory (mycotic) in origin. Marfan syndrome is inherited as an autosomal dominant trait or occurs as a spontaneous mutation. The predominant clinical features are arachnodactyly, lens dislocations, and cardiovascular abnormalities. The primary defect is abnormal collagen synthesis with resultant cystic medial necrosis of the ascending aorta and aneurysm formation, dilatation of the sinuses of Valsalva, and/or aortic regurgitation. The central pulmonary arteries may enlarge diffusely and myxomatous degeneration of the mitral valve results in the "floppy"-valve syndrome.[50]

Ehlers–Danlos syndrome is another manifestation of defective collagen synthesis, of which there are five identifiable clinical subtypes. Laxity of the skin, bruising, and hyperextensibility of the joints are integral features of the syndrome. Virtually every artery in the body, including the aorta, may undergo aneurysmal dilatation and progress to rupture.[13,15] The ecchymotic subtype is particularly prone to developing complications from angiography and should be approached carefully in this regard.

Mycotic aneurysms are often heralded by the sudden appearance and rapid enlargement of a mediastinal or abdominal mass. The most commonly isolated organisms are streptococcus, staphylococcus, pneumococcus, and salmonella.[51] The focus of infection is usually set up at points of turbulence or intimal injury rather than being related to invasion of the aortic wall from a contiguous focus. The most common site of involvement is the descending thoracic aorta, often distal to aortic coarctation or adjacent to the

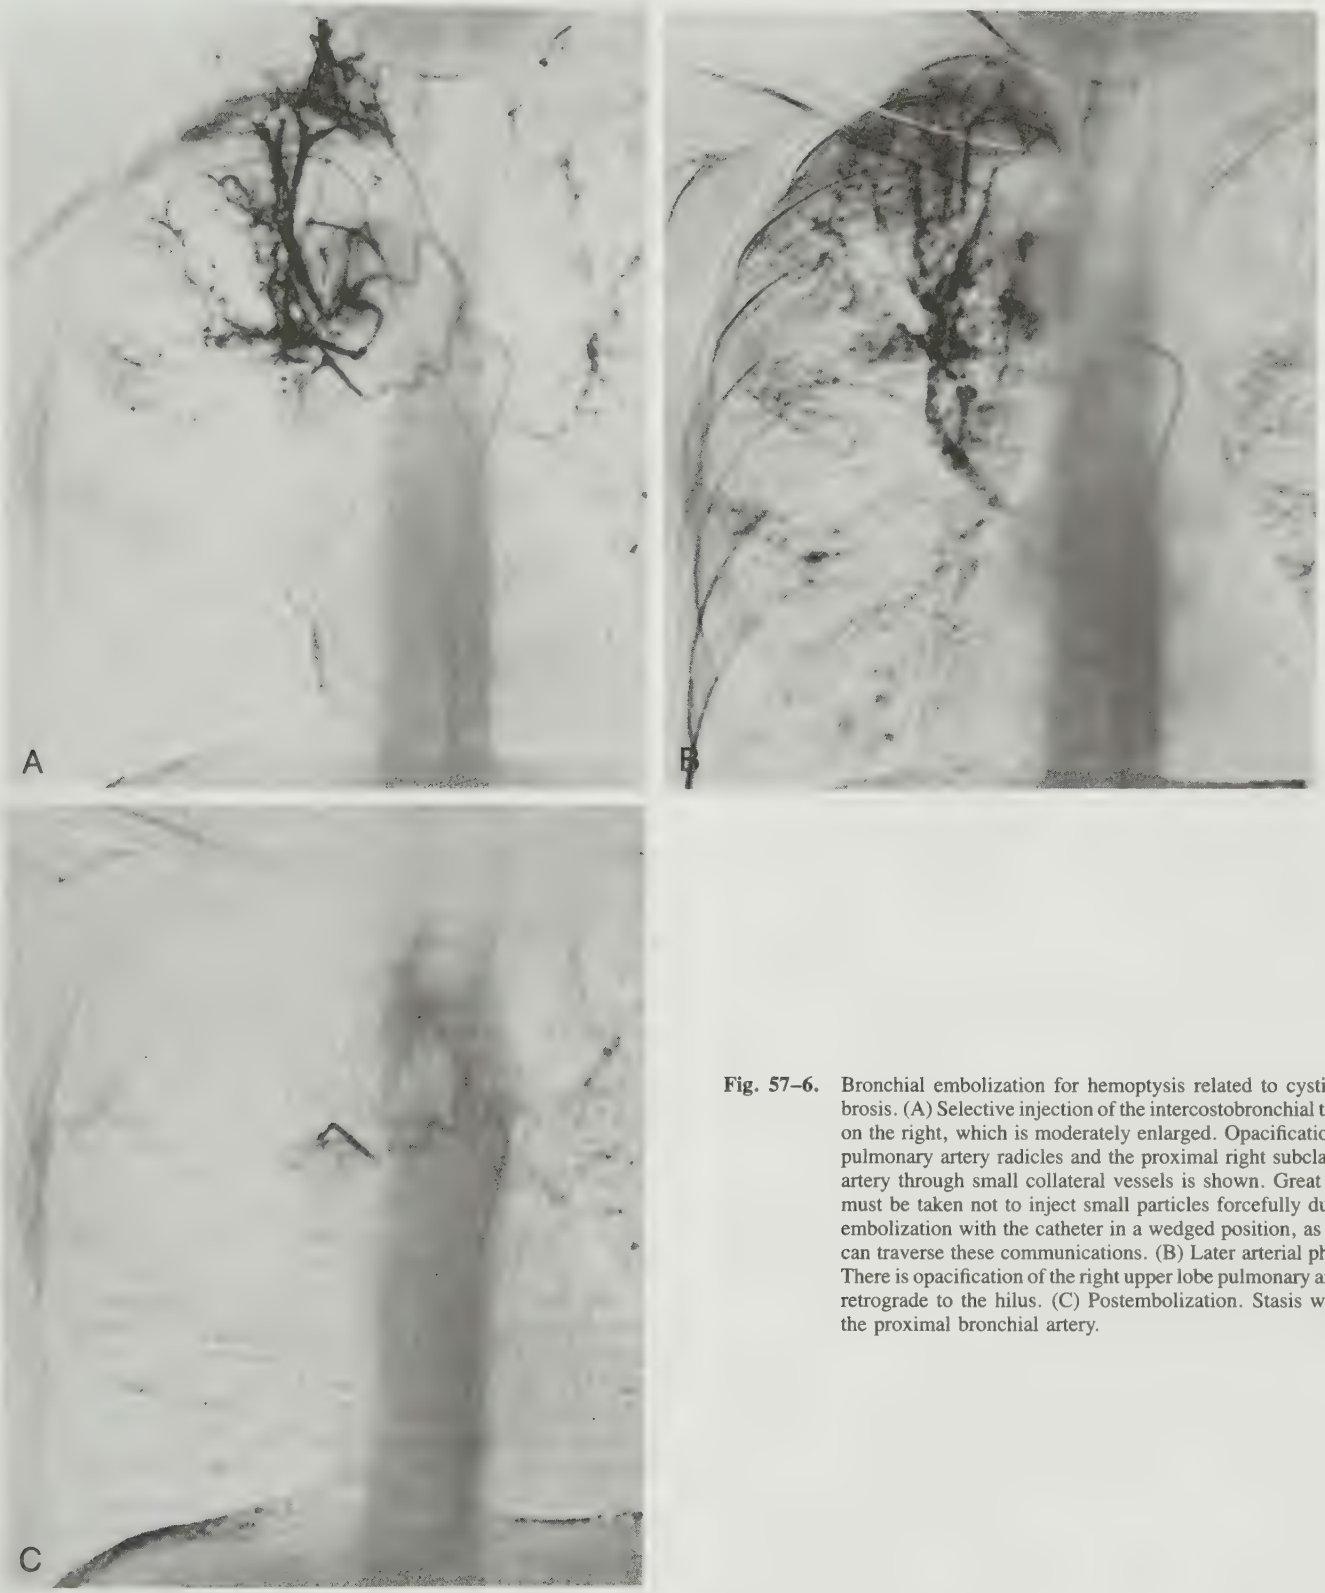

Fig. 57–6. Bronchial embolization for hemoptysis related to cystic fibrosis. (A) Selective injection of the intercostobronchial trunk on the right, which is moderately enlarged. Opacification of pulmonary artery radicles and the proximal right subclavian artery through small collateral vessels is shown. Great care must be taken not to inject small particles forcefully during embolization with the catheter in a wedged position, as they can traverse these communications. (B) Later arterial phase. There is opacification of the right upper lobe pulmonary artery retrograde to the hilus. (C) Postembolization. Stasis within the proximal bronchial artery.

tip of an umbilical arterial catheter (Fig. 57–8).[51–53] It is preferable to avoid direct injection of contrast into the aneurysm as a shower of peripheral septic emboli may result.

Other causes of aortic aneurysms include syphilis, prestenotic and poststenotic dilatation associated with coarctation, and trauma.

ABDOMINAL AORTOGRAPHY

The abdominal aorta is the direct continuation of the thoracic aorta as it passes through the diaphragmatic hiatus at the T12–L1 level. Major visceral branches include the celiac axis and the superior and inferior mesenteric arteries. The aorta terminates at L4, where it bifurcates into the common iliac arteries.

The celiac axis arises ventrally just caudal to the diaphragm. It supplies the liver, spleen, stomach, pancreas, and duodenum via the radicles of the left gastric, splenic, and common hepatic arteries. The superior mesenteric artery arises at the L1–L2 level and supplies the small bowel and colon from the ligament of Trietz to the splenic flexure. The left colon distal to the splenic flexure

Fig. 57–8. Mycotic aortic aneurysm at the junction of the descending thoracic and abdominal aortae. The side holes of the pigtail catheter are immediately adjacent to the aneurysm—the catheter should optimally be positioned more superiorly (see text).

is perfused by the inferior mesenteric artery, whose origin is usually at L3, slightly to the left of midline.

Visceral blood is returned via the portal venous system. The superior and inferior mesenteric, splenic, and left gastric veins converge in the upper abdomen to form the portal vein which courses obliquely upward to the right to enter the liver. Blood flows through the hepatic sinusoids into the hepatic veins and returns to the heart by way of the inferior vena cava.

Variations in visceral arterial anatomy are common, particularly in the blood supply to the liver. The right and left hepatic arteries are branches of the common hepatic artery in only half of the general population. The other half may have partial or total supply to the right lobe arising from the proximal superior mesenteric artery or the left hepatic artery originating from the left gastric artery.

Catheterization of the abdominal aorta and visceral arteries is most often performed for the investigation of hypertension, gastrointestinal bleeding, visceral masses, or transplants. In neonates, the examination may be accomplished by umbilical arterial catheterization; the transfemoral route is used after 2 weeks of age.

Abdominal Aortic Coarctation

Congenital fusiform narrowing of the abdominal aorta is proposed to result from abnormal fusion of the paired primitive dorsal aortae. Stenosis is most marked at the level of the renal arteries, and hypertension is a common presenting feature.

Hypoplasia of the abdominal aorta associated with renal and/or pulmonary artery stenoses may be seen in Williams[54] and con-

genital rubella[55] syndromes. In the former, mental retardation, "elfin facies," hypercalcemia, and supravalvular aortic stenosis are present. The syndrome is believed to be related to abnormal vitamin D metabolism. Babies suffering from the sequelae of prenatal rubella infection may have patent ductus arteriosus, ventricular septal defect, or other cardiovascular abnormalities.

Abdominal aortic coarctation is also a manifestation of Takayasu's arteritis (Fig. 57–9) and neurofibromatosis, both of which are discussed elsewhere in this chapter. Irradiation of abdominal or retroperitoneal neoplasms early in life, particularly in cases of Wilms' tumor, have resulted in a similar angiographic appearance.[56]

Liver Neoplasms

Hemangiomas and hemangioendotheliomas are benign hepatic neoplasms that classically present in the first year of life with cardiac failure, hepatic enlargement, and/or cutaneous hemangiomata.[57] Hepatic malignancies, including hepatoblastoma and hepatocellular carcinoma, are usually discovered in children who fail to thrive or who exhibit other nonspecific constitutional symptoms and have palpable hepatomegaly. Hepatoblastomas are found in the neonatal period, while hepatocellular carcinomas usually present after the fifth year; associated congestive heart failure is rare.[58,59]

Benign hepatic neoplasms are often differentiated from malignancies on the basis of clinical features and noninvasive diagnostic examinations.[60,61] Angiography is primarily used for presurgical vascular mapping or before embolotherapy. The presence of arteriovenous shunting, usually hepatic artery to hepatic vein, and sinusoidal pooling (Fig. 57–10) are distinctly more common in benign tumors, while segmental or main portal vein occlusion and arterial encasement are indicative of malignancy.[57,62] Marked hypervascularity may be seen in both groups.

Although histologically benign, hemangiomas and hemangioendotheliomas are sometimes associated with significant morbidity and mortality. Treatment has traditionally consisted of corticosteroids, radiation, or chemotherapy. Transcatheter embolization may be employed as a primary therapeutic modality or when the above options fail.[63]

Hepatoblastoma and hepatocellular carcinoma are usually surgically excised. If the neoplasm is unresectable, embolization may be offered in lieu of chemotherapy or radiation therapy.

Liver Transplant

Angiographic evaluation before and after liver transplantation has decreased in the past few years because of the refinement of Doppler ultrasonography and computed tomography.[64–67] Angiography is used to clarify abnormalities found during these studies or in cases in which noninvasive imaging is technically unsatisfactory.

The portal vein and inferior vena cava are evaluated preoperatively for patency and size. Most surgeons prefer the portal vein to be at least 4 to 5 mm in diameter before attempting transplantation.[68] Selective injection of the superior mesenteric or splenic arteries with filming carried into the venous phase will usually adequately visualize the portal vein (arterial or indirect portography). Direct injection into the inferior vena cava is performed via the percutaneous femoral venous approach.

Postoperatively, hepatic arterial abnormalities remain one of the most frequent causes of failed transplantation and may manifest angiographically as stenosis, thrombosis, or alternating foci of narrowing and dilatation indicative of rejection.[67,69] Abdominal aortography and/or selective hepatic angiography will detect these abnormalities; selective injection of the superior mesenteric artery should be added in cases of hepatic artery thrombosis, as collaterals to the liver have been reported in some patients.[69] This obviates the need for emergency retransplantation.

Portal Hypertension

Portal hypertension presents most commonly with upper gastrointestinal bleeding at 3 to 5 yr of age.[70] Hepatosplenomegaly and hypersplenism are often present at the time of diagnosis.

Gastroesophageal varices in children are most often formed on the basis of extrahepatic portal venous occlusion, which may occur congenitally (cavernous transformation) or develop postnatally secondary to umbilical venous catheterization, omphalitis, or sepsis.[62,71,72] Children with intrahepatic diseases, including biliary atresia, congenital hepatic fibrosis, cystic fibrosis, and viral hepatitis usually have jaundice or other stigmata of hepatic dysfunction before their first bleeding episode.[62]

Angiography and splenoportography are important in evaluating for sites of greatest collateral (hepatofugal) flow and thus in determining which decompressive shunt will be effective. Arterial portography, or opacification of the portal venous system following injection of the splenic and/or superior mesenteric arteries, provides information about venous anatomy and flow patterns. Splenoportography, or direct injection of contrast into the splenic pulp, provides superior anatomic detail of the venous drainage pathways (Fig. 57–11) at the risk of bleeding, particularly in children with clotting abnormalities related to liver dysfunction or hypersplenism. It is usually performed when arterial portography is inconclusive. Measurement of splenic pulp pressure, which mirrors hepatic sinusoidal pressure, is an added benefit of this method of examination.

Venous flow is typically bidirectional in extrahepatic obstruction, with hepatofugal flow through abdominal or retroperitoneal varices and hepatopetal flow through numerous worm-like veins in the liver hilus. In cases of intrahepatic disease, hepatopetal flow progressively decreases as hepatic sinusoidal pressure increases until total reversal of flow or thrombosis within the portal vein ensues. Collateral pathways visualized include esophagogastric, mesenteric, and periumbilical varices, as well as spontaneous splenorenal shunts.

The treatment of portal hypertension centers on the surgical creation of various portosystemic shunts.[70] Most surgeons prefer to defer operation until 5 yr of age, if possible, to allow the vessels to reach adequate size. Esophageal sclerotherapy and liver transplantation have played increasingly important roles in the management of these patients. Prognosis is considerably better in the extrahepatic forms of the disease, in which hepatopetal collaterals may enlarge over time and reduce flow through varices, sometimes eliminating the need for shunt surgery.

Gastrointestinal Bleeding

Gastrointestinal bleeding in children is most frequently related to esophagogastric varices as just discussed. Upper gastrointestinal bleeding of arteriocapillary origin may be from gastroduodenitis or ulceration. Sources of lower gastrointestinal bleeding include

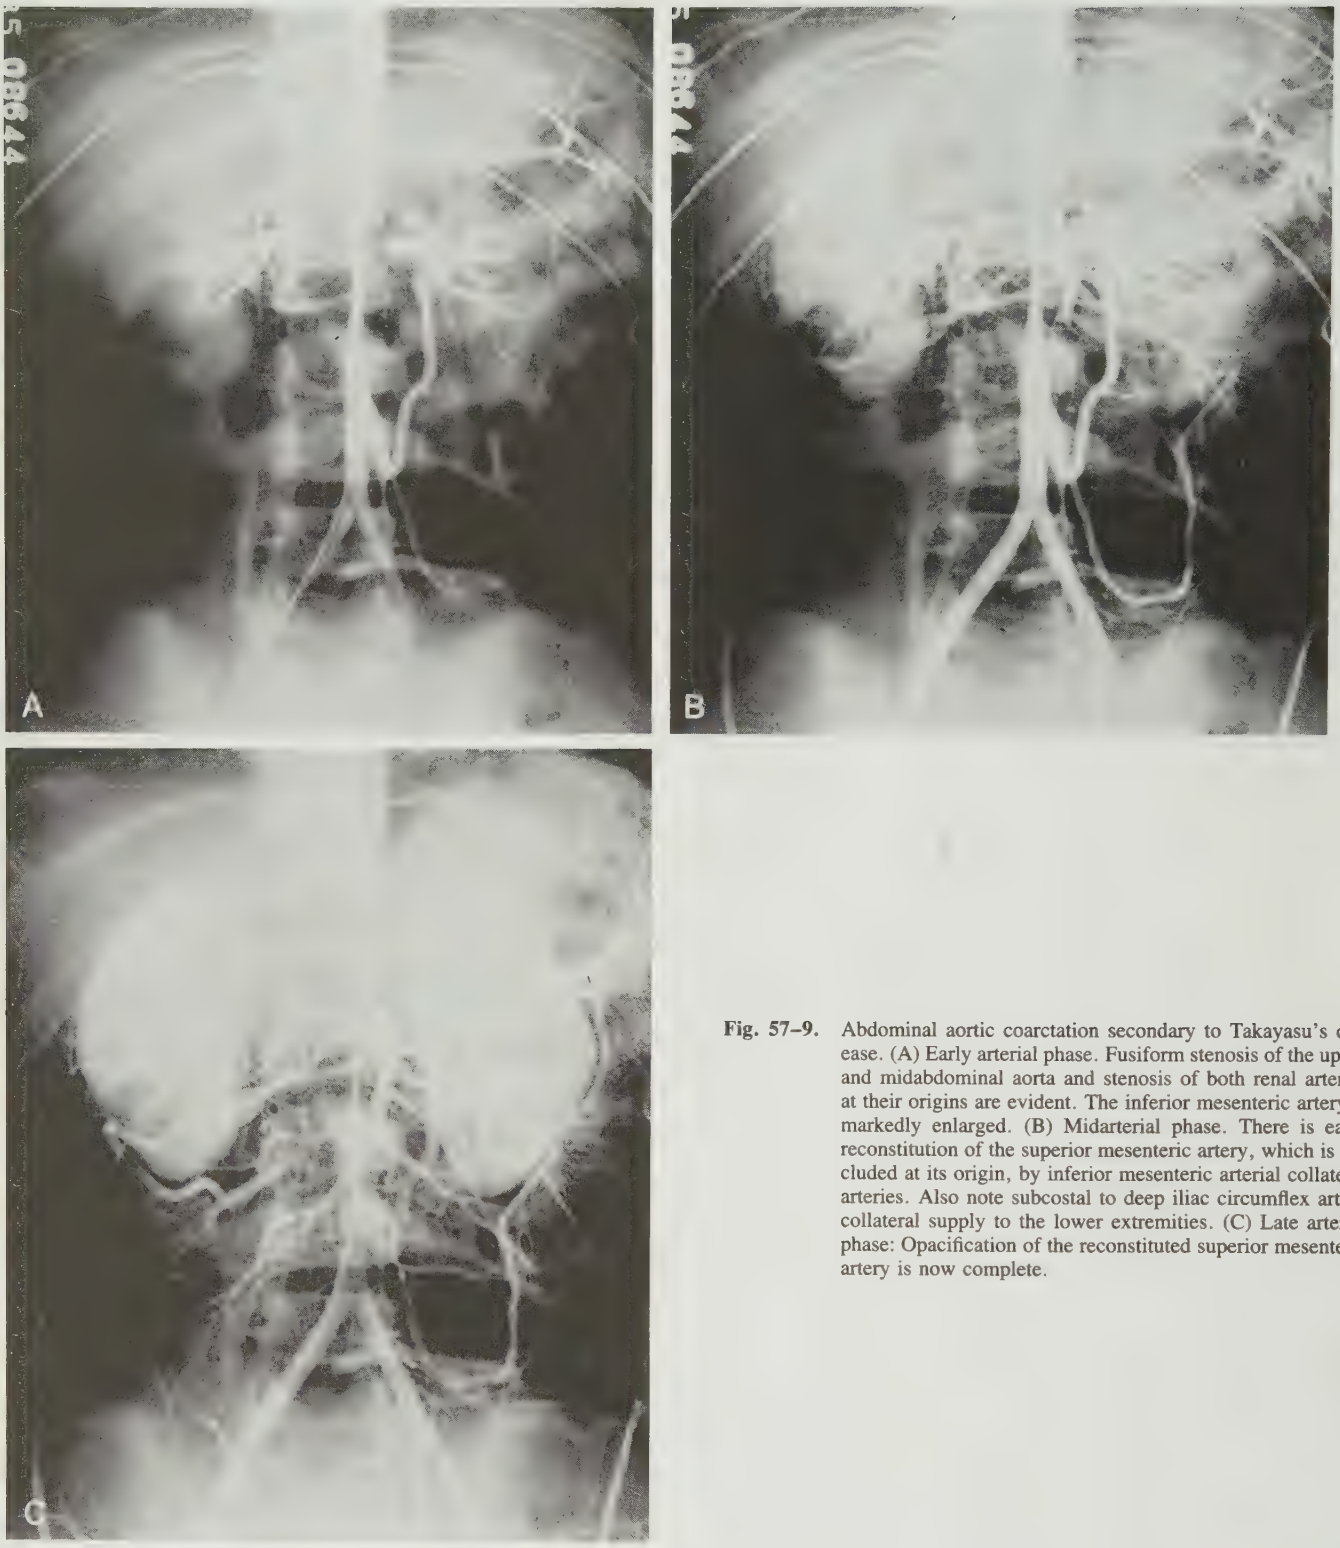

Fig. 57–9. Abdominal aortic coarctation secondary to Takayasu's disease. (A) Early arterial phase. Fusiform stenosis of the upper and midabdominal aorta and stenosis of both renal arteries at their origins are evident. The inferior mesenteric artery is markedly enlarged. (B) Midarterial phase. There is early reconstitution of the superior mesenteric artery, which is occluded at its origin, by inferior mesenteric arterial collateral arteries. Also note subcostal to deep iliac circumflex artery collateral supply to the lower extremities. (C) Late arterial phase: Opacification of the reconstituted superior mesenteric artery is now complete.

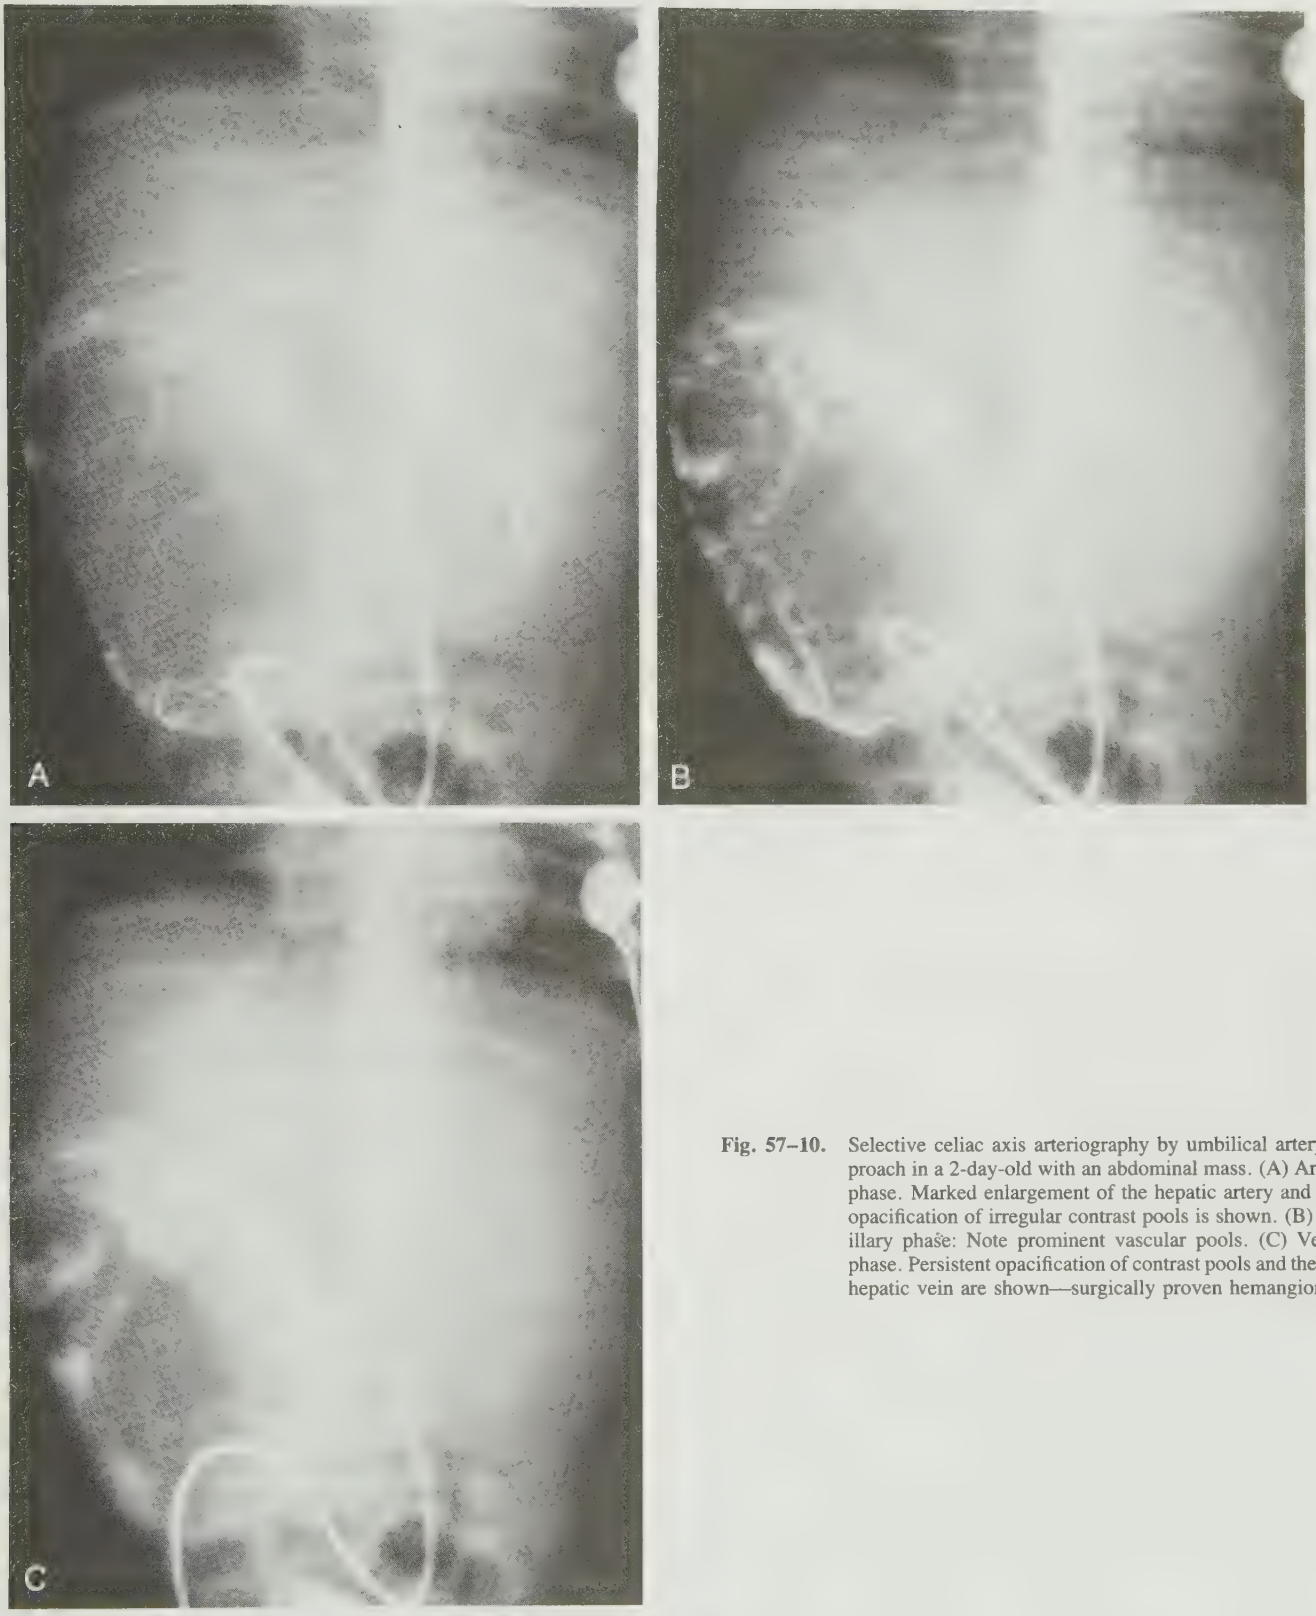

Fig. 57–10. Selective celiac axis arteriography by umbilical artery approach in a 2-day-old with an abdominal mass. (A) Arterial phase. Marked enlargement of the hepatic artery and early opacification of irregular contrast pools is shown. (B) Capillary phase: Note prominent vascular pools. (C) Venous phase. Persistent opacification of contrast pools and the right hepatic vein are shown—surgically proven hemangioma.

Fig. 57–11. Splenoportogram in a child with cavernous transformation of the portal vein. Two main channels comprise the portal vein in the hepatic hilus. Collateral flow through the left gastric vein (arrowhead), inferior mesenteric vein (large arrow), and a spontaneous splenorenal shunt (small arrow) are noted.

anal fissure, colitis, polyp, vascular malformation, typhlitis, and Meckel's diverticulum.[73–79] Aggressive diagnostic workup is indicated in cases of hemorrhage in which the source is not obvious clinically. Evaluation commences with appropriate endoscopic or nuclear medicine studies; barium is not administered before angiography in patients with moderate to severe hemorrhage, as it will obscure the mesenteric vasculature. Angiography is performed in patients with positive endoscopy or scintigraphy in whom further diagnostic information or transcatheter therapy is desirable.

A cobra-shaped or reverse-curve catheter is placed selectively in the celiac axis, left gastric, gastroduodenal, and/or superior mesenteric arteries in cases of upper gastrointestinal bleeding. The celiac axis and superior and inferior mesenteric arteries are injected when bleeding is believed to be from a lower gastrointestinal source. Intravenous vasopressin therapy should be terminated at the time of the study for the best chance of demonstrating active extravasation. Bleeding rates as low as 0.5 mL/min may be detected angiographically.[80] Findings include diffuse vascular spasm related to hypovolemia, contrast extravasation (Fig. 57–12), vascular malformation, and intense mucosal stain in cases of inflammation (e.g., colitis, gastritis, duodenitis). Arteriovenous shunting may be observed in malformations or inflammatory processes.

Transcatheter therapy in the form of vasopressin infusion or embolization have emerged as viable alternatives to the more traditional surgical approaches to gastrointestinal bleeding.[79,81] Vasopressin (Pitressin) may be administered into the left gastric, superior, or inferior mesenteric circulations in a dosage of 0.05 to 0.3 unit/min. After 15 min of infusion, a repeat angiogram is performed to confirm cessation of bleeding without excessive vasoconstriction, which could lead to bowel infarction. Embolization, generally with Gelfoam, is reserved for the left gastric artery. Caution is advisable when previous gastric or upper abdominal surgery has been performed as potential collateral pathways may have been severed. Occlusion of superior mesenteric and inferior mesenteric radicles should be avoided, as bowel infarction is likely.

Therapeutic Splenic Infarction

Hypersplenism related to congestive splenomegaly in a number of hematologic disorders (Banti's syndrome) has traditionally been treated by splenectomy. However, this procedure is associated with impairment of immunologic defenses and an increased incidence of overwhelming sepsis. Partial splenic embolization was proposed in an effort to preserve some splenic parenchyma and therefore immunologic integrity. Although initial efforts were marred by frequent complications, there has been renewed interest in the procedure after modifications, as set forth by Spigos et al. in 1979.[82] Their protocol calls for transcatheter ablation of two thirds of the splenic parenchyma with small Gelfoam pledgets soaked in antibiotics. Liberal use of parenteral antibiotics and narcotic analgesics for 5 days after the procedure has dramatically reduced postprocedural splenic abscess, sepsis, and hypostatic pneumonia.

Kumpe et al. reported successful partial splenic embolization in 10 of 11 children with biliary atresia and/or portal venous thrombosis.[83] Hypersplenism was corrected in 7 of 8 individuals and the frequency of variceal bleeding was reduced in all 10 patients. Reversal of leukopenia and thrombocytopenia secondary to hypersplenism in renal transplantation,[84] thalassemia,[85] and Gaucher's disease[86] has also been reported.

RENAL ANGIOGRAPHY

Catheterization for the investigation of renal abnormalities is the most frequently performed vascular examination in many pediatric radiology departments. Indications include evaluation for renal vascular hypertension, vasculitis, renal transplant donors and recipients, and less commonly, traumatic or neoplastic disease. The renal arteries usually are found at the L1–L2 level, although they may arise anywhere along the course of the distal abdominal aorta or common iliac arteries. The renal origins are optimally demonstrated in a slight right posterior oblique projection. Multiple arteries are present in up to 35% of normally positioned kidneys and in the majority of ectopic and horseshoe kidneys.[87]

The segmental veins converge at the renal hilus to form the main renal veins, which course cranially to join the inferior vena cava at the L1–L2 level. The most common venous variant is a circumaortic left renal vein in which dorsal and ventral components of a venous collar around the aorta are found. Its recognition is important when performing renin sampling or in evaluation of renal donors. Venous anatomy is extremely variable in ectopic and horseshoe kidneys.

Selective renal arteriography should always be preceded by midstream abdominal aortography so that spasm induced by the catheter is not mistaken for a focus of fixed pathologic narrowing and so that the number of arteries to each kidney is determined. Aor-

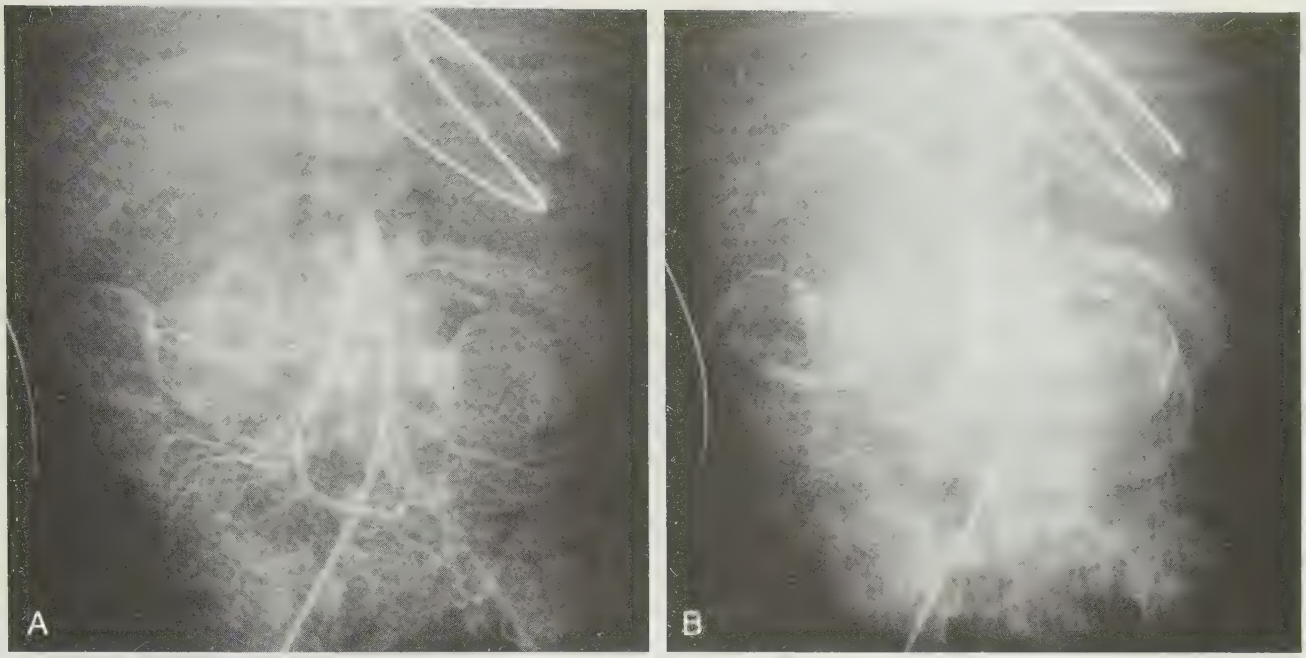

Fig. 57–12. Acute gastrointestinal hemorrhage. Arterial (A) and venous (B) phases of a selective superior mesenteric arteriogram. Contrast extravasation is seen to the left of L2 secondary to an ulcer in the proximal jejunum.

tography is performed with a No. 4 or No. 5 French pigtail catheter; a simple, reverse-curve or cobra catheter is suitable for selective injection.

Renal Vascular Hypertension

Hypertension is uncommon in the pediatric age group, affecting only 1 to 2% of this population.[88] High blood pressure may be discovered incidentally during an office visit or may present with nonspecific symptoms of headache, visual disturbances, nausea, or vomiting.[89,90] Sustained diastolic pressure of greater than 90 mm Hg is generally considered elevated in older children; pressures standardized for height and weight are available for younger children.[91]

Patients discovered fortuitously to have elevated pressure do not necessarily require extensive workups for renal vascular disease unless they are under 10 yr of age. A noninvasive evaluation consisting of urinalysis, complete blood count, determination of serum levels of blood urea nitrogen and creatinine, and ultrasound for kidney size is recommended in these patients.[89] If, however, there is an audible bruit, acceleration of hypertension, or if control of blood pressure is refractory to medical therapy, angiography should be performed. My colleagues and I also routinely perform angiography in patients under 10 yr old with hypertension; in fact, the younger the child, the more likely a renal vascular cause will be found.[92]

For children who present with nonspecific symptoms, a noninvasive evaluation as described above is followed by a percutaneous biopsy if the urinalysis, blood urea nitrogen, and creatinine suggest renal parenchymal disease. If these parameters are normal, angiographic evaluation is undertaken. In the series of Londe, 78% of patients had parenchymal disease to account for their hypertension, 12% had renovascular causes, and the remainder had miscellaneous abnormalities.[89]

Angiography is preceded by bilateral selective renal vein renin samples, which are obtained via a femoral venous approach. A cobra-shaped catheter is usually most effective; the catheter tip should be advanced distal to the gonadal vein orifice on the left side for accurate sampling. Samples are also taken from the inferior vena cava above and below the level of the renal veins. Arterial DSA is helpful in localizing veins in cases of ectopic and horseshoe kidneys, in which anomalous drainage pathways are common. A detailed discussion of renin interpretation may be found elsewhere;[93,94] however, a renin ratio of greater than 1.5 from one kidney to the other suggests a significant parenchymal or vascular lesion.

Abdominal aortography and selective injection of both renal arteries are then performed; the latter should be done for a complete examination. The most frequent cause of renal vascular hypertension is fibromuscular dysplasia.[93–97] Lesions may be focal, web-like or broad, smooth stenoses, unlike the classic "string of beads" found in adults. The distal two thirds of the main renal artery and segmental arteries are most commonly affected; the adjacent aorta is normal.

When tubular narrowing of the abdominal aorta is observed in association with compromise of the renal arteries, Takayasu's disease, neurofibromatosis, and other causes of abdominal aortic coarctation are the main differential considerations.[26–28,54–56,97–99] As previously discussed, the renal arteries are involved in up to 75% of cases of Takayasu's disease. Angiographically, stenoses are found at the ostium and proximal one third of the renal artery; poststenotic aneurysm formation is not uncommon. Although both Takayasu's disease and neurofibromatosis may produce identical angiographic pictures, they are usually easily distinguished on clinical grounds. When stenosis of neurofibromatosis uncommonly occurs in the distal two thirds of the renal artery, differentiation from fibromuscular dysplasia is difficult (Fig. 57–13).

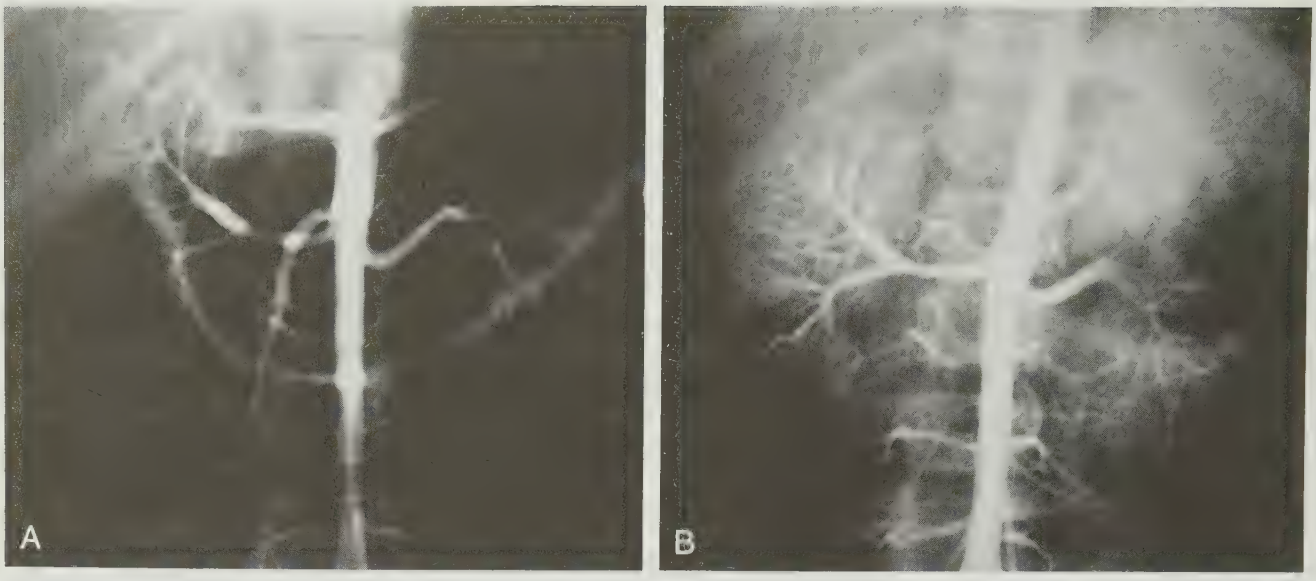

Fig. 57–13. Renal artery stenosis in a young boy with neurofibromatosis and hypertension. (A) High-grade focal stenosis of the distal right renal artery with poststenotic dilatation extending into the upper pole segmental artery. Neurofibromatosis more commonly affects the renal artery ostia, although it may compromise the distal vessel. The appearance of this lesion is indistinguishable from fibromuscular dysplasia. (B) The same view after transluminal angioplasty, with excellent results.

Hypertension is also known to be associated with placement of umbilical arterial catheters in the neonatal period.[100–102] In the short term, evidence of thromboemboli to the main or segmental renal arteries is observed. In later years, angiography may reveal renal infarcts or a globally small renal artery and kidney indistinguishable from other causes of hypoplasia or atrophy. Hypertension is also a common feature of vasculitis, which is discussed in the next section.

After the discovery of a renal stenosis, transluminal angioplasty may be attempted. A vascular surgeon must always be immediately available in case there are complications. Antihypertensive medication should be discontinued to avoid postprocedural hypotension. The narrowed segment is first traversed by a tapered soft-tipped straight guide wire such as a Bentson guide wire (Cook Co., Bloomington, IN), over which a catheter is advanced into the distal renal artery. A reverse-curve shape is the most effective in crossing tight stenoses. Heparin is routinely administered through the catheter in a dose of 50 to 100 units/kg; spasm may be relieved at any time during the procedure by intra-arterial nitroglycerin. A more rigid wire (i.e., Rosen, Bard Inc., Billerica, MA) is then placed into the distal renal artery, followed by the double-lumen balloon catheter. Balloon size should be equal to the luminal diameter of the normal renal artery just distal to the stenosis as measured on conventional angiographic films; care should be taken not to choose a site of poststenotic dilatation for the measurement. With the balloon centered on the lesion, one or more inflations for 30 sec to 1 min are made until the "waist" has been eliminated. The wire is removed and pressure tracings and readings are obtained to ensure a good result with no residual gradient. My colleagues and I usually perform arterial DSA of the abdominal aorta to angiographically document the results.

Increasing numbers of series in the literature document the utility and success of renal dilatation.[103–108] Angioplasty has been recognized as the treatment of choice for renal vascular hypertension secondary to fibromuscular dysplasia and is curative in the majority of these patients.[109] Although initial reports of dilatation in Takayasu's disease and neurofibromatosis were less than optimal,[110] recent reports are more encouraging. Dong et al. report cure or marked improvement in 22 hypertensive patients followed an average of 25.5 mo after renal angioplasty.[111] However, Mali et al. suggest that lesions occurring within the proximal third of the artery are less responsive to dilatation.[103]

Vasculitis

Polyarteritis nodosa is a systemic necrotizing vasculitis that is probably related to immune complex deposition in medium and small vessels. The pulmonary arteries are spared; any other artery in the body may be affected. Clinical findings include fever, weight loss, hypertension, abdominal pain, and peripheral or central nervous system symptomatology.[112] There are no set criteria for the diagnosis of polyarteritis. Presumptive diagnosis is established by histologic evidence of necrotizing vasculitis or typical angiographic features in the proper clinical setting.

Abdominal aortography and selective visceral injections classically reveal aneurysms 1 to 5 mm in diameter in the hepatic, splenic, renal, and mesenteric vasculature. The series of Sellar et al. suggests that aneurysms are found only during periods of florid activity[113]; regression has been documented with appropriate medical therapy and coincides with clinical improvement.[114,115] Abnormal vessel tapering with areas of fusiform dilatation, occlusion, and visceral infarctions may be observed (Fig. 57–14). These angiographic features alone are indistinguishable from other causes of necrotizing angiitis and hypersensitivity, including amphetamine abuse, collagen vascular disease, and particularly, systemic lupus erythematosus.

Glucocorticosteroids and cytotoxic drug therapy have been reported to improve the 5-year survival rate to about 80%. Approx-

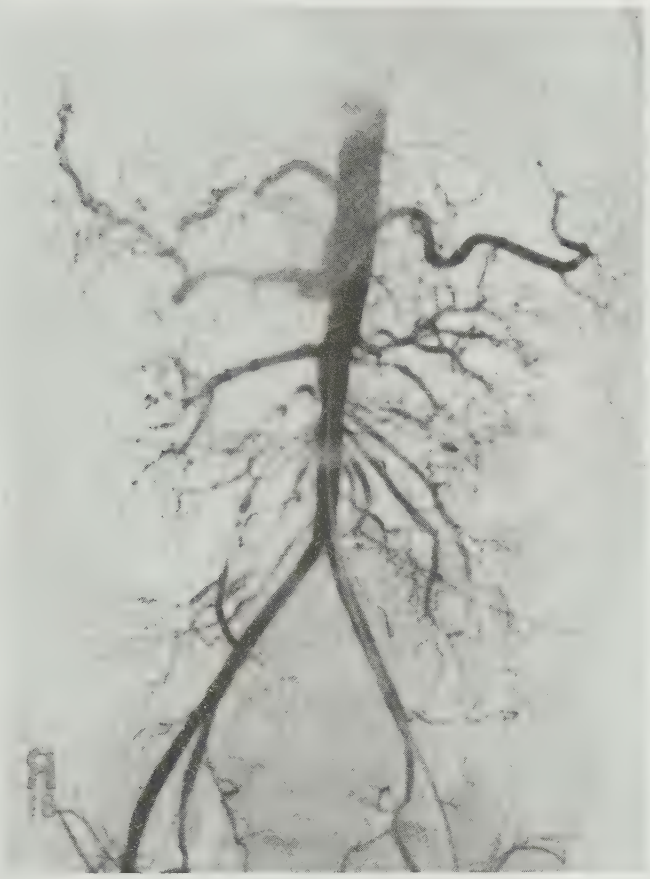

Fig. 57–14. Midstream abdominal aortogram in a young girl with clinically suspected polyarteritis nodosa. There is irregular tapering of numerous small and medium-sized mesenteric, visceral, and pelvic arteries with alternating foci of narrowing and dilatation. Marked spasm of the left external iliac artery is seen about the catheter. The patient's pedal pulses returned shortly after removal of the catheter.

imately 50% of patients eventually die from renal complications of their disease.[30]

Renal Donor and Transplant Evaluation

Angiography is performed in prospective renal donors to assess the number of renal arteries, length of the undivided main renal artery, and unsuspected arterial or venous abnormalities.[116] Arterial DSA of the abdominal aorta via the femoral artery approach is done on an outpatient basis. Filming is in the anteroposterior projection and supplemented with oblique views as necessary. Conventional film angiography and selective renal injections are rarely needed.

After transplantation, deteriorating renal function and hypertension may be related to vascular compromise as well as a number of parenchymal problems. Noninvasive imaging with Doppler ultrasound is quite helpful in the evaluation for vascular integrity.[117] Patients with equivocal results on Doppler study or evidence of a hemodynamically significant stenosis undergo subsequent angiography.

Selective injection of the common iliac artery ipsilateral to the transplant in a steep posterior oblique or lateral projection is usually necessary to demonstrate the arterial anastomosis. Filming is extended through the capillary and venous phases.

Stenosis may occur at or just distal to the anastomosis and range from very focal to smoothly tapering types (Fig. 57–15).[118] Poststenotic dilatation or arterial occlusion may also be observed. Percutaneous transluminal angioplasty has been effective in the nonsurgical management of these patients.[119–121] Retrograde puncture of the ipsilateral common femoral artery is the preferred approach to most lesions. High-pressure balloons are sometimes needed for resistant stenoses related to fibrosis.

If hypertension and renal insufficiency are performed on the basis of transplant rejection, irregular tapering and occlusion of segmental and more peripheral radicles with decreased arborization is observed. Slow flow and a patchy capillary phase are the result of an overall increase in vascular resistance through the transplant.

Renal Trauma

Renal injury is a result of blunt, penetrating, or iatrogenic trauma. Hematuria is the most common presenting feature, although its absence does not preclude a serious vascular or parenchymal insult. Indications for renal angiography include hematuria, hypotension following flank trauma, nonvisualized kidney on IVP, or absence of perfusion on computed tomography. Occlusion, arteriovenous fistula, extravasation, aneurysm formation, renal fracture, and subcapsular or perirenal hematoma can be demonstrated angiographically; arteriovenous fistula may result from renal biopsy.[122]

Transcatheter embolization may be performed in individuals in whom there is clinical evidence of persistent hemorrhage. The catheter is advanced peripherally in close proximity to the lesion in an effort to preserve a maximum amount of renal parenchyma.

Fig. 57–15. Arterial DSA demonstrating a tight anastomotic stenosis of a left iliac fossa renal transplant in a 2-yr-old boy.

Small Gelfoam pledgets are most often employed for occlusion in these circumstances.

Renal Neoplasm

Wilms' tumor is the most common solid abdominal tumor of childhood, and is usually discovered in the first 6 years of life. Children may present with an abdominal mass, pain, or hypertension. The major objectives in the initial staging efforts are determination of local extension, venous invasion, and distant metastasis. Ultrasound and computed tomography have all but eliminated the need for preoperative angiography because of their ability to accomplish these goals noninvasively.[123]

The utility of angiography is in its ability to delineate arterial and venous anatomy, particularly in large neoplasms before resection, and in determining the feasibility of limited resection in cases of bilateral tumors.[124] More than 90% of cases are hypervascular with typical tumor vessels (irregular tapering, abrupt angulations, unpredictable course) (Fig. 57–16). Aneurysms and arteriovenous shunting may be observed. Avascular foci within the mass usually represent necrosis. Preoperative embolization of these neoplasms has been reported.[125]

PELVIS AND EXTREMITIES

The vascular supply to the pelvis and lower extremities is schematically represented in Figure 57–17. The internal iliac arteries are important sources of collateral blood supply to the lower extremities and give rise to posterior (superior gluteal) and anterior (inferior gluteal, obturator, and internal pudendal) division radicles. These vessels have rich anastomoses with the iliac and femoral circumflex arteries caudally, and send branches across the midline of the pelvis. Other important collateral pathways not shown in the diagram include internal mammary to inferior epigastric and superior to middle and inferior hemorrhoidal arteries.

The profunda femoris artery is an important vessel in circumventing occlusions of the superficial femoral artery via its muscular branches. The superficial femoral artery becomes the popliteal artery as it exits the adductor canal in the lower thigh; the latter gives rise to the peroneal, anterior, and posterior tibial arteries, which serve as the distal "runoff" vessels.

The most common variations in pelvic arterial anatomy involve the anterior division branches of the internal iliac arteries. It is often possible to ascertain their origins only by tracing them retrogradely from their more constant distal ramifications. The branches of the popliteal artery are also quite variable; the anterior tibial artery frequently arises above the knee joint.

An uncommon anomaly is persistence of the embryologic sciatic artery. During early development, this enlarged continuation of the inferior gluteal artery serves as the axial vessel to the lower extremity. When regression fails to occur, its aberrant course posterior to the hip joint predisposes it to chronic trauma with subsequent occlusion or aneurysm formation. A lateral arteriogram of the pelvis is diagnostic.

The vasculature to the upper extremity is as illustrated in Figure 57–18. The axillary artery is the direct continuation of the subclavian artery distal to the first rib. The axillary artery becomes the brachial artery at the level of the anatomical neck of the humerus; the latter gives rise to the radial, ulnar, and interosseous arteries in the forearm.

A rich collateral vascular network is present about the shoulder joint, which is beyond the scope of this discussion. Collateral circulation about an occluded brachial artery at the level of the elbow joint is provided primarily by the superior and inferior ulnar collateral, deep brachial and radial, ulnar, and interosseous recurrent arteries.

The most common variants in the arterial supply to the arm involve the origin of the radial or ulnar arteries from the axillary or proximal brachial vessels. Persistence of the median artery, an embryologic vessel, is analogous to persistence of the sciatic artery in the legs. Associated absence of the radial and/or ulnar arteries may be found.

The pelvis and lower extremities can be imaged on a single film in the neonate and young infant. However, radiologic examination in older children and adolescents requires specialized equipment. Stepping tables move incrementally to follow the contrast as it flows distally; films are exposed at appropriate preset intervals. Long film changers image the entire extremity on 14-by-51-in. cassettes while the table remains stationary. Neither stepping tables nor long film changers are used in upper extremity angiography. Multiple runs are usually required to cover the entire arm, since the field that can be imaged on each injection is limited by the size of the image intensifier in the case of DSA or the film changer for conventional studies.

Visualization of the peripheral upper- and lower-extremity vasculature in infants and children is frequently limited by spasm. Intra-arterial injection of vasodilators, including tolazoline (Priscoline) or nitroglycerin will offer enhanced visualization of these vessels. Caution is advised when instilling these agents into the upper extremities, as reflux into the vertebral or carotid arteries may result. After administration of these agents, injection rates are increased 25 to 50% to compensate for the increased flow.

Congenital Abnormalities

Vascular malformations comprise the majority of congenital abnormalities of the pelvis and extremities and will be discussed in Chapter 85. Popliteal artery entrapment syndrome is a rare congenital cause of lower-extremity vascular insufficiency related to an abnormal course of the popliteal artery or adjacent muscular attachments. There is a male preponderance (8:1) and bilateral involvement in 20% of cases.[126] Angiographic features are medial or, less commonly, lateral deviation and narrowing of the midportion of the popliteal artery; popliteal artery thrombosis; or aneurysm formation (Fig. 57–19). Characteristic findings may be elicited by passive plantar flexion of the foot if not apparent on neutral position arteriography. Treatment is surgical and is usually curative.

Trauma

Iatrogenic iliofemoral arterial trauma secondary to diagnostic or therapeutic catheterization may result in acute ischemia or chronic sequelae, including limb-length discrepancy. There is considerable controversy regarding the frequency at which limb shortening develops as a result of catheterization.[18–20] Most authors feel that uncomplicated transfemoral percutaneous catheterization in children does not impair the blood flow to the limbs. However, there appears to be a relation between documented thrombosis and subsequent limb-length discrepancy. The younger the age at which thrombosis occurs, the greater the growth retardation appears to

Fig. 57–16. Wilms' tumor. (A) Selective renal artery injection reveals typical neovascularity. (B) Capillary phase. (C) Inferior venacavogram showing tumor thrombus protruding from left renal vein into the inferior vena cava.

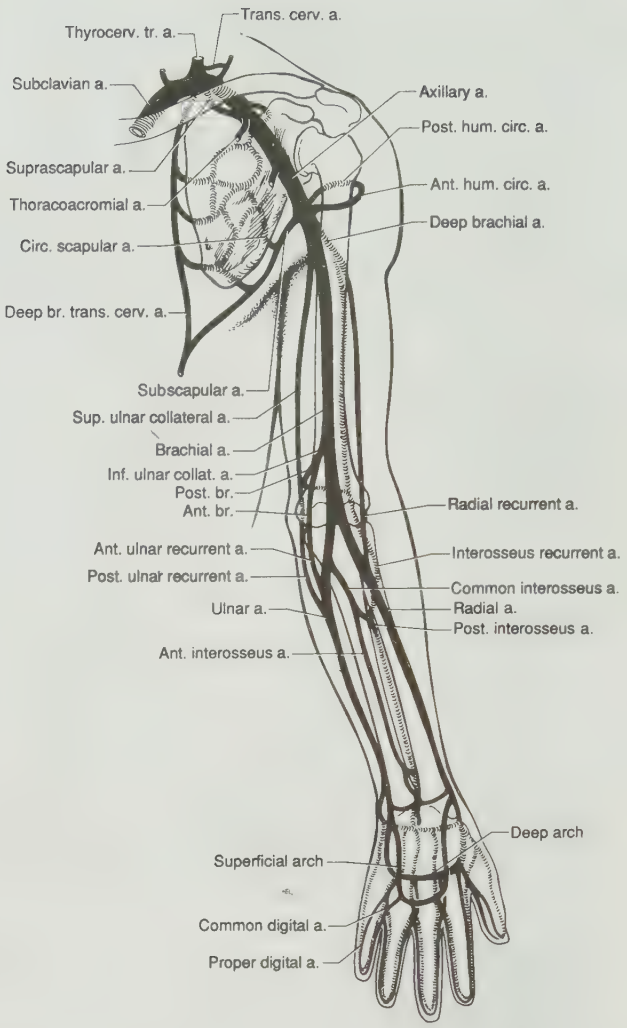

Fig. 57–18. The vasculature to the upper extremity. a = artery; br. = branch; Inf. = inferior.

be.[19] A higher incidence of postprocedural thrombosis is found in children who have undergone surgical arteriotomy for vascular access as compared with percutaneous catheterization by the Seldinger technique.[19]

Immediately after the trauma, angiography reveals intraluminal thrombus, dissection, occlusion, or spasm. Examination of the entire lower extremity is appropriate to rule out distal embolization. Chronically, stenosis or occlusion is found (Fig. 57–20). Collateral blood flow from the internal iliac arteries is generally well established. Investigation in these cases is via retrograde puncture of the contralateral femoral artery and injection of contrast at the aortic bifurcation.

Angiographic evaluation of the pelvis and extremities after severe blunt or penetrating trauma is performed to optimize surgical treatment or before performance of transcatheter embolization. Crush and penetrating injuries of the pelvis should be studied as early as clinically feasible.[127]

Indications for emergency angiography after extremity trauma are pulsatile bleeding, expanding hematoma, decreased or absent peripheral pulses, distal ischemia, bruit, or neurologic deficit.[128,129] The frequent association of vascular injury with supracondylar

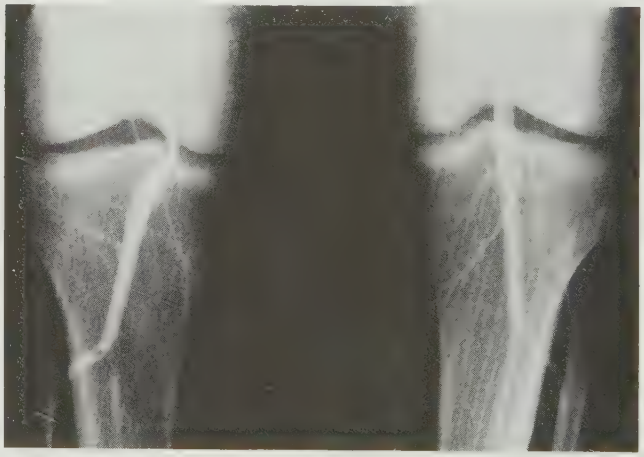

Fig. 57–19. Popliteal artery entrapment syndrome with aneurysm formation and subsequent embolization to the trifurcation vessels on the right side. The left popliteal artery appears normal.

Fig. 57–20. Fusiform stenosis throughout the course of the left external iliac artery related to prior catheterization. The child had a mild limb-length discrepancy. Note the enlargement of the left internal iliac artery, which serves as the main source of collateral supply to the left leg.

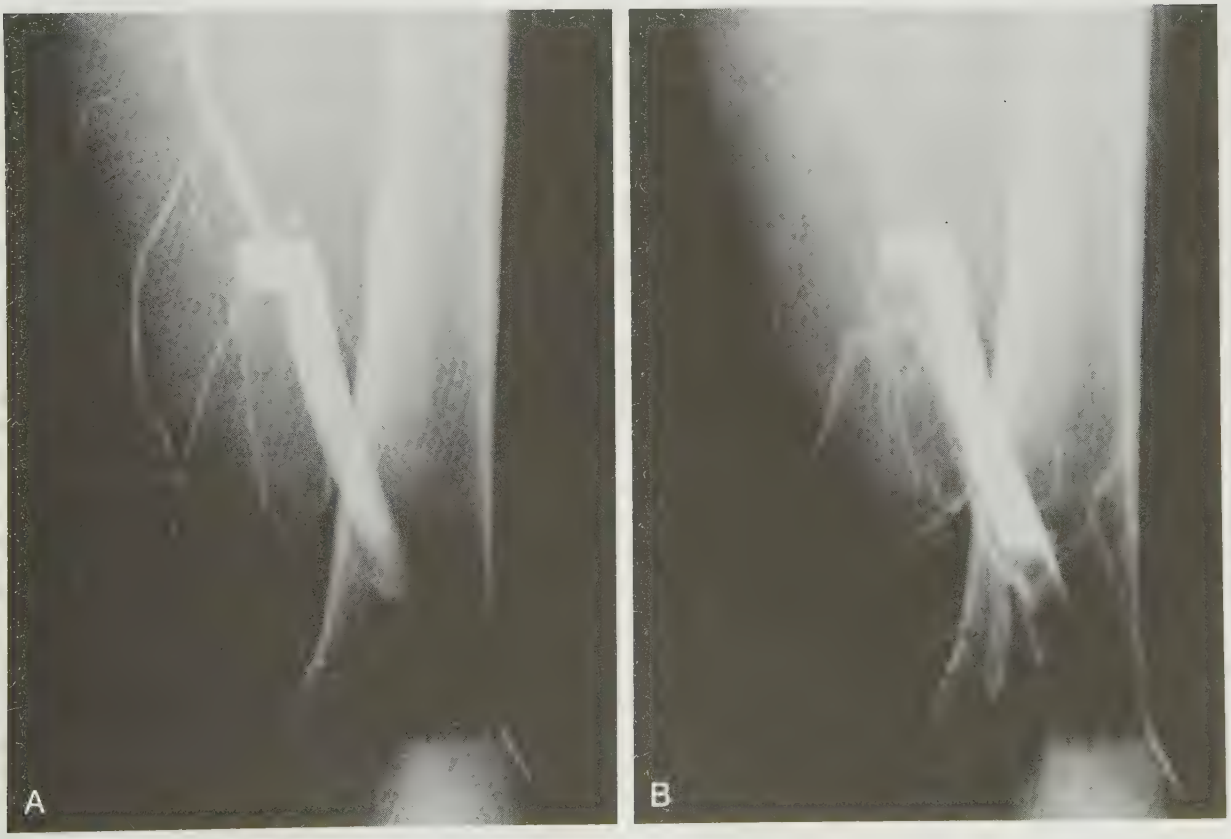

Fig. 57–21. Traumatic arteriovenous fistula between superficial femoral artery and femoral vein secondary to a stab injury. (A) Early phase. (B) Late phase. Note the thrombus within the femoral vein and poor filling of the proximal popliteal artery with abrupt termination (arrows), also secondary to intraluminal thrombus, proven surgically.

fractures of the humerus and femur warrants routine angiographic assessment. Penetrating trauma in the proximity of a major vessel may be studied electively if clinical signs do not suggest vascular compromise.

Vascular studies may disclose extravasation, thrombosis, arteriovenous fistula (Fig. 57–21), pseudoaneurysm, intimal flap, or fusiform narrowing related to spasm or hematoma. Distal aortic and subsequent selective internal iliac arteriograms are quite sensitive in detecting extravasation in the pelvis; arterial DSA or conventional film studies may be obtained. Investigation of trauma to the extremities should be performed in a second projection for clarification of an abnormality or if an abnormality is not disclosed on the first injection. Actively bleeding internal iliac arterial radicles or muscular branches in the extremities that are deemed to be clinically significant at the time of angiography may be embolized with small Gelfoam pledgets.[130,131]

Risks of transcatheter occlusion include errant placement of embolic material, muscular or skin necrosis, and ischemia to the sciatic nerve.[132]

Neoplasm

Plain films, ultrasound, computed tomography, and/or magnetic resonance imaging are integral and complementary examinations in the diagnostic evaluation of pelvic and extremity neoplasms. Angiography is not commonly performed for diagnostic purposes, although it is a necessary prelude to transcatheter embolization or infusion.

Preoperative embolization of benign vascular osseous neoplasms including aneurysmal bone cyst, osteoblastoma, and giant-cell tumor is helpful in limiting hemorrhage related to resection or curettage of these lesions.[133] In surgically inaccessible regions such as the lower lumbar vertebrae or pelvis, this procedure may serve as the primary mode of therapy.

Intra-arterial chemotherapy for osteosarcoma permits high drug concentrations to be delivered to a localized neoplasm. Encouraging results after infusion of doxorubicin (Adriamycin) or cisplatin (*cis*-diamminedichloroplatinum II) for potential limb salvage and as an adjunct to radiation therapy in surgically inaccessible regions have been achieved.[134]

Dialysis Access Evaluation

Internal dialysis access is achieved by creation of an arteriovenous anastomosis or graft. The Brescia–Cimino internal fistula is an arteriovenous anastomosis between the radial artery and cephalic vein in a side-to-side fashion within the forearm. Occasionally, the distal ulnar artery and an adjacent vein are used. An arteriovenous graft is constructed with synthetic material, usually expanded polytetrafluoroethylene, in a U-shaped subcutaneous tunnel within the proximal forearm between the brachial artery and antecubital vein.[135]

Access failure may be related to thrombosis, arterial or venous stenosis, or infection. Thrombosis and infection are usually evident clinically and do not require radiographic evaluation. Arterial stenosis will present as reduced inflow into the uptake dialysis catheter or peripheral ischemia. Venous stenosis, which is more common, is manifest as distal varicosities, upper extremity edema, increased venous perfusion pressure, and pain at the fistula site. Poor filtering may occur as a result of preferential recirculation to the arterial side of the fistula rather than anterograde flow through the stenosis.

Fig. 57–22. Venous stenosis proximal to an arteriovenous interposition graft in the forearm (adjacent to metallic clips).

Fistulography is performed as described by Gilula et al.[136] An 18- or 20-gauge butterfly needle is placed into the venous side of the fistula or anastomosis. A blood pressure cuff is inflated on the upper arm to above systemic arterial pressure, and 15 to 25 mL of low-osmolarity contrast material is injected at approximately 3 to 4 mL/sec. Contrast material will flow both anterogradely through the venous side as well as retrogradely to the arterial side. The cuff is then deflated to observe washout. Visualization of the venous system centrally to the superior vena cava is recommended as stenosis remote from the access site is possible (Fig. 57–22).

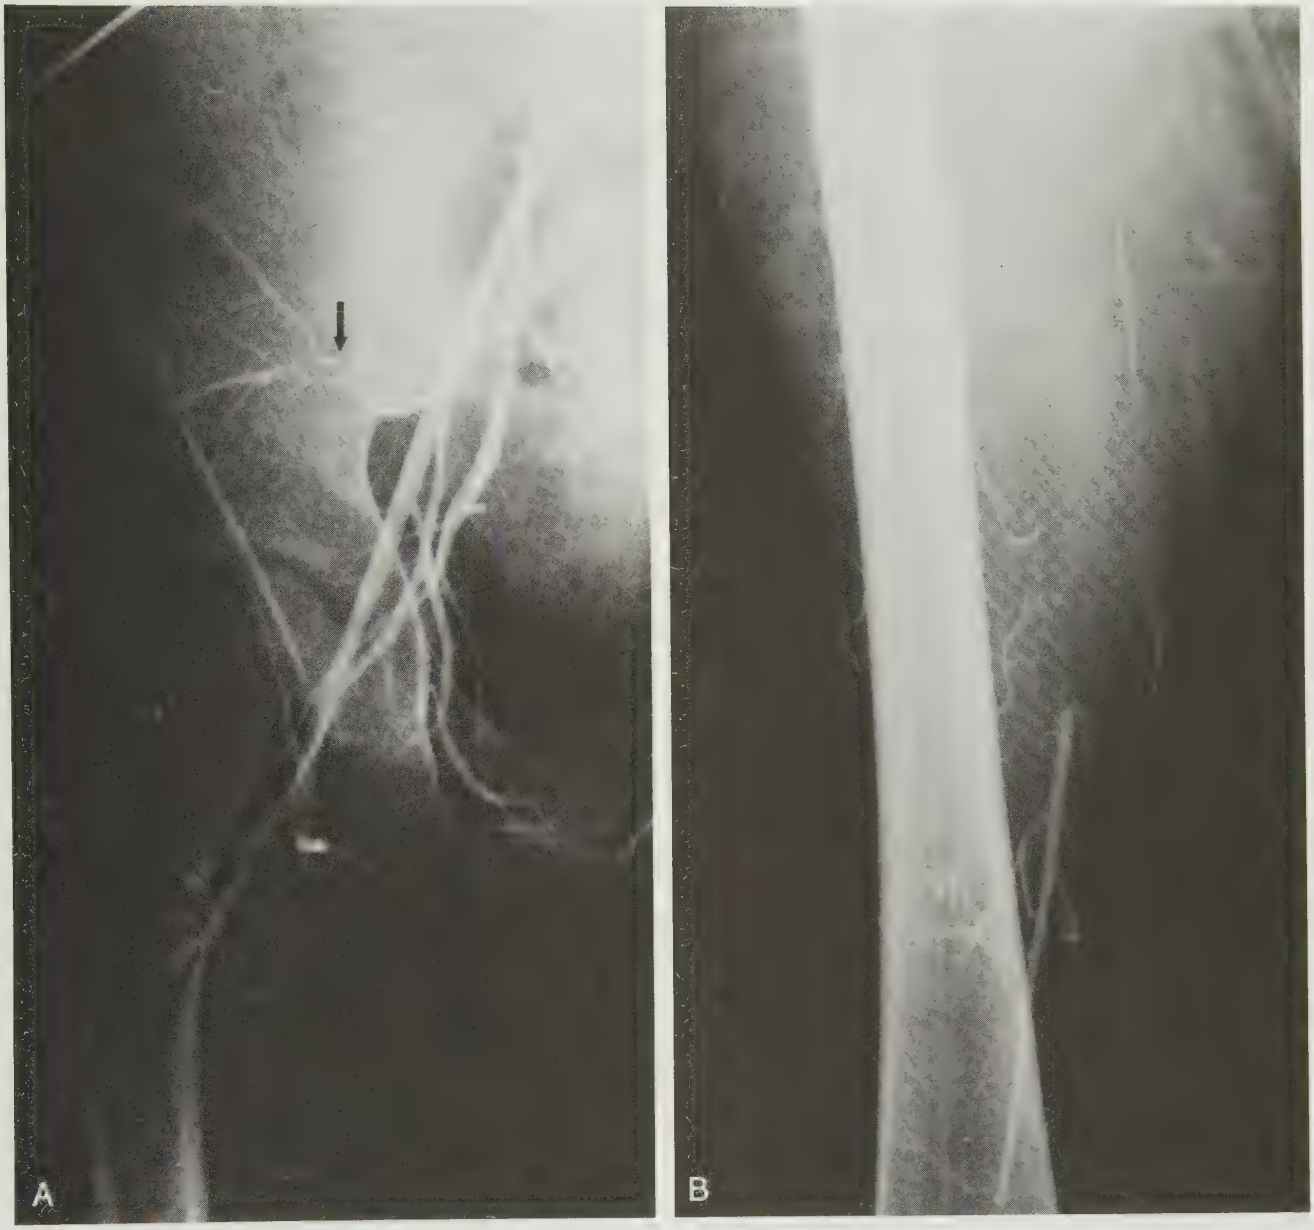

Fig. 57–23. Multiple emboli to the internal iliac (arrow), profunda femoris (A) and superficial femoral (B) arteries secondary to subacute bacterial endocarditis.

Pseudoaneurysms of the arteriovenous anastomosis or graft are commonly observed, and are related to dialysis trauma.

Transluminal angioplasty of dialysis access stenosis has been reported by several authors.[135,137–139] The procedure is best attempted via direct puncture of the venous side of the anastomosis and subsequent anterograde or retrograde passage of the catheter through the site of narrowing. Balloon sizes are generally chosen to be 1 mm larger than the expected normal luminal caliber. High-pressure balloons are often necessary to eliminate pressure gradients across stenotic foci related to dense fibrosis.

MISCELLANEOUS DISORDERS

As previously discussed, emboli to the peripheral vasculature may be secondary to umbilical artery catheters used in the neonatal period. In later childhood and adolescence, friable valvular vegetations of bacterial endocarditis are the most common source of peripheral emboli (Fig. 57–23). Emboli related to an aneurysm or tumor are rare.

Peripheral arterial aneurysms are most frequently posttraumatic, although they have been described in Ehlers–Danlos syndrome, polyarteritis nodosa,[140] Kawasaki disease, and fibromuscular hyperplasia. Mycotic aneurysms more commonly involve the aorta, though infrequently they occur peripherally.

Angiographic evidence of peripheral arteritis, namely contour irregularity with abnormal tapering, may be seen in the necrotizing vasculitides of which polyarteritis nodosa is the prototype. This entity is covered in the discussion on renal angiography.

Vasospastic disorders such as Raynaud's disease are associated

with spasm and occlusive changes in the medium and small vessels of the extremities. When found in association with an underlying disorder such as rheumatoid arthritis or systemic lupus erythematosus, it is referred to as Raynaud's phenomenon. A triphasic disorder consisting of initial vasoconstriction (digital pallor) followed by relaxation of the capillaries and venules (cyanosis) and reactive hyperemia (rubor) is clinically observed. This sequence is initiated by cold or emotional stimuli. Angiographically, proximal vessels are normal; distally, intense spasm or occlusion of medium-sized and small vessels is present.

THE FUTURE

One of the most promising vascular imaging methods to be developed in recent years is magnetic resonance imaging (MRI). The high inherent contrast between the arterial lumen and surrounding soft tissue lends itself to the generation of an MRI "angiogram" when a thick-slice technique is used.[141] Resolution, expense, and time requirements are presently suboptimal, although they will improve as new techniques such as narrow flip-angle excitation with gradient refocusing are used.[142] Examination of the aorta and its major branches with MRI is now possible; further refinements are expected to obviate and/or complement angiography in imaging smaller and more peripheral arteries.

Expandable metallic vascular stents designed by Gianturco[143] and Palmaz[144] are being evaluated for use in both arteries and veins. Rather large introducing sheaths are required for their placement, which may limit their application in infants. In older children, these stents will likely have a favorable impact in the therapy of pulmonary, aortic, and branch-vessel stenoses, particularly in Takayasu's disease and neurofibromatosis.

Introduction of low-osmolarity contrast agents into clinical practice has been received with great enthusiasm. Ongoing research in this field will undoubtedly result in the approval of newer solutions that are iso-osmolar to plasma, without sacrificing iodine content. It is hoped that this may be achieved at a substantial reduction in cost and result in a safer agent. Iotrolan, a high-molecular-weight nonionic dimer, is one of several such compounds currently undergoing clinical trials in Europe.[8]

Finally, it is well known that local complications at the puncture site may be minimized by using the smallest possible catheter. A minipuncture catheterization technique has been recently described by Cope et al.,[145] which may be helpful in achieving this end. Double-lumen angioplasty catheters with smaller shafts are being developed; balloons up to 8 mm in diameter on 5 French shafts have recently been introduced (Medi-Tech, Inc., Watertown, MA) and will perhaps become even more streamlined for less traumatic introduction into the vascular system in future years.

UNIT 4

STRUCTURAL CONGENITAL CARDIOVASCULAR DEFECTS

CHAPTER 58

Clinical Physiology of Left-to-Right Shunts

Madeline S Mas
J Timothy Bricker

The purpose of the four clinical physiology chapters of this text (Chapters 58, 62, 70, and 76) is to provide a brief overview for the beginning student of congenital heart disease. It is expected that these chapters, written at the level of the pediatric resident, will supply some introductory concepts and serve as a framework for the concepts and references discussed in greater detail in the chapters of the book that follow. It is also hoped that these four brief chapters might help the more experienced trainee in pediatric cardiology solidify concepts important in patient management.

Although there are limitations inherent in the reduction of complex physiology to simple prototypes, this is often helpful in the attempt to ascertain the physiologic importance of a cardiac defect in a specific patient. There is a seemingly infinite number of rare variants of complicated types of malformations, but it is relatively easy to reduce the defects to those with one of five types of physiology: left-to-right shunts, right-to-left shunts, transposition physiology, obstructive lesions, and regurgitant lesions. Thus, the patient with a single ventricle who does not have pulmonary stenosis can be understood in consideration of his or her left-to-right shunt physiology regardless of whether the great arteries are transposed and in spite of very complicated atrial or ventricular anatomy. Of course, it is possible for several of these types of physiology to coexist in the same patient. For example, the patient with truncus arteriosus may have the physiology of a left-to-right shunt from unrestricted blood flow to the pulmonary arteries and also have physiology similar to a patient with aortic regurgitation from an associated problem: severe truncal valve regurgitation. It is also likely that a specific category of structural cardiac defect will include patients with different types of physiology. For example, some infants with truncus arteriosus will have increased pulmonary blood flow and severe pulmonary edema similar to other patients with a large left-to-right shunt. However, those infants with truncus arteriosus and severe stenosis of the pulmonary ostia will have the physiology of a right-to-left shunt.

DEFINITION OF A LEFT-TO-RIGHT SHUNT

The patient with a left-to-right shunt has a higher blood flow to the pulmonary circulation than to the systemic circulation. The difference between the amount of blood delivered to the pulmonary circulation and that delivered to the systemic circulation equals the amount of already-oxygenated blood that is pumped back to the lungs, which equals the left-to-right shunt. The volume of deoxygenated blood delivered to the pulmonary circulation per minute is the usable or ''effective'' pulmonary blood flow. Calculation of the effective pulmonary blood flow and total pulmonary blood flow (Q_p) at cardiac catheterization is usually done with application of the Fick equation (Table 58–1) as discussed in Chapter 54. The left-to-right shunt is the total pulmonary blood flow minus the effective pulmonary blood flow. The pulmonary to systemic flow ratio (Q_p/Q_s) can be calculated without calculation of flows.

DETERMINANTS OF THE MAGNITUDE OF A LEFT-TO-RIGHT SHUNT

Clinical features of a left-to-right shunt are influenced by a number of variables. Included are the age of the patient, the anatomic location of the shunt, the size of the communication, and

Table 58–1. Calculation of Left-to-Right Shunt

1. Left-to-right shunt = $Q_p - Q_{ep}$
2. Q_p = pulmonary blood flow = $\frac{\text{Oxygen uptake}}{(\text{Pulm. artery } O_2 \text{ content} - \text{Left atrial } O_2 \text{ content})}$
3. Q_{ep} = effective pulmonary blood flow = $\frac{\text{Oxygen uptake}}{(\text{Pulm. venous } O_2 \text{ content} - \text{Mixed venous } O_2 \text{ content})}$
4. Pulmonary to systemic flow ratio = Q_p/Q_s = $\frac{\text{Aorta saturation} - \text{Mixed venous saturation}}{\text{Pulm. vein saturation} - \text{Pulm. artery saturation}}$

the relative resistances of the right- and left-sided circulations (Table 58–2). This chapter will furnish a brief overview of how these physiologic variables relate to the clinical features of the patient with a left-to-right shunt.

Age and Maturity of the Patient

The age and maturity of the patient influence the clinical features of a left-to-right shunt. The premature infant, because of relatively undeveloped pulmonary arteriolar musculature, develops a larger left-to-right shunt than does a more mature patient. A relatively small patent ductus arteriosus or ventricular septal defect in the premature infant may result in severe pulmonary edema. In contrast, a large ventricular septal defect or atrioventricular canal in a full-term newborn infant may be asymptomatic because of the high pulmonary vascular resistance that is present at the time of birth. The full-term infant with a large ventricular septal defect or atrioventricular canal is likely to develop symptoms of pulmonary edema by 4 to 6 weeks of age as pulmonary vascular resistance diminishes. Clinical manifestations of excessive pulmonary blood flow can develop such that surgical therapy in infancy is required.

In the era before surgery was available for these babies, those who survived infancy were observed to improve eventually in most cases. Typically there was a "golden period" between the severe heart failure of early infancy and symptomatic pulmonary vascular obstructive disease in the second decade of life. During this "golden period," the child developing pulmonary vascular disease was hemodynamically well balanced with minimal symptoms. Sequelae of pulmonary vascular obstructive disease developed in the older patient who had a left-to-right shunt earlier in life including cyanosis, hemoptysis, symptomatic right-sided heart failure, arrhythmias, and sudden death. A left-to-right shunt that is well tolerated in youth can become symptomatic with aging even without developing vascular disease. The shunt that was tolerated earlier in life may cause exercise intolerance, congestive heart failure, arrhythmias, or exacerbation of ventricular dysfunction in the older individual. Right-to-left shunting without pulmonary vascular disease may develop as a consequence of aging.

Table 58–2. Factors that Influence Clinical Features of a Left-to-Right Shunt

Age of the patient
Anatomic location of the shunt
Size of the communication between systemic and pulmonary circulation
Pulmonary and systemic resistance ratios (for post-tricuspid shunts)
Instantaneous interatrial pressure differences affected by compliance differences between the atria, differences in pulmonary and systemic venous compliance, and ventricular filling (for pretricuspid shunts)

Table 58–3. Pretricuspid Left-to-Right Shunts

Atrial septal defect
Secundum type
Primum type
Sinus venosus type
Coronary sinus type
Inferior vena caval type
Totally anomalous pulmonary venous connections, unobstructed
Partially anomalous pulmonary venous connection

Anatomic Location of the Shunt

The anatomic location of a left-to-right shunt will influence the clinical presentation. Lesions can be conveniently categorized as those resulting in a pretricuspid or a post-tricuspid left-to-right shunt (Tables 58–3 and 58–4). The prototype pretricuspid left-to-right shunt is the atrial septal defect. Typically, the patient with a pretricuspid shunt is mildly symptomatic or asymptomatic in infancy. There is usually increased pulmonary blood flow without pulmonary hypertension. Right ventricular volume overload results in right ventricular hypertrophy. The increased flow across the tricuspid valve causes a low-frequency diastolic rumble in the tricuspid area. Even with a high pulmonary-to-systemic flow ratio, in a pretricuspid shunt the risk of development of pulmonary vascular obstructive disease is low. Determinants of the magnitude of a pretricuspid left-to-right shunt include whether there is obstruction between the left- and right-sided circulations (e.g., the size of an atrial septal defect), the systemic and pulmonary venous capacitance, and the diastolic compliance of the right ventricle. The physiology of the left-to-right shunt in the atrial septal defect patient is discussed further in Chapter 60.

The prototype post-tricuspid left-to-right shunt is the ventricular septal defect. A patient with a large post-tricuspid shunt typically develops symptomatic pulmonary edema in infancy. Increased pulmonary blood flow is associated with pulmonary artery systolic hypertension unless the communication between the left- and right-sided circulation is stenotic. Volume overload of the left ventricle leads to left ventricular hypertrophy. Increased pulmonary venous return to the left atrium leads to excessive flow across the mitral valve and causes a low-frequency, diastolic murmur in the mitral area. If the left-to-right communication is not stenotic, pulmonary artery systolic hypertension is expected and eventual development of pulmonary vascular obstructive disease may occur. Determinants of the magnitude of a post-tricuspid left-to-right shunt include the size of the left-to-right communication (e.g., whether the ventricular septal defect is stenotic), the systemic vascular

Table 58–4. Post-Tricuspid Left-to-Right Shunts

Ventricular septal defect
Ruptured sinus of Valsalva (into RV)
Truncus arteriosus
Aorticopulmonary window
Aorticopulmonary fistula
Patent ductus arteriosus
Atrioventricular canal defect with ventricular component

Table 58–5. Characteristics of "Obligatory" Left-to-Right Shunts

Gerbode defect—left ventricular-to-right atrial defect
Atrioventricular canal with left ventricular-to-right atrial component (e.g., mitral regurgitation with ostium primum atrial septal defect)

resistance, and the pulmonary vascular resistance. The pulmonary vascular resistance is dependent upon the pulmonary arteriolar resistance and the pulmonary venous pressure. The physiology of the patient with a ventricular septal defect is discussed further in Chapter 59.

The patients with a left ventricular-to-right atrial shunt are considered to have an "obligatory" shunt (Table 58–5). The anatomic size of the communication between the right- and left-sided circulations (and to a minimal extent, right atrial compliance) determines the magnitude of an "obligatory" shunt. This is called "obligatory" since the left ventricular systolic and diastolic pressures are higher than the right atrial pressures throughout the cardiac cycle, causing shunting that is unaltered by the pulmonary vascular resistance and diastolic filling of the right ventricle. For this reason, pulmonary artery banding will not successfully palliate a patient with an obligatory shunt. The left ventricular-to-right atrial shunt has clinical physiologic features similar to a ventricular septal defect with a superimposed increase in tricuspid flow and right ventricular volume overload. Risk of development of pulmonary vascular disease is similar to a pretricuspid shunt (Table 58–6).

Table 58–6. Generalizations about Features of Pre- and Post-Tricuspid Left-to-Right Shunts

	Pretricuspid Shunt	*Post-tricuspid Shunt*
Murmur	systolic; pulmonary flow	systolic; at shunt
	diastolic; tricuspid rumble	disastolic; mitral flow rumble
Symptoms	uncommon in infancy	common in infancy
Pulmonary hypertension	unlikely	likely, if not restrictive
Electrocardiogram	right ventricular hypertrophy	left ventricular hypertrophy
Volume overload	of right ventricle	of left ventricle

Relative Resistances of the Right- and Left-Sided Circulations

The amount of left-to-right shunt in a patient with a large patent ductus arteriosus or aorticopulmonary window will decrease if pulmonary vascular resistance increases. The relative resistances of the pulmonary and systemic vascular beds determine the amount of left-to-right shunt in the case of a nonrestrictive communication at the level of the great arteries. For a shunt at the level of the ventricles which is nonrestrictive and in which there is not outflow obstruction of either ventricle, the magnitude of the shunt is also determined by the pulmonary and systemic resistances.

The magnitude of the shunt with a large atrial septal defect is determined by the instantaneous pressure differences between the right and left atrium during the cardiac cycle. Factors that affect these atrial pressures include the compliance of the atria, the resistance to ventricular filling (due to the diastolic compliance of the ventricle or due to an anatomic obstruction to ventricular filling), and the capacitance of the venous circuit to which the atrium is connected. It has been shown that one can find a right-to-left shunt across the atrial septal defect during some phases of the cardiac cycle (during and immediately after atrial systole) even though the net shunt is left-to-right as discussed in Chapter 60.

DEVELOPMENT OF PULMONARY VASCULAR OBSTRUCTIVE DISEASE

Pulmonary vascular obstructive disease is a devastating complication of left-to-right shunts. This important topic is discussed in great detail in Chapters 21 and 116 of this text. The tendency to develop pulmonary vascular obstructive disease involves a number of variables. The patient who has a post-tricuspid shunt that is anatomically large (and thus under high pressure) is at greatest risk for developing vascular disease. Pulmonary vascular obstructive disease does not usually occur at less than 1 year of age; however, vascular disease potentially develops as early as 6 months of age in patients with Down's syndrome and in patients in whom a cyanotic defect is associated with high pulmonary blood flow (e.g., tricuspid atresia with transposition, truncus arteriosus, or transposition of the great arteries with ventricular septal defect). Cardiac centers at high altitude have a much different clinical experience with their infants with anatomically large post-tricuspid communications than that which is observed in cardiac centers at sea level. Life at high altitude is associated with hypoxic pulmonary vasoconstriction (as discussed in Chapter 26), which decreases the severity of pulmonary edema in early infancy but increases the risk of children with left-to-right shunts being referred late and developing pulmonary vascular disease.

CHAPTER 59

Ventricular Septal Defect

Carl H Gumbiner
Atsuyoshi Takao

Ventricular septal defect (VSD) is the most common cardiac abnormality found in children. A practicing pediatric cardiologist encounters a patient with VSD nearly every day. Progress in the evaluation and management of ventricular septal defect over the past 40 years has paralleled and exemplified the evolution of pediatric cardiology as a medical discipline. Because of its frequency and because of the range of anatomic and physiologic disturbances that may constitute this abnormality, VSD remains a focus for the on-going evolution of anatomic terminology, invasive and noninvasive assessment technology, and therapeutic advancement. Management of the patient with ventricular septal defect represents both fundamental and state-of-the-art pediatric cardiology.

HISTORY

Although ventricular septal defect was a known anatomic entity much earlier, credit for its first clinical description is generally given to Roger's article published in 1879.[1] The phrase ''maladie de Roger'' is still used to refer to small VSD in the asymptomatic patient. When Eisenmenger described a patient with ventricular septal defect, cyanosis, and pulmonary hypertension,[2] this complex was regarded as a different and separate clinical entity. In her classic text, Abbott correlated the clinical findings of ventricular septal defect with the anatomic abnormality itself.[3] In an early attempt to explain the clinical differences among patients with VSD, Taussig attributed the presence or absence of symptoms to the location of the defect in the septum.[4] Later, studies began to relate the physiologic disturbance with the size of the defect in the septum.[5,6]

The earliest surgical treatment of ventricular septal defect was pulmonary artery banding.[7] Lillehei reported successful closure of VSD using the cross-circulation technique in 1955.[8] Soon thereafter, the advent of cardiopulmonary bypass made the intracardiac repair of ventricular septal defect a routine procedure. As surgical repair of VSD was becoming a reality, the effect of pulmonary vascular resistance on clinical course and surgical outcome was recognized.[9,10] In 1958, Heath and Edwards described the morphologic changes associated with pulmonary vascular disease,[11] and their six categories of vascular change have remained the standard of comparison to the present time. Lev's early descriptions of the anatomy of the conduction system in association with septal defects significantly enhanced surgical outcome by reducing the incidence of complete atrioventricular block.[12,13]

The technique of axial cineangiography provided the surgeon with far more specific preoperative delineation of the size, location, and number of defects.[14] Since 1979, real-time two-dimensional (2-D) echocardiography has dramatically improved the noninvasive anatomic assessment of ventricular septal defect and has resulted in an entirely new anatomic classification.[15–17]

DEFINITION

Although ventricular septal defect is one of the most common isolated congenital cardiac malformations, it is also frequently found in association with other lesions and found as part of more complex cardiac malformations. In this chapter, we consider VSD as an isolated condition, in the absence of a conotruncal malformation, and in the presence of two normally related ventricles. This discussion, therefore, does not include VSD as part of cono-

truncal malformations (i.e., persistent truncus arteriosus, transposition of the great arteries, tetralogy of Fallot, or double-outlet right ventricle). It also excludes all forms of univentricular heart and complete atrioventricular canal defect. We have also chosen to exclude discussion of VSD as part of a complex with associated lesions that are discussed elsewhere in this text, such as coarctation of the aorta and interrupted aortic arch.

Certain acquired conditions result from the presence of the ventricular septal defect itself, and therefore warrant consideration here. These include acquired right ventricular outflow tract obstruction, acquired left ventricular outflow tract obstruction, aortic regurgitation, and so-called aneurysm of the ventricular septum.

INCIDENCE AND PREVALENCE

Isolated ventricular septal defect accounts for approximately 20% of patients followed in large pediatric cardiology clinics.[18,19] In Mitchell's prospective study of 56,109 total births, the incidence of congenital heart disease was 8.14/1,000 births, and 29% of those children affected had ventricular septal defect.[20] Hoffman found a similar incidence of congenital heart disease and proportion of those with VSD.[21,22] Dickinson et al.[23] found the incidence of VSD in Liverpool to be 1.8/1,000 live births. Although most estimates have ranged from approximately 1.5 to 2.0/1000 live births,[18,22] evidence suggests that the incidence of ventricular septal defect in the United States has increased significantly in the past 15 years,[24] and may be as high as 2.6/1,000 live births.[25] This increased incidence is unexplained, but is not believed to be a function only of increased detection.[24]

ANATOMY

The nomenclature of ventricular septal defect has changed over the past decade due to the enhanced clinical ability to localize defects using the techniques of axial cineangiography and, more recently, real-time two-dimensional echocardiography. Precise localization of the defect, and the description thereof, is more than a semantic exercise. The location of the defect has implications for the likelihood of change in the size of the defect with time. Certain types of defects may predispose to secondary conditions, such as aortic regurgitation or subaortic obstruction. In a patient for whom surgery is contemplated, precise preoperative description of the defect may determine the surgeon's approach to the repair, usually tells him the relationship of the defect to the specialized conduction system, and helps determine the expected complications. Terminology must therefore facilitate communication between angiographers, echocardiographers, and surgeons, as well as embryologists and pathologists.

Roger's early description of ventricular septal defect was a clinical one with little anatomic reference.[1] Abbott described defects occurring in the subaortic region of the septum, or more rarely in the lower, muscular portion of the septum.[3] She noted a difference in location of the defect to be a determinant in the clinical course of the patient. Taussig's early text[4] described two types of defects: "simple" defects (maladie de Roger) and "high" defects with aortic override. Subsequent reports related clinical course to the size of the defect,[5,12,26] and the anatomic localization of defects included the concepts of "membranous" VSD and "outflow" VSD. Becu et al.[26] pointed out that the term "membranous" VSD was incorrect, but the phrase was widely used until the mid 1970's.

A clinically useful classification scheme divides ventricular septal defects into four types: I, II, III, and IV.[27] Type I, or so-called "supracristal" defects, lie just beneath the pulmonic valve and communicate with the right ventricular outflow tract above the supraventricular crest. They comprise approximately 5% of defects seen in this country,[19] and are associated with a significant incidence of aortic regurgitation. Type II defects, the "infracristal" or "membranous" defects, are the most common types found, accounting for up to 80% of defects.[19] Type III defects, located in the posterior region of the septum, beneath the septal leaflet of the tricuspid valve, are often associated with left axis deviation on the surface electrocardiogram, and are also referred to as "atrioventricular canal type" defects. Approximately 8 to 10% of ventricular septal defects are of this type.[19] Type IV defects, found in 5 to 20% of patients with VSD,[19] are bounded entirely by muscular septum and are often multiple. This scheme, while appealingly simple, has never been ideal for embryologists and anatomists, and is inadequate to describe the location and boundaries of the defects as they are delineated by current cineangiography and real-time 2-D echocardiography. It has been replaced with a somewhat complex, but more descriptive, classification[15–17,28–33] described below.

The intact interventricular septum is a complex, non-planar, helical structure which can be divided into four zones according to landmarks on its right ventricular aspect (Fig. 59–1A). The inlet septum is predominantly smooth walled and extends from the septal attachment of the tricuspid valve leaflets to the distal attachment of the tricuspid tensor apparatus. The apical trabecular zone separates the coarse trabecular portion of the right ventricle from the finely trabeculated left ventricular apical septum. The smooth-walled outlet, or infundibular, septum is separated from the trabecular portion of the septum by the septal band[26] or the trabeculae marginalis.[28,31] These three muscular zones radiate from the small membranous septum, which lies adjacent to the anteroseptal tricuspid commissure on the right side, and adjacent to the right posterior aortic commissure and anterior mitral valve leaflet on the left side (Fig. 59–1B). The term "crista supraventricularis" designates a muscular zone in the normal heart separating the tricuspid and pulmonary valves, as well as the pulmonary and aortic valves.[28] Defects in the ventricular septum may be adjacent to the membranous septum or may lie entirely within the muscular septum. Complete absence of the membranous septum seldom occurs with simple VSD. Furthermore, defects adjacent to the membranous septum have a partial margin consisting of muscle. For these reasons, the term "membranous" defect has been replaced by the more anatomically correct "perimembranous" defect. Perimembranous defects are divided into three major subtypes (Fig. 59–2A), according to the adjacent portion of muscular septum: perimembranous inlet, perimembranous trabecular, and perimembranous outlet defects.[15,28–31,33,34] Perimembranous inlet defects (included in other classifications as AV canal type defects and Type III defects) lie posterior to the septal leaflet of the tricuspid valve. Perimembranous trabecular defects comprise the most common group of simple VSDs, and are the majority of previously designated Type II defects. Perimembranous outlet defects comprise a portion of previously designated Type I defects (along with muscular defects of the outlet septum). Depending on

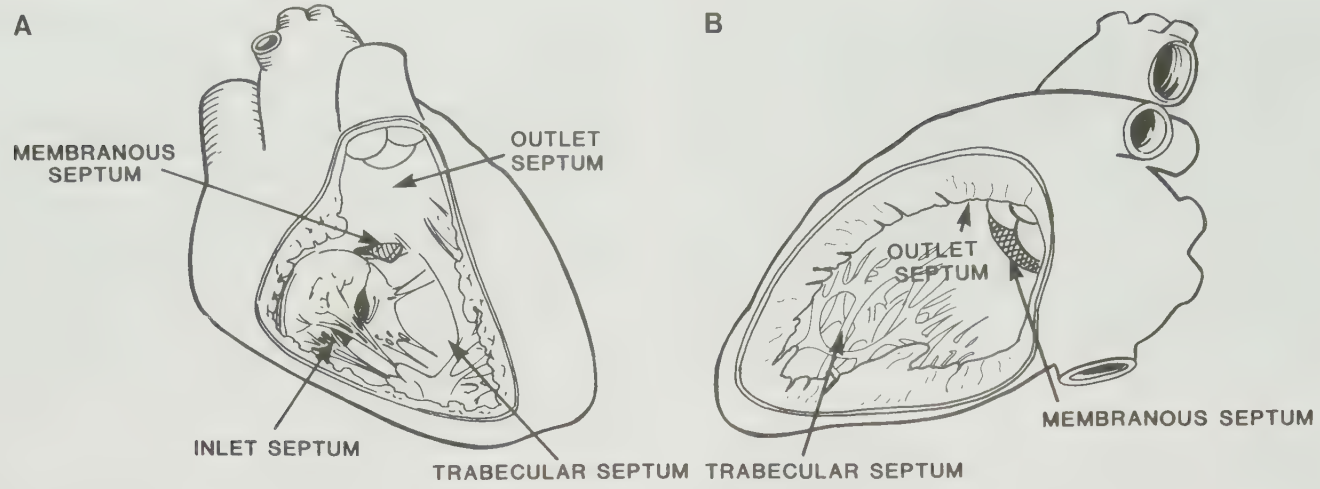

Fig. 59–1. Schematic representation of the regions of the ventricular septum from *A*. the right ventricular aspect, and *B*. the left ventricular aspect.

size and shape of a perimembranous defect, it may overlap two or more of the three categories. By virtue of adjacency to the membranous septum, all perimembranous defects are subaortic[33] (Fig. 59–2B).

Muscular ventricular septal defects, bounded entirely by a muscular rim, may also be divided into three categories: inlet, trabecular, and infundibular. Muscular trabecular defects (previously designated Type IV defects) may be multiple and have given rise to the graphic phrase "Swiss cheese septum."[35]

Defects of the outlet septum beneath the pulmonic valve have caused particular controversy in classification. The term "supracristal" defect is inaccurate because: a) position relative to the crista is, in fact, variable; b) the crista, a landmark of the normal septum, is often distorted or absent in the presence of ventricular septal defect; and c) the importance of defects in this position is not based on their position relative to the muscular crista, but to the semilunar valves. Often, these defects are termed "subpulmonic."[36] Perimembranous outlet defects are subaortic as well, however, so the presently preferred label is the somewhat cumbersome "doubly committed subarterial defect."[28,30,31,33] These defects, more common in Oriental populations,[37] often undermine the muscular support of the right coronary cusp of the aortic valve and may be associated with aortic regurgitation.

Defects of the inlet septum—particularly perimembranous inlet defects—may involve some degree of malalignment of the ventricular septum with the atrial septum. In such defects, there is generally overriding or straddling of the tricuspid or mitral valve.[15] Perimembranous defects of the outlet septum may be associated with malalignment of the ventricular septum with the infundibular septum.[15] This may occur occasionally in isolated VSD,[38,39] but is, of course, more usually associated with more complex conotruncal malformations, such as persistent truncus arteriosus or tetralogy of Fallot.

The relationship of the specialized atrioventricular conduction system to defects of the ventricular septum has been a subject of investigation since the early work by Lev[13] and Truex[40] in the late 1950s. This information is critical to the surgeon faced with repair of these defects. With perimembranous defects, and normally re-

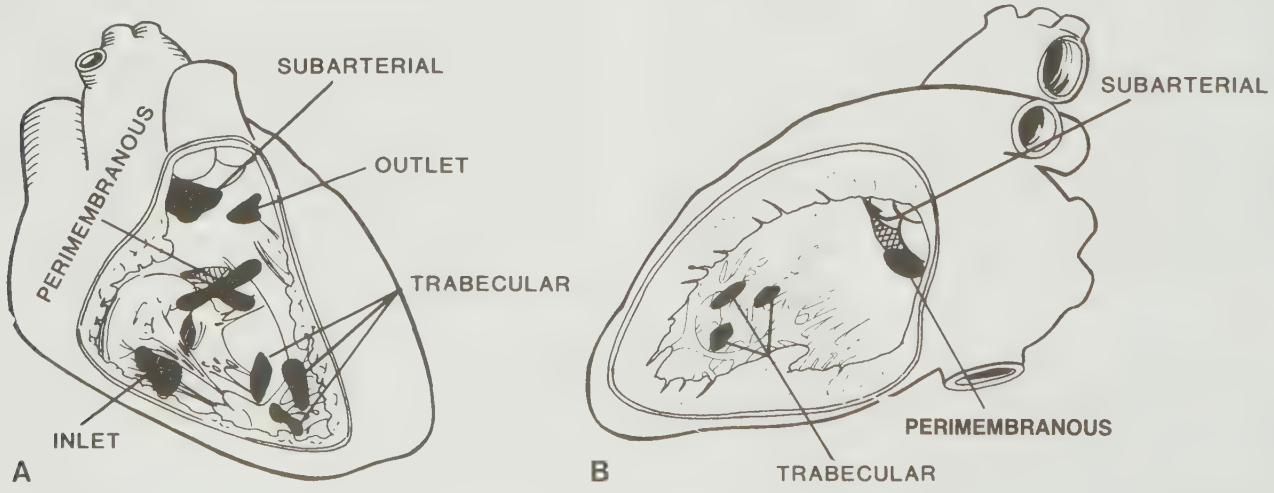

Fig. 59–2. Schematic representation of the location of various types of ventricular septal defect from *A*. the right ventricular aspect, and *B*. the left ventricular aspect.

lated ventricles, the atrioventricular conduction tissue is always related to the posterior inferior aspect of the defect itself.[13,28,31,40,41] In muscular defects, the atrioventricular conduction tissue maintains its position at the margin of the membranous septum and will hence lie superior and anterior to the defect[28,31] and usually separate from it. With ventricular inversion, the conduction tissue lies anterior to the VSD. This is discussed fully in Chapter 73.

Associated Conditions

Ventricular septal defect is present in many complex structural heart anomalies, which are considered elsewhere in this book. Certain associated conditions, however, arise because of the ventricular defect itself. These include secondary aortic regurgitation, subaortic obstruction, and right ventricular outflow tract obstruction.

Aortic regurgitation with ''doubly committed subarterial'' (type I) ventricular septal defect is a well-known association.[36,42–49] It is due to the poorly supported right coronary cusp, combined with a Venturi effect produced by the VSD jet.[50] Prevalence of this association is approximately 3% of ventricular septal defects in this country.[43] The incidence of subarterial ventricular septal defect (and associated aortic regurgitation) is substantially higher (up to 20 to 30% of patients with VSD) among Oriental populations.[36,37]

A less well-defined, and possibly less common, associated condition is ventricular septal defect with discreet fibrous subaortic stenosis. This has been described by several investigators[51–55] and may represent an incidental association[52] or, in many cases, may be a direct result of septal malalignment and secondary development of a fibrous ridge.[55] Its significance lies in the potential development of left ventricular outflow tract obstruction in patients with small or surgically corrected ventricular septal defect.

Right ventricular outflow tract obstruction occurs secondary to ventricular septal defect in 3%[56] to 7%[57] of patients. This is generally due to hypertrophy of anomalous muscle bundles,[58] although it may result from septal malalignment.[59]

Perimembranous ventricular septal defects are often associated with ''aneurysm'' of the ventricular septum.[60] This phenomena is thought, in part, to be responsible for the decrease in size and/or spontaneous closure seen in up to 40% of patients with these defects.[61] Morphologic,[62,63] angiographic,[64] and echocardiographic[65] studies have demonstrated such aneurysms rarely to be composed of septal tissue and most often composed of adherent or reduplicated tricuspid valve tissue.[63,65] This occurs most frequently with perimembranous trabecular defects, but this adherence of tricuspid valve tissue does not occur with defects of the outlet septum, which seldom close spontaneously. True aneurysm of the ventricular septum does occur occasionally and may produce right ventricular outflow tract obstruction.[66]

EMBRYOLOGY

The embryologic formation of the normal ventricular septum has been described in a number of elegant studies.[67–70] After cardiac looping at 23 to 25 days gestation, the primitive left ventricle, formed from the ventricular portion and the primitive right ventricle, formed from the proximal portion of the bulbis cordis, are connected by the primary interventricular foramen. Growth and trabeculation of the ventricles accounts for formation of the major portion of the muscular septum as the medial walls of the ventricles become apposed and fuse together.[68,69] While the ventricles enlarge, the atrioventricular canal moves rightward, such that the atria communicate with the primitive right ventricle. As this happens, the plane of the primary interventricular foramen shifts leftward, and, as the interventricular foramen II, it gives access from the left ventricle to the posteromedial portion of the conus cordis. The conus swellings appear at approximately the same time as the truncal swellings and the atrioventricular cushions. They ultimately merge to form the conus septum, separating the conus cordis into the anterolateral and posteromedial portions.

The conus septum also separates the interventricular foramen (now foramen III) from the AV canal. Completion of the interventricular septum is accomplished by fusion of endocardial cushion tissue from the conus septum, with the superior portion of the muscular septum and a portion of the right superior endocardial cushion.[67,68] With this fusion, the interventricular foramen III is closed. Later, this portion of the septum thins to become the membranous interventricular septum.

The formation of the membranous and perimembranous septum is a late and multifaceted developmental event and is subject to numerous aberrations that may manifest later as perimembranous ventricular septal defect.[70] Defects of the outlet septum are felt to represent failure of fusion of portions of the conus septum.[67] Inlet defects may represent failure or complete fusion of the right superior endocardial cushion tissue with the muscular septum. Muscular defects, particularly in the trabecular septum, are probably due to excessive excavation of the septum during the growth of the ventricle, or inadequate merger of the medial walls of the ventricles.

PHYSIOLOGY

The presence of a defect in the ventricular septum, and the consequent communication between the systemic circulation and the pulmonary circulation at that level, may have two adverse effects: altered hemodynamics because of a left-to-right shunt, and an altered pulmonary vascular bed. While mutually related, these are separate effects that are best considered individually.

The phrase ''left-to-right'' shunt implies the recirculation of oxygenated (pulmonary venous) blood through the pulmonary capillary bed. When it occurs at the ventricular level, the magnitude of left-to-right shunting is dependent upon the size of the ventricular septal defect and upon the resistance in the pulmonary vascular bed. Defects are generally divided into three categories: small, moderate and large, based not only on physical size, but also on circulatory dynamics, although there is a general correlation between the two. Various distinguishing criteria have been proposed.[18,19,71–73] Small defects limit flow and restrict pressure equalization between the ventricles. The left-to-right shunt is small, and right ventricular pressure is normal or minimally elevated. Large defects offer little resistance to flow and have equal pressure in the ventricles. The magnitude of the left-to-right shunt is entirely dependent on relative pulmonary and systemic vascular resistance. Anatomically, large defects are those equal to or greater in size than the cross-sectional area of the aortic root.[71] Moderate-size defects are those that offer resistance to pressure, but usually little resistance to flow. The right ventricular pressure is less than that of the left ventricle, but is often elevated above normal. In moderate defects, the magnitude of the left-to-right shunt is dependent

on both the size of the defect and the pulmonary vascular resistance.

There has been considerable discussion on the influence of the location of the VSD on its physiologic effect.[10] Presently there is little evidence to suggest that location of the defect (e.g., muscular trabecular vs. perimembranous outlet) is a significant determinant of either shunt or resistance, per se. A question has also been raised about the effect of change in size or shape of the defect with septal contraction during the cardiac cycle. This phenomenon occurs with small defects, but is probably insignificant with moderate or large ones. It may well influence the murmur characteristics of small defects, but is probably irrelevant to hemodynamic considerations.

A left-to-right shunt at the ventricular level has three adverse hemodynamic consequences: 1) left ventricular volume overload, 2) pulmonary overcirculation, 3) compromise of systemic cardiac output. The increased volume demand on the left ventricle results in dilation and hypertrophy. The former produces elevation of end-diastolic pressure by virtue of the familiar length-tension relationship.[74] The latter minimizes wall tension increase, but, by altering myocardial compliance, further aggravates the increase in end-diastolic left ventricular pressure. This elevation in end-diastolic pressure is reflected in increased left atrial pressure and consequently in pulmonary venous pressure.

Pulmonary overcirculation tends to increase the pressure in the pulmonary capillary bed, altering its pressure relationship with the pulmonary interstitial space. An abnormal equilibrium is established, with a resultant increase in pulmonary interstitial fluid.[75] This alters pulmonary compliance[76] and, to a lesser extent, pulmonary gas exchange. In its severe form, increased pulmonary interstitial fluid may manifest as frank pulmonary edema, but lesser degrees of interstitial edema also have an adverse influence upon pulmonary function.

The increased pressure of the pulmonary capillary bed is a function of both pulmonary overcirculation and elevated pulmonary venous pressure, due to left ventricular volume overload. This is evident from observation of patients with other conditions. The pulmonary overcirculation associated with atrial septal defect tends to have less effect on pulmonary compliance largely because the left atrium is "vented" and the left ventricular end-diastolic pressure is not elevated.[75] Conversely, myocardial abnormalities producing only modest elevation of left-sided filling pressures are often well tolerated in the absence of pulmonary overcirculation.

Pulmonary recirculation by the left ventricle is accomplished at the expense of systemic blood flow or cardiac output. Compensatory mechanisms maintain organ perfusion and blood pressure. These include increased circulating catecholamines and increased activity of the sympathetic nervous system, both serving to increase systemic vascular resistance. Decreased renal blood flow tends to evoke the retention of sodium and water retention via the renin-angiotensin system.[77] This, in turn, raises both systemic and pulmonary venous pressure, promoting formation of both systemic and pulmonary interstitial edema.

The magnitude of these effects is a function of the size of the left-to-right shunt, which is, as mentioned above, dependent upon pulmonary vascular resistance, as well as anatomic size of the ventricular septal defect. The terms "pulmonary hypertension," "high pulmonary resistance," and "pulmonary vascular disease," often used interchangeably, must not be confused with each other. As pressure is determined by flow and resistance, elevated pulmonary artery pressure (i.e., pulmonary hypertension) may result from a predominant increase in flow or from a predominant increase in resistance. In the former, a VSD with pulmonary hypertension may manifest all the physiologic consequences of a large left-to-right shunt. With high resistance, however, a VSD with pulmonary hypertension may show little evidence of LV volume overload or pulmonary interstitial fluid formation.

Pulmonary resistance is a function of numerous factors, including age,[78] altitude,[9] hematocrit,[79] level of activity,[80] and structural integrity of the pulmonary vascular bed.[11,81,82] It should not be equated with pulmonary vascular obstructive disease—one cause of elevated pulmonary vascular resistance. Pulmonary vascular resistance is elevated in the normal newborn,[22,71] and clinical manifestations of left-to-right shunting are unusual in this age group. This elevation of resistance is primarily due to increased medial wall thickening of muscular arterioles,[83,84] although Lister et al.[78] pointed out the effect of increased hematocrit in those infants as well. Premature infants are prone to a more early manifestation of left-to-right shunting, presumably because of decreased development of small, muscular arterioles.[84]

Pulmonary vascular resistance usually declines in the first three months of life, with increase in flow, although this process is inhibited in the presence of an existing left-to-right shunt, lung disease, or residence at higher elevations. Vogel et al.[9] compared the incidence of symptomatic congestive heart failure among infants with ventricular septal defect living in Colorado with those living in Texas. They found significantly fewer patients demonstrating congestive heart failure and attributed this phenomenon to the lower oxygen tension in Colorado and its effect on pulmonary vascular resistance.

Pulmonary vascular disease, as described by Heath and Edwards[11] and others[8,82,85] may develop as a consequence of left-to-right shunting. This usually follows a period of decreased resistance and high flow, but may occur in patients who never manifest a large left-to-right shunt.[86,87] The ultimate consequences of pulmonary vascular obstructive disease are irreversible vascular changes and pulmonary resistance equal to or exceeding systemic resistance. The latter causes reversed shunting (right-to-left) at the ventricular level and systemic arterial oxygen desaturation, or cyanosis. This combination of ventricular septal defect, pulmonary vascular disease, and cyanosis is termed Eisenmenger's complex.[10] In combination with other systemic-pulmonary communications, pulmonary vascular disease and cyanosis are referred to as the Eisenmenger syndrome.[10]

Experimental Models

Several investigators have successfully created animal models of ventricular septal defect for evaluation of left-to-right shunt physiology, medical intervention, and diagnostic techniques. Strains of animals with congenital VSD have not been reported; but surgically created defects have been reported since 1925.[88] Griffin and Essex were able to create defects of known size in dogs and study their chronic effect on blood volume, hemoglobin, and the dogs' electrocardiograms.[88]

In 1970, Mesel reported a study of acutely instrumented dogs in which electromagnetic flow probes were wedged into surgically created ventricular septal defects.[89] He correlated flow across the defect with pulmonary blood flow measured by the Fick technique.

He also demonstrated flow across the defect, amounting to 15 to 25% of total left-to-right shunt.[89]

Syndhorst et al., also using an acute canine model, created ventricular septal defects of known size by insertion of a flanged prosthesis into the muscular septum.[90] They demonstrated a salutary effect on left-to-right shunt hemodynamics with pharmacologic lowering of systemic vascular resistance. Boucek et al. reported similar findings with afterload-reducing agents administered to chronically instrumented lambs with surgically created ventricular septal defects.[91] Their work is particularly significant for their use of an immature animal model of what is, from a therapeutic standpoint, basically a pediatric condition. Sherman et al. used a VSD model in open-chested dogs to assess the utility of color-flow Doppler mapping in detection of ventricular septal defect.[92] The near future will doubtless see other investigators making use of animal models—most probably chronic models in immature animals—to assess newer diagnostic and therapeutic techniques.

CLINICAL MANIFESTATIONS

The clinical presentation and manifestations of children with ventricular septal defect have been reviewed in numerous articles and texts.[6,18,19,22,71,93,94] The wide spectrum of symptoms and physical findings relates to the size of the defect and the magnitude of the left-to-right shunt.

Small Defects

Small defects are associated with mild symptoms or, more commonly, with none at all. Patients most often come to the attention of the cardiologist because of a murmur detected on routine examination or at the time of an incidental illness. Pulmonary vascular resistance, elevated in the normal newborn, declines rapidly over the first few weeks of life,[71] creating a large pressure-gradient between left ventricle and right ventricle, usually with a loud murmur. The murmur is most often detected between 2 and 6 weeks of age. Not infrequently, however, it may be heard in the second or third day of life, prior to dismissal from the newborn nursery. In these cases, one can infer a very rapid decline in pulmonary vascular resistance, and almost invariably, a small defect. Other conditions producing a murmur that mimics that of VSD must be excluded, especially tricuspid regurgitation. A murmur heard in the first 18 hours of life is seldom due to isolated ventricular septal defect. Murmurs that appear later than the fourth month of life are seldom due to isolated small VSD. Late appearance of the murmur implies a delayed decline in pulmonary vascular resistance, and hence a larger defect or a different lesion. Of course, a murmur may be overlooked in the examination of a crying child, so attention must be paid to the frequency and circumstances of prior examinations. The murmur of small ventricular septal defect does not appear de novo in a child older than 6 months.

A small ventricular septal defect usually causes no symptoms. While a small left-to-right shunt may slightly alter pulmonary compliance with resultant mild tachypnea, this does not usually interfere with feeding or normal weight gain. In the older infant and child, the presence of symptoms is inconsistent with the diagnosis of small VSD.

The abnormal physical findings are primarily those of the cardiac examination. With the possible exception of mild tachypnea, the vital signs are usually normal. The lungs are clear. There is little evidence of systemic fluid retention and no jugular venous distension, hepatomegaly, or edema. Physical assessment of cardiac size in an infant is difficult. The precordial impulse may be mildly hyperactive, or most often is normal, although a systolic thrill along the left sternal border may be present. The second heart sound may be obscured entirely by the murmur, but when audible is of normal intensity. Physiologic splitting of second heart sound is usually present, but is often difficult to appreciate in the infant.

The murmur of ventricular septal defect is characteristically a harsh holosystolic murmur, heard loudest along the lower left sternal border. Small defects tend to produce a murmur of a somewhat higher pitch, but this is not a constant feature. On the other hand, a high-pitched or "squeaky" holosystolic murmur implies a small defect. The murmur may have a marked change in quality during systole or may not be holosystolic. This is most often due to change in size or shape of the defect with septal contraction and, once again, implies a small defect.

The location of the murmur is variable. Loud murmurs are usually heard over the entire precordium, and occasionally may be referred to the back. Localization of the murmur to the left third or fourth intercostal space also implies a small defect. Some observers have associated a murmur low along the left sternal border with a muscular defect, and a murmur heard high along the left sternal border with an outlet defect,[95] but these features are inconsistent and quite dependent upon the examiner. In older infants and children, small ventricular septal defect does not produce a diastolic murmur. In small infants, a soft diastolic filling sound may be present along the lower left sternal border. A louder flow rumble implies a larger defect with a significant left-to-right shunt.

Moderate-Size Defects

In the presence of a moderate size ventricular septal defect, the normal decline in pulmonary vascular resistance is somewhat delayed,[22,71] so detection of a murmur in the newborn period is uncommon. More often, a murmur is detected between 2 and 6 weeks of age, and may change in quality over several weeks as resistance continues to fall. The appearance of the murmur usually precedes the presence of significant symptoms in the child, but depending on the time of its detection, signs and symptoms may or may not be present.

Early signs of moderate size ventricular septal defect may be subtle and may suggest a small defect. These include mild tachypnea and mild tachycardia. As left-to-right shunting increases, signs and symptoms become more evident. Pulmonary compliance is abnormal, so that tachypnea is usually present and may be associated with increased work of breathing. This is especially true during feeding, with consequent compromise of caloric intake and resultant poor weight gain. With decreased pulmonary compliance there is frequently a history of one or more episodes of pneumonia, often as the presenting complaint leading to the detection of a murmur. Upper respiratory infections are also a frequent complaint, although this rather subjective observation is less easy to relate to the physiologic disturbance of a left-to-right shunt.

Sweating, especially with feeding, is a frequent manifestation of congestive heart failure in infants and is due to increased activity of the sympathetic nervous system. This finding is valuable in

very young infants, but is extremely nonspecific in infants greater than six months of age. If an infant "sweats the bedclothes through," this is more likely to be significant.

Physical findings with moderate size VSD reflect the size of the left-to-right shunt and degree of congestive heart failure. While moderate size defects tend to have smaller shunts than large defects (depending on resistance), the classification of the defect as moderate does not preclude significant congestive heart failure. The infant may be tachypneic but only rarely has intercostal or suprasternal retractions, or expiratory grunting. Resting heart rate is increased. The infants usually show poor weight gain. Often the decline in weight percentile has its onset at 2 to 4 months, reflecting the time of fall of pulmonary vascular resistance. Longitudinal growth is usually normal. Because of compromised systemic output and vasoconstriction, the infants may be pale and are often diaphoretic. Peripheral pulses are usually normal. There may be prominent neck veins in the upright position. The liver is usually palpable and may be significantly enlarged with a firm, rounded margin. Splenomegaly usually does not accompany significant hepatomegaly. Pulmonary rales may be present but are a late finding and indicate marked congestive heart failure or pneumonia.

The precordial impulse is increased in intensity and a precordial thrill is often present. The first heart sound is normal, and the second heart sound is usually obscured. If audible, the second heart sound may be single or narrowly split, with an accentuated pulmonary component. The harsh holosystolic murmur is usually low in pitch and can be heard over the entire precordium, the loudest at the lower left sternal border. A diastolic filling sound is often present. A low-pitched, mid-diastolic rumble, thought to be due to increased flow through the mitral valve, is present if the left-to-right shunt is large. Clinicians often relate the presence or absence of a flow rumble to the size of the shunt, and it is felt that a flow rumble is rarely evident with pulmonary-to-systemic flow ratios of less than 2:1.

Older children with moderate size defects do not develop signs and symptoms of congestive heart failure. Those with large left-to-right shunts manifest symptoms earlier and are treated or improve. Those with elevated pulmonary vascular resistance may present to the clinician later, but do not demonstrate evidence of congestive heart failure (see below).

Large Defects

The manifestations of large ventricular septal defect are similar to those of moderate size defects with high flow. Presentation is often delayed until the third or fourth month of life, when pulmonary vascular resistance falls. At that time, signs and symptoms of congestive heart failure may rapidly progress. They include the respiratory symptoms mentioned above, along with poor weight gain, diaphoresis, and frequent lower respiratory tract infections. These infants are often irritable. When failure is severe and long-standing, longitudinal growth may be impaired, as well as weight gain.

Likewise, physical findings are those of congestive heart failure with tachycardia, tachypnea, neck vein distension, and hepatomegaly. If failure is severe or if there is superimposed pneumonia, there may also be retractions and grunting. Peripheral edema is unusual in infants, even with severe congestive heart failure, and pulmonary rales are a late finding.

Precordial activity is increased, with a left parasternal lift. A systolic thrill is less common with a large defect than with a moderate defect—relating the thrill less to the flow across the defect than to the pressure gradient. The murmur is a low-pitched, holosystolic sound, poorly localized, and there is usually a diastolic flow rumble audible at the lower left sternal border.

Ventricular Septal Defect with High Pulmonary Vascular Resistance

The typical manifestations of ventricular septal defect—the harsh holosystolic murmur and evident congestive heart failure—are dependent upon substantial left-to-right shunt through the defect. In children with large defects (and occasionally moderate size defects) with high pulmonary vascular resistance, findings may be far more subtle, or may be different entirely. As mentioned, the normal elevation of pulmonary vascular resistance in the newborn delays the appearance of a murmur and the appearance of symptoms at that time. Careful palpation of the precordium in these infants will disclose a prominent right ventricular impulse, and auscultation reveals an enhanced second heart sound. Similar findings will be present in older infants in whom persistent elevation of pulmonary vascular resistance precludes the appearance of a typical holosystolic murmur. These infants may display respiratory symptoms and impaired weight gain, or may be asymptomatic. Referral to a cardiologist is often late because of the absence of significant murmur. Occasionally, parents will report the child to have cyanosis, especially with crying, indicative of right-to-left shunting through the defect.

Older children with large ventricular defect and pulmonary vascular obstructive disease have little complaint of respiratory symptoms, except with exertion. They may be only mildly cyanotic at rest, but develop profound reduction in O_2 saturation with exercise, which they tolerate poorly. There is often clubbing of the fingernails. A right ventricular parasternal lift is indicative of right ventricular hypertrophy, but the increased precordial activity felt with high flow ventricular septal defect is less evident. The second heart sound is markedly accentuated and well heard because the systolic murmur is a quiet one, if present at all. There is seldom a diastolic rumble, but a short early diastolic murmur of pulmonary regurgitation ("Graham Steele") may be heard.

ELECTROCARDIOGRAPHIC FEATURES

The electrocardiogram of the child with ventricular septal defect reflects the severity of the hemodynamic disturbance. With small VSD, the electrocardiogram is usually normal. Occasionally, a deeper-than-normal S wave in the right precordial leads or a mildly increased R wave in lead V_5 or V_6 will indicate mild left ventricular hypertrophy associated with the volume overload of the left ventricle. This feature, however, is usually masked by the normal prominence of right-sided forces in the newborn and young infant. In older children with small ventricular septal defect, the electrocardiogram is generally normal.

With moderate-size defects, the ECG usually shows some degree of left ventricular hypertrophy. Right ventricular hypertrophy may also be evident, depending on pulmonary artery pressure. Electrocardiographic evidence of left atrial enlargement may occasionally be noted but is uncommon, even in the presence of large pulmonary blood flow and large venous return to the left atrium.

Large defects may also manifest left ventricular hypertrophy on surface electrocardiogram, but nearly always there is evidence of combined right and left ventricular hypertrophy in the form of large, equiphasic voltage recordings in the midprecordial leads (Katz-Wachtel phenomenon).[96] Right axis deviation of the frontal plane QRS vector often accompanies the combined ventricular hypertrophy of large VSD. Older children with VSD and pulmonary vascular obstructive disease may have predominantly right ventricular hypertrophy on electrocardiogram. A pattern of pure right ventricular hypertrophy in infants and small children (beyond that normal for age), renders the diagnosis of isolated VSD suspect.

Perimembranous defects of the inlet septum may be associated with an electrocardiographic pattern of left axis deviation of the frontal plane QRS vector, with Q waves in standard leads I and AVL. This pattern, characteristic of atrio-ventricular canal defects, suggests an abnormal position of the specialized conduction system. One explanation for the left axis deviation is early separation of the left posterior fascicle from the left bundle branch.[97]

RADIOGRAPHIC FEATURES

As with the electrocardiogram, the radiographic findings of a patient with ventricular septal defect are not specific for that anatomic malformation, but reflect the size of the left-to-right shunt and the state of the pulmonary vascular bed. With small defects, the chest roentgenogram is usually normal. Occasionally there is a left ventricular contour to the cardiac silhouette, with a slight displacement of the cardiac apex downward and to the left. Pulmonary vascular markings may be mildly prominent as well, indicating the modest increase in pulmonary blood flow.

With moderate-size defects, the cardiac silhouette is enlarged, with a prominent left ventricular contour (Fig. 59–3). If pulmonary hypertension is present, the right ventricle may be enlarged as well, most evident as a "filling in" of the retrosternal space on a lateral projection. The left atrium is usually enlarged. On posterior-anterior projection, this may be evidenced by uplifting of the air column of the left mainstem bronchus. In lateral projection, the left atrium bulges posteriorly, often displacing the esophageal air column. This finding is evident on plain film, but is more dramatically illustrated with a barium swallow examination. The increased pulmonary blood flow is evidenced by enhancement of the pulmonary vascular markings, both centrally and peripherally. With pulmonary hypertension, the hilar markings may be more prominent than the peripheral markings, and the main pulmonary artery segment may be dilated. With large left-to-right shunts and congestive heart failure, interstitial edema, alveolar fluid, and Kerley B lines (indicating pulmonary venous engorgement) may be present. The reduced pulmonary compliance and increased respiratory effort are often reflected by chest hyperexpansion and flattening of the diaphragms.

Large defects with high flow show cardiomegaly with a more globular cardiac silhouette, due to right and left ventricular, as well as left atrial, and occasionally right atrial, enlargement (Fig. 59–4). The lateral projection shows a "filling in" of the retrosternal space and posterior enlargement of the left atrium. Pulmonary vessels are engorged, the lungs are usually hyperexpanded, and interstitial edema is often evident.

In older children with large defects and pulmonary vascular obstructive disease, the heart size is normal or mildly enlarged. Hypertrophy and dilation of the right ventricle may be evident by the anterior widening in the lateral projection. The main pulmonary artery segment is usually dilated and the central hilar vascular markings appear engorged, with peripheral markings normal or diminished (Fig. 59–5).

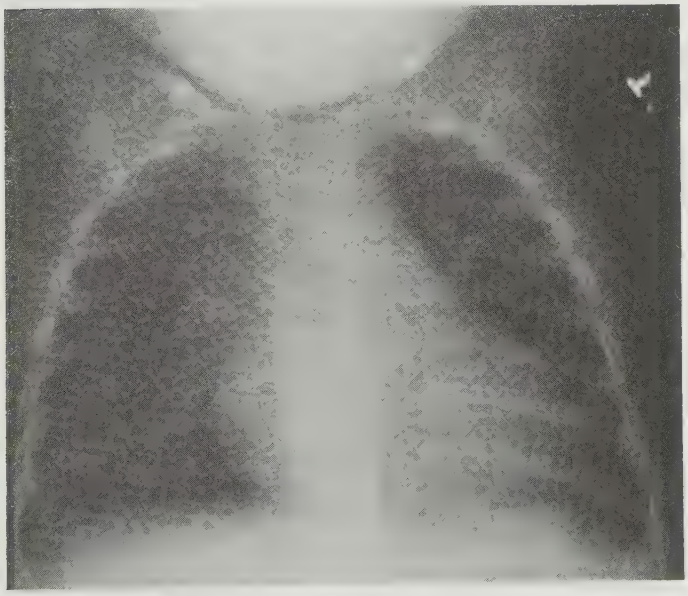

Fig. 59–3. Chest roentgenogram of a child with a moderately sized ventricular septal defect. The heart is enlarged. Pulmonary vascular markings are accentuated.

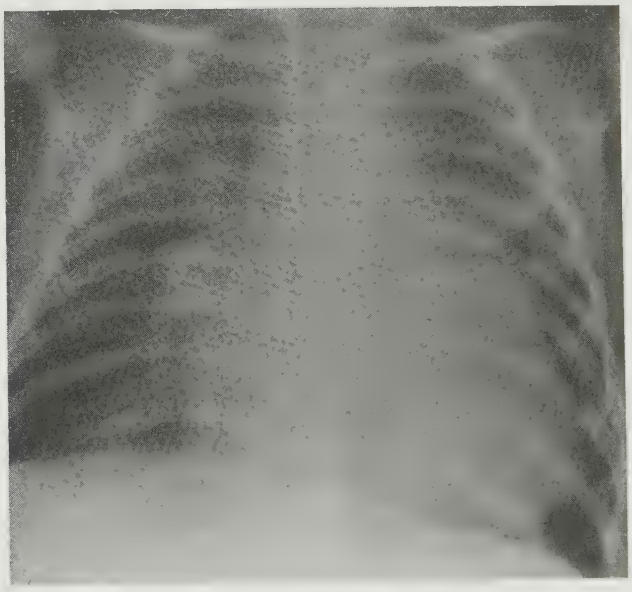

Fig. 59–4. Chest roentgenogram of an infant with a large ventricular septal defect. The cardiac silhouette is globular and significantly enlarged. Pulmonary vascular markings are accentuated, and evidence exists of pulmonary edema.

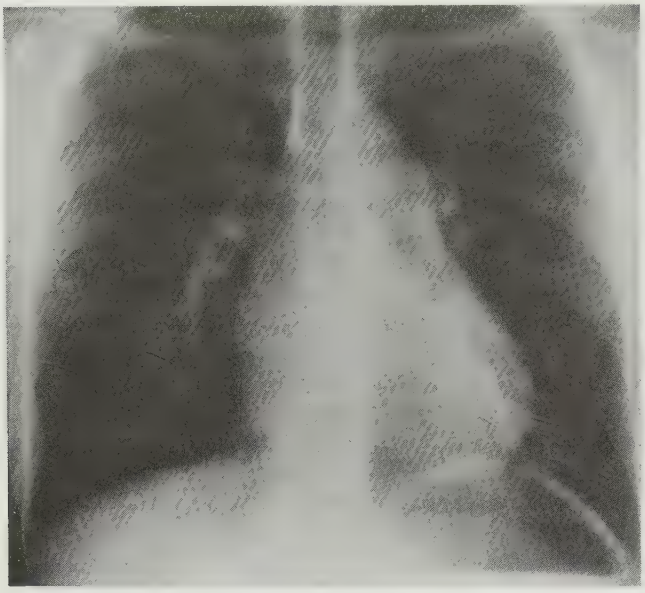

Fig. 59–5. Chest roentgenogram of an older child with ventricular septal defect and severe pulmonary vascular disease. The heart is only minimally enlarged. The main pulmonary artery segment is enlarged. The central hilar pulmonary markings are accentuated. The vascular markings in the peripheral lung fields are diminished.

ECHOCARDIOGRAPHY

The utility of echocardiography in the diagnosis and assessment of ventricular septal defect has progressed over the past 12 years in a fashion closely paralleling the advance of cardiac ultrasound technology: from M-mode to real-time 2-dimensional imaging techniques, and from pulsed Doppler through continuous wave and color-flow Doppler study.

Early M-mode echocardiography was useful for indirect assessment of the hemodynamic abnormality associated with left-to-right shunting.[98] In the presence of large left-to-right shunts, left atrial and left ventricular dilation can be demonstrated, although neither left atrial size[99] nor left atrial-to-aortic root diameter ratio[100] are reliably correlated to measured pulmonary blood flow. Demonstration of septal discontinuity on M-mode scan is unreliable for detection of all but the largest defects.[98,99] Systolic fluttering of the tricuspid valve has been cited as an M-mode feature of certain defects,[101] but this finding has limited diagnostic value.

Currently, M-mode echocardiography remains a useful adjunct to the assessment of patients with VSD, not in the visualization of the defect itself, but in the indirect assessment of pulmonary artery pressure. The M-mode pattern of pulmonary valve motion[98] and the right ventricular systolic time intervals, as measured from the M-mode echocardiogram,[102] may be helpful in estimation and longitudinal followup of pulmonary artery pressure.

Real-time 2-dimensional (2-D) echocardiography became a clinically useful modality in the mid-1970s[98,103] and was rapidly adapted to the evaluation of children with congenital heart disease.[104] Two studies early in the 1980s[105,106] described reasonable sensitivity and specificity of 2-D echocardiography for the detection of ventricular septal defects. Subsequent reports[15–17,98,107] attest to the increased accuracy of this technique acquired with experience and improved technology. Canale et al.[107] pointed out the value of the "T artifact" (broadening of septal edge at the margins of the defect) in improving specificity of echocardiographic diagnosis. Kececioglu-Draelos[108] demonstrated that actual VSD dimensions usually exceeded the measured VSD image in the 2-D echocardiogram. Other reports have demonstrated usefulness of 2-D echo for detection of left ventricle to right atrial shunts,[109,110] aneurysms of the ventricular septum,[111] aortic valve prolapse associated with VSD,[46] and assessment of the patient after VSD repair.[112] Recent work has led to revision of the nomenclature of ventricular septal defect based on echocardiographic as well as morphologic criteria.[15–17]

The evaluation of the child with ventricular septal defect by 2-D echocardiography requires a complete, segmental study including parasternal long axis, multiple parasternal short axis, apical and subcostal 4-chamber and suprasternal views. A complete examination is essential to provide accurate information about the presence, size, location, and number of septal defects, as well as the presence of associated lesions.

The standard parasternal long axis view demonstrates the outlet septum and most accurately demonstrates perimembranous or muscular outlet defects, particularly defects of the malalignment type.[15] Muscular trabecular defects are occasionally identified in this view, but perimembranous trabecular defects are generally not.[106] "Aneurysm" associated with perimembranous defects may often be visualized in the parasternal long-axis view.

Medial angulation of the transducer from the standard parasternal long axis view permits imaging of the tricuspid valve and a portion of the membranous septum. Perimembranous trabecular and perimembranous inlet defects will often be seen. Lateral angulation permits imaging of the right ventricular outflow tract and pulmonary valve, and doubly committed subarterial defects.[15,17]

Parasternal short axis views, with careful base-to-apex scanning, permits imaging of the entire ventricular septum and most ventricular septal defects (Fig. 59–6). When the septal and Moderator bands of the right ventricle can be identified, inlet and outlet defects are more easily classified.[15] Likewise, the medial papillary muscle of the tricuspid valve can help to distinguish defects in the outlet septum from those of the membranous septum. The former are located superior and to the left of that landmark, while the latter are positioned inferior and to the right.

Fig. 59–6. Parasternal short axis view, demonstrating a large perimembranous VSD.

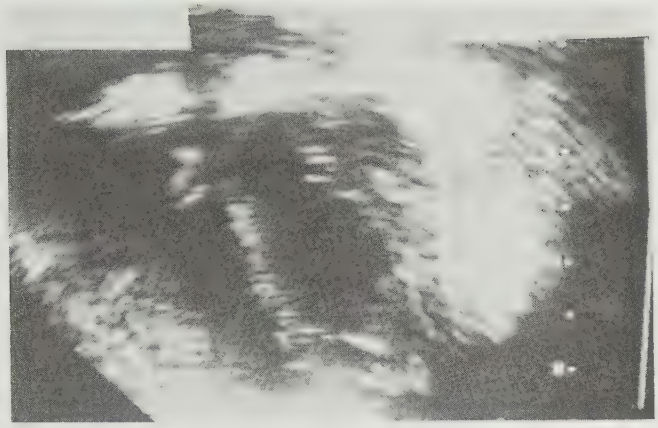

Fig. 59–7. Apical four-chamber view, demonstrating a small perimembranous VSD with ''aneurysm'' projecting toward the right ventricle.

Four-chamber views from the apical and subcostal positions best demonstrate muscular inlet and muscular trabecular defects, as well as most perimembranous defects (Figs. 59–7 and 59–8). They also best demonstrate atrioventricular valve morphology and help identify defects of the atrioventricular canal.

Contrast echocardiography has been used to enhance the sensitivity and amplify the assessment of VSD by both M-mode and 2-D techniques.[98] Serwer et al.[113] used contrast M-mode echo to help classify patients into four groups based on right ventricular pressure dynamics. Those with small VSD and normal right ventricular pressure had contrast injected from a peripheral vein appear to the right ventricle only. Those with moderate-size VSD and moderate right ventricular hypertension had appearance of contrast in the left ventricle during diastole, but none in the aorta. Those with large VSD and low resistance showed contrast in the left ventricle during diastole only, but also in the aorta. A single patient with large VSD and high resistance had a similar finding, with right-to-left shunting of contrast much earlier in diastole.

Two-dimensional echocardiography with contrast permits demonstration of left-to-right shunting by visualization of ''negative'' contrast jets. This may occasionally enhance the sensitivity of 2-D echo in detection of ventricular septal defect.[114,115] Demonstration of right-to-left shunting of contrast on 2-D echocardiography is strongly suggestive of right ventricular hypertension.

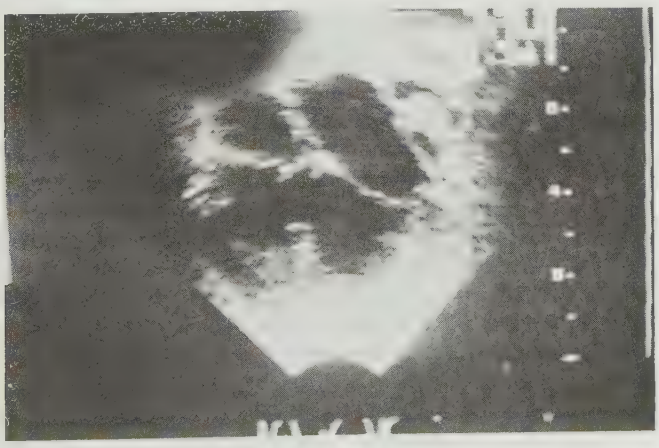

Fig. 59–8. Apical four-chamber view demonstrating a large perimembranous VSD. The tricuspid valve is closed, but the tricuspid valve annulus appears to override the defect.

Doppler echocardiography has been a helpful adjunct for enhancing the sensitivity/specificity of conventional imaging echocardiography in detection of ventricular septal defects. It is becoming a powerful modality for assessing hemodynamics as well. Stevenson[116,117] used pulsed Doppler in conjunction with M-mode echocardiography to identify left-ventricle–to–right-ventricle jets, localize defects, and distinguish VSD from mitral regurgitation. He also demonstrated the value of the pulsed Doppler evaluation when performed in conjunction with the 2-D echocardiogram.[118] The current 2-D echocardiographic examination, as described above, is ordinarily accompanied by pulsed Doppler interrogation of the imaged ventricular septum,[119,120] with confirmation of flow through actual defects, and its absence at the site of imaging artifacts.

Pulsed Doppler has also been used to assess cardiac output by combining flow velocity measured with imaged valve area.[121] This technique has been adapted to patients with VSD as well as other left-to-right shunts in the noninvasive assessment of pulmonary-to-systemic flow ratio.[122] Continuous-wave Doppler echocardiography, more useful in the accurate quantitation of flow velocity, recently has been applied to the assessment of pulmonary artery pressure. Continuous-wave Doppler measurement of flow velocity across a defect itself reliably correlates with left-ventricle–to–right-ventricle pressure gradients.[123,124] Continuous-wave Doppler measurement of regurgitant flow velocity in patients with mild tricuspid regurgitation has also been used to estimate right-ventricle–to–right-atrium pressure gradients and identify patients with significant right ventricular hypertension.

Color-flow Doppler imaging, a relatively new technique, has begun to enhance the sensitivity of the Doppler/2-dimensional echocardiographic assessment of the child with congenital heart disease.[125] Color-flow imaging of VSD flow has been demonstrated to be a sensitive and reliable finding.[125–128] Its utility in assessment of this defect presently lies in improved detection of small areas of left-to-right flow in small, difficult-to-image, defects.[125,126]

Ultrasound examination has become an essential part of the noninvasive assessment of the child with suspected or known ventricular septal defect. All children with symptomatic ventricular septal defect, and all children in whom surgical repair of ventricular septal defect is planned, should undergo a complete 2-D echocardiographic and Doppler examination. It is the most powerful noninvasive tool presently available for assessment of the presence, number, size and location of ventricular septal defects—as well as the presence of associated lesions. In addition, all children over the age of 2 years whose ventricular septal defect has not closed spontaneously should undergo complete 2-D echocardiogram and Doppler evaluation. Doubly committed subarterial defects, which may predispose to the later development of aortic regurgitation,[36] and small malalignment defects, which may be associated with left ventricular outflow tract obstruction,[39] can hence be identified.

Limitations of the echocardiographic examination are not to be overlooked. Very small defects, those often confused with functional murmurs, may elude detection by even meticulous 2-D echocardiography and pulsed Doppler interrogation. Color-flow

imaged Doppler may help alleviate this problem. More important is the considerable technical skill required to perform a "complete" echocardiographic examination and the inherent dependence on the skill and diligence of the echocardiographer. Finally, while real-time 2-D imaging technology has maximized the noninvasive evaluation of VSD anatomy, the Doppler echocardiographic evaluation of hemodynamics has developed more gradually and has not, as yet, replaced invasive hemodynamic assessment of these patients.

OTHER NONINVASIVE STUDIES

Several other noninvasive techniques may be employed in the assessment of the child with ventricular septal defect. Unlike echocardiography, which has become quite standard in most institutions, their frequency of utilization varies widely from center to center.

Radionuclide studies in children have been available since the early 1970s.[129,133] These studies provide sensitive detection of left-to-right shunts, and are more accurate in the quantitation of pulmonary-to-systemic flow ratios when compared to the Fick method than is echocardiography.[129] Radionuclide studies also provide useful information about left and right ventricular function.[134] They have the disadvantage of providing minimal anatomic information. Moreover, nuclear studies are not completely "noninvasive" and the requirement for a timely bolus intravenous injection can be a significant disadvantage in infants.

Gated magnetic resonance imaging studies, as yet available in only a few centers, appear to be capable of providing excellent anatomic information about ventricular septal defect, as well as other cardiac malformations.[135,136] The data collected are static, but image quality is comparable to current echocardiography. Presently this technique is of limited value in infants, however, both because of limited resolution and the long data acquisition time.[136]

Computerized tomography has not generally been helpful in assessment of cardiac anatomy because of heart motion. The newer technique of cine computerized tomography may be valuable, but is only beginning to be applied to small children with congenital heart disease.

Pulmonary input impedance studies have been applied to experimental animals,[137] as well as children,[138] as an indicator of pulmonary vascular resistance, but have not yet found widespread clinical use.

CARDIAC CATHETERIZATION

Cardiac catheterization, usually performed in conjunction with selective cineangiocardiography, can provide accurate and valuable information about the child with ventricular septal defect. This includes confirmation of the defect, information about size and location of defects, the presence of associated defects, the magnitude of the left-to-right shunt, the pulmonary artery pressure and resistance, and the responses of either the resistance or shunt to acute pharmacologic intervention. With the noninvasive technology that is available at the present time, careful consideration must be given to selection of patients for catheterization based on specific unanswered and necessary questions. Previous authors have advocated cardiac catheterization for all infants with congestive heart failure,[19,71] for all patients in whom surgical repair of VSD is contemplated, and for all children in whom there is a question of elevated pulmonary artery pressure. Current practice in most institutions is somewhat more selective as to which patients undergo cardiac catheterization. Infants with small defects, and asymptomatic infants under 6 months of age with larger defects, are not usually catheterized. Symptomatic infants (as well as asymptomatic infants suspected of having a moderate or large defect) undergo a careful 2-D echocardiogram and Doppler study. If that study discloses simple ventricular septal defect, medical management of symptoms (see below) is undertaken. If the echocardiogram is not definitive for a diagnosis of simple VSD, or cannot adequately exclude associated lesions, then cardiac catheterization is performed. If medical therapy is unsuccessful and intracardiac repair is contemplated, cardiac catheterization is usually undertaken. At our institution, we routinely perform cardiac catheterization and cineangiography prior to intracardiac repair of all ventricular septal defects, although other centers are now referring patients for intracardiac repair without invasive study.[17]

Infants whose symptoms are alleviated with medical therapy and those whose noninvasive studies suggest a defect that is not small are routinely catheterized in our institution before 1 year of age. Older children undergo catheterization if there is suspicion of persistent significant left-to-right shunt or elevation of pulmonary artery resistance. Increasing reliance of many centers on Doppler echocardiographic estimates of pulmonary-to-systemic flow ratios and pulmonary artery pressure will tend to decrease the future number of children catheterized in this category.

Techniques of right and left heart catheterization are well described elsewhere in this text and by others.[71,139–141] Complete right heart catheterization should be performed, including measurement of mean and phasic pulmonary artery wedge pressures, and pressures in the pulmonary branches, pulmonary trunk, right ventricle, and right atrium. Accurate blood oxygen saturations should be determined in the pulmonary arteries, pulmonary trunk, right ventricle, right atrium, superior and inferior vena cavae. Oxygen consumption should be measured using the flow-through or Douglas bag techniques to facilitate calculation of actual pulmonary blood flow and pulmonary vascular and systemic arterial resistances.[71]

We routinely employ continuous femoral arterial pressure monitoring during catheterization of the child with ventricular septal defect. Left heart study and ventriculography are included in the catheterization protocol of these infants as well. These may often be performed through a patent foramen ovale. Otherwise, the retrograde arterial or transseptal approach is utilized.

Determination of systemic-to-pulmonary flow ratio is made using the Fick principle and comparison of systemic arterial oxygen saturation with pulmonary and mixed venous oxygen saturation. This ratio is adequate for the assessment of flow in the presence of normal pulmonary artery pressure, and hence low pulmonary artery resistance. If pulmonary artery pressure is elevated (mean pulmonary artery pressure equal to one-half mean systemic pressure or greater), oxygen consumption should be measured to permit calculation of actual pulmonary blood flow and pulmonary resistance. Care must be taken in this instance to exclude anomalies of left ventricular inflow which might exacerbate pulmonary hypertension.

When pulmonary vascular resistance is significantly elevated (Rp/Rs ratio >0.3), reactivity of the pulmonary arterial tree is

ordinarily assessed by administration of oxygen.[71] Oxygen is delivered in a concentration of 0.95 to 1.0 via headbox for 5 minutes, and repeat measurements of pulmonary and systemic pressures and pulmonary arterial, systemic arterial, and mixed venous oxygen content are repeated. Systemic and pulmonary arterial blood gas determinations are also essential to assess adequacy of ventilation, and include dissolved oxygen estimation into the calculation of pulmonary and systemic blood flows. If elevated pulmonary vascular resistance is unresponsive to oxygen, further assessment of reactivity should be made by the administration of tolazoline, 1 mg/kg[71] or isoproterenol, 0.05 mg/kg/min.[142] It should be mentioned that some laboratories do not routinely employ techniques for assessment of pulmonary vascular reactivity, feeling that resistance under measured baseline conditions alone is the best indicator of operative survival.[143]

Cineangiography

Cineangiographic evaluation in the child with ventricular septal defect should be carefully designed to identify associated conditions and define the precise anatomy of the defect itself. Right ventriculography or pulmonary arteriography may be indicated, especially the latter in instances where pulmonary vein stenosis, cor triatriatum, or mitral valve abnormality is a suspected cause of pulmonary hypertension. Some centers frequently employ magnification pulmonary wedging angiography[144] as part of their evaluation of the child with pulmonary vascular obstructive disease. Pulmonary arteriography with left heart follow-through is inadequate for visualization of the precise anatomy of ventricular septal defect.

Selective cineangiography of the aortic root may be indicated in instances of outlet VSD with aortic valve prolapse or aortic regurgitation.[47] Aortography may also be necessary to evaluate the contribution of patent ductus arteriosus to a large left-to-right shunt in the infant.

Demonstration of the VSD demands selective left ventriculography, preferably with biplane projections. Ideal visualization of the defect requires alignment of the plane of the defect parallel to the x-ray beam. The curvilinear and helical configuration of the septum occasionally makes this difficult, but 2-dimensional echocardiography has become a boon to the angiographer by helping to localize the defect prior to catheterization, thus minimizing the number of injections required. Optimal visualization is achieved with 1.5 to 2.0 ml of 75% contrast per kilogram of body weight,[34] delivered in no more than one second.

The concept of axial cineangiography described by Bargeron,[14] and used by most centers today, finds no better application than in the demonstration of defects of the ventricular septum.[14,29,34,145–147] Angulation can be achieved by maneuvering of the patient's position with conventional angiographic equipment, or angling of the tube and image intensifier with newer equipment.

Defects of the perimembranous septum are usually well demonstrated with a steep left anterior oblique (LAO) projection (75°), with cranial angulation of 20°[29,34] (Fig. 59–9). Doubly committed subarterial defects may also be visualized in this view, or occasionally with a steep right anterior oblique projection.[29,34] This combination of projections is also effective for demonstration of perimembranous defects with left-ventricle–to–right-atrial shunting.[147]

Posterior defects, those of the perimembranous or muscular inlet septum, may appear to lie in the midmuscular septum of the LAO projection.[34] They are best demonstrated in the four-chamber view (45° cranial and 20° left anterior oblique).[34,145] Defects of the muscular trabecular septum, often multiple, are usually identified in the cranially angulated long-axial oblique view (Fig. 59–10), and its biplane counterpart, the steep right anterior oblique projection. Occasionally, the four-chamber view may also be useful, however, to demonstrate additional defects.[34,146]

Fig. 59–9. Left ventriculogram taken in the steep LAO; cranial projection, demonstrating a small perimembranous VSD.

NATURAL HISTORY AND CLINICAL COURSE

Management decisions for patients with ventricular septal defect depend, as with most conditions, on a knowledge of the natural history of the defect. Such information is, of course, not entirely available, since longitudinal patient followup entails some degree of patient management. A number of investigators have reported the clinical course and outcome of large cohorts of children with VSD.[16,20–23,56,57,148,152] These reports vary in their patient substrate and the extent to which they reflect "natural history" as opposed to clinical outcome. Nonetheless, taken in conjunction with other observations and numerous smaller studies, they provide several general conclusions which form the basis for current management (Table 59–1).

A substantial portion of patients with ventricular septal defect have a small defect. This is especially true if the diagnosis is made

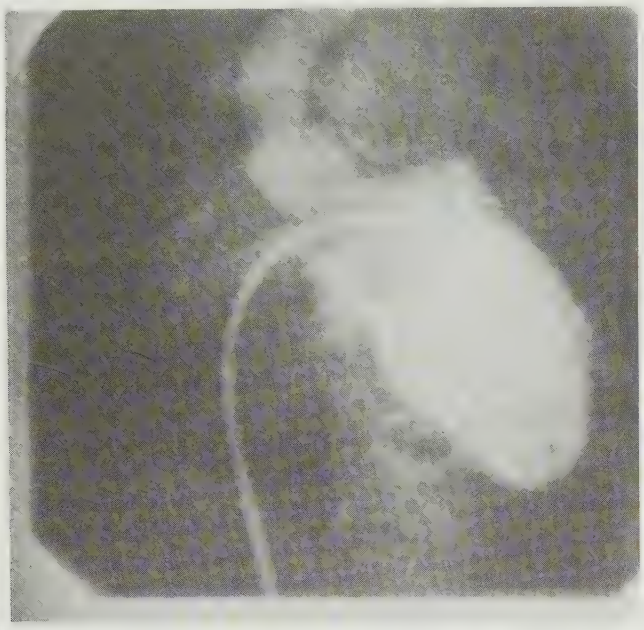

Fig. 59–10. Left ventriculogram taken in the steep LAO; cranial projection, demonstrating three small defects in the muscular trabecular septum.

only on the basis of a murmur[16,23] and if the diagnosis is made in patients who present late.[56] However, even if patient selection is restricted to infants,[149] or to patients studied invasively,[22,56] a number of patients will have a small defect.

Many small defects close spontaneously—with estimates ranging from 9%[56] to 75%,[152] depending on patients evaluated—but with an actual number probably exceeding 35%.[16,20,21,23,149,153] While this figure reflects the rate of spontaneous closure for perimembranous trabecular defects, the incidence is higher for defects of the muscular trabecular septum[152] and perimembranous inlet septum,[16] whereas spontaneous closure of defects of the outlet septum is probably rare.[16] Closure most commonly occurs prior to 2 years of age,[22,152] but may occur later in childhood,[23,56,149,152] and has been reported in adults.[154] Regardless of closure, patients with small defects do well and do not require surgical intervention. Whether they are judged "small" by hemodynamic (normal pulmonary artery pressure, pulmonary-systemic flow ratio less than 2:1) or clinical criteria (normal pulmonic closure sound, minimal abnormal radiographic findings, minimal left ventricular hypertrophy, and no right ventricular hypertrophy by electrocardiogram), there is no indication that these patients have significant functional impairment in childhood or limited longevity. There is likewise no evidence that pulmonary vascular resistance increases later.[56] Adults with small VSD may have subclinical compromise of cardiac "reserve," but, as yet, the relevance of this observation to the management of children with VSD is unclear.[155] There is some tendency for moderate and large defects to close spontaneously as well, though this is less frequent than with small defects.[22,23,56] The natural history study reported in 1977 found an 8% rate of spontaneous closure of large defects by 2 years of age. Those defects that do not close may reduce in size with time.[56]

Pulmonary vascular resistance must also be considered. Moderately elevated resistance (pulmonary-systemic resistance ratio <0.5) tends not to increase during infancy, but may worsen (or may improve) later during childhood.[56] Severely elevated resistance seldom improves, and significant pulmonary vascular obstructive disease may develop as early as the second year of life.[19,22,56,156–158]

Most infants with moderate-size defects who present with congestive heart failure can be managed medically[19,22,56] (see below), as can a number of infants with large defects. The advantage of conservative therapy over surgery in VSD is the tendency for these defects to become smaller or to close, potentially obviating the need for surgery altogether. Infants whose congestive heart failure cannot be controlled are generally referred for surgical repair. Certain infants are known to be at higher risk for uncontrollable congestive heart failure. These include infants born prematurely or with low birth weight, infants with chromosomal defects, and those with major extracardiac anomalies.[23,56,159] These infants are known to be at high risk for surgical mortality as well.

Table 59–1. Clinical Course of Children with Isolated VSD

1. Many have small defects
2. Children with small defects do well
3. Small defects frequently close
4. Large defects may close and often become smaller
5. Modest elevation of pulmonary vascular resistance does not progress in the first year of life
6. Severe elevation of resistance may progress early
7. Most infants with congestive heart failure can be managed medically
8. Some infants are considered "high risk"

MEDICAL THERAPY

Infants

The medical treatment of infants with ventricular septal defect is directed at the control of congestive heart failure. The goal of therapy is the relief of symptoms, minimization of frequency and severity of respiratory infections, and normal growth.

Infants with a large defect may manifest severe congestive heart failure at the time of their initial diagnosis. These infants should be hospitalized for initial management, which should include fluid restriction (usually 60 to 80 ml/kg/day), alleviation of temperature stress by careful attention to a normothermic environment, and gentle handling to minimize physical exertion. Occasionally mild sedation (morphine, 0.05 mg/kg) will relieve some of the metabolic expenditure of the irritable infant. It may initially be difficult to differentiate bacterial pneumonia superimposed upon congestive heart failure. In that instance, blood and possibly tracheal cultures should be obtained, and broad-spectrum antibiotic therapy provided until infection is excluded. Severe pulmonary edema may be associated with hypoxemia and supplemental oxygen may be required. It must be kept in mind, however, that oxygen is a pulmonary vasodilator, which may decrease pulmonary vascular resistance, increase left-to-right shunting, and exacerbate congestive heart failure. Oxygen should be used judiciously only to relieve hypoxemia, demonstrated by blood gas determination or noninvasive oximetry. Increased respiratory effort without hypoxemia is best treated by other means. Severe respiratory distress should be treated with endotracheal intubation and continuous

positive airway pressure, with or without mechanical ventilation. The benefit of positive end-pressure and mechanical ventilation in the early stabilization of severely ill infants can be dramatic.

Diuretic therapy should be instituted promptly for the infant with congestive heart failure. Furosemide or ethacrynic acid given intravenously two or three times daily is usually effective.

Digoxin has long been part of the conventional management of infants and children with symptoms of congestive heart failure due to left-to-right shunt.[18,19,160] Hospitalized children are usually given a loading dose over 24 hours, and then continued on maintenance therapy. While the inotropic effect of cardiac glycosides on the immature myocardium has been questioned,[161–163] studies[163] and clinical experience[18,19,160] attest to the beneficial effect of digoxin in some, if not all, infants with ventricular septal defect. Other inotropic agents generally are not required in the management of isolated ventricular septal defect.

Considerable interest has been directed at the utility of systemic afterload reduction for VSD.[163,164,166–168] In acute congestive heart failure, secondary to left-to-right shunting, hydralazine appears to improve pulmonary-to-systemic flow ratios in those patients with measured elevation of systemic resistance.[166–168] Nitroprusside may be less effective or even detrimental,[165] while studies in dogs suggest that prazosin may be more effective.[164] As yet, the effect of chronic use of afterload reducing agents for patients with ventricular septal defects remains to be demonstrated.

Infants who present earlier, or with less severe manifestations of congestive heart failure, may often be treated at home. Oral digoxin therapy may be instituted in a maintenance dose, with anticipated achievement of steady-state serum concentration in 4 to 7 days. Diuretic therapy consists of furosemide, ethacrynic acid, or hydrodiuril given two or three times daily. Potassium wasting with each of these effective agents may warrant addition of spironolactone and/or oral supplemental potassium replacement. In occasional patients, oral hydralazine therapy may be added to the pharmacologic regimen, but, as mentioned, the long-term benefit has not been documented.

Poor weight gain in the presence of congestive heart failure is due to the combined effects of increased metabolic expenditure and poor caloric intake.[159] Pharmacologic therapy helps decrease abnormal respiratory effort, decreasing caloric utilization and improving intake. Poor weight gain may still be a problem, however, and failure to thrive has commonly been the indication for early repair of ventricular septal defect. Caloric supplementation by the addition of carbohydrate and medium-chain triglyceride preparations to conventional formulas may improve weight gain. In recent years, the use of home nasogastric tubes for bolus, nighttime, or continuous drip feedings, has become a possible method of improving caloric intake and achieving acceptable weight gain.[169] Clearly, the dietitian has become an essential member of the cardiology team caring for these infants.

Older Children

Older children with ventricular septal defect are seldom symptomatic and require little in the way of medical therapy. Children with significant left-to-right shunts or elevated pulmonary artery pressure generally undergo surgical repair. Medical followup in the older age groups then consists of periodic evaluation, encouragement of full activity, and education about the proper use of antibiotic prophylaxis for bacterial endocarditis.

Patients with ventricular septal defect and pulmonary vascular obstructive disease who are deemed "inoperable" because of irreversibly elevated resistance (see below) require more intensive support and symptomatic therapy as cyanosis progresses and activity becomes more limited. While specific drug therapy of the vascular obstructive disease itself is not available, some centers are using antiplatelet agents, such as aspirin or dipyridamole, in an effort to retard the progression of the disease process. Improvement in the symptoms associated with polycythemia of Eisenmenger's complex—headache, extreme fatigue, and extreme dyspnea—may be provided by partial exchange transfusion for red cell volume reduction.[170] There is no evidence that the symptomatic therapy has any beneficial effect on the mortality rate or life expectancy with this condition.

SURGICAL THERAPY

Since Lillehei's early report of successful closure of ventricular septal defect using the cross-circulation technique,[8] the surgical approach to the condition has been the subject of numerous publications.[171–186] Attention is focused on questions of palliative versus definitive surgery, indications for surgery, surgical techniques, and surgical results.

Palliative surgery for left-to-right shunts with congestive heart failure was recommended by Muller[7] in 1952 and was popular in the 1960s as part of a two-stage repair of ventricular septal defect.[185,187] Disadvantages of pulmonary artery banding are numerous[176,188] and include early operative mortality, persistent congestive heart failure after banding, technical difficulty with debanding at the time of second-stage repair, development of subaortic stenosis, and overall combined mortality of the two-staged repair. Improved techniques and operative survival, even for small infants, with definitive repair[178,179,181,183–186,188] has rendered the two-stage approach for simple VSD obsolete in most centers.[173,176,188] Pulmonary artery banding remains useful in certain "high risk" patients (multiple VSDs, extremely small patients, those with concomitant lung disease)[179,181,189] and for certain patients with associated conditions (coarctation of the aorta, interrupted aortic arch),[186] but for the majority of patients with simple VSD who require operative intervention, primary intracardiac repair is the procedure of choice.[179,188]

Indications for surgical repair of ventricular septal defect were developed in the decade after Lillehei's initial surgical report,[171] but have not changed a great deal since the mid-1960s.[19,172,188,189] Early experience demonstrated the high risk associated with repair of larger VSD with severe pulmonary vascular obstructive disease.[10,190,192] At the same time, consideration of the natural history of small defects and their benign course led to a minimum left-to-right shunt size as an indication for surgery.[19,172,186] Current indications for surgery are reasonably standard[19,172,185,186,189] (Table 59–2). Surgical repair in infancy is undertaken for control of intractable congestive heart failure, including recurrent lower respiratory tract infections or growth failure. Patients with large defects whose congestive heart failure is controlled but whose pulmonary artery pressure remains elevated (>½ systemic) are repaired prior to 2 years of age,[156–158] or, in many centers, before 1 year of age. Older children undergo surgical correction if pulmonary-to-systemic flow ratio is >2:1[19,186] or, in some centers,[18] >1.5:1. Pulmonary arteriolar resistance equal to systemic resis-

Table 59–2. Surgical Repair of Ventricular Septal Defect

Age	*Indications**
Under 6 months	Uncontrolled congestive heart failure
6 to 24 months	Pulmonary hypertension or symptoms
Over 24 months	$Q_p/Q_s > 2/1$
*Contraindications	
Absolute	$R_p/R_s > 1/1$ or $R_p > 12$ Wood units
Relative	$R_p/R_s > 0.75/1$ or $R_p > 8$ Wood units

tance, or pulmonary arteriolar resistance greater than 12 Wood units,[10] is regarded as a contraindication to surgery. Pulmonary-to-systemic resistance ratio between 0.5 and 1.0, or pulmonary arteriolar resistance between 8 and 12 Wood units, is generally felt to substantially increase the risk of surgical correction and unfavorably affect long-term prognosis.[158] These patients usually undergo further evaluation with provocative testing in the catheterization laboratory,[71,142–144,192–194] pulmonary wedge angiography,[144] or lung biopsy[193,194] to elucidate the severity of pulmonary vascular disease prior to surgical correction.

The technical aspects of surgical repair of VSD are well described.[172,175,176,180–186,195–198] The majority of perimembranous defects may be closed by a transatrial approach,[173,182,184,186] although many surgeons prefer a right ventriculotomy.[176] Defects of the inlet septum may occasionally require detachment of the septal leaflet of the tricuspid valve for exposure.[196] Defects of the muscular trabecular septum, particularly when multiple, are often best approached through a left ventriculotomy.[175,197] Results with this approach suggest that the improved visualization of multiple defects from the left ventricular aspect offsets the potential compromise of left ventricular function.[175,197] Nonetheless, many surgeons prefer not to perform incisions in the systemic ventricle. Defects of the outlet septum are best approached through a ventriculotomy, or through the pulmonary artery.[195] The technique of profound hypothermia and circulatory arrest[173,176,184,198] is employed by many centers for VSD repair in infants less than 1 year of age, while most centers employ conventional cardiopulmonary bypass for older infants and children.

Intracardiac repair of ventricular septal defect can be accomplished with reasonable safety. Early operative mortality rates range from 1 to 2% for uncomplicated defects in older children.[182,186] In infants under 1 year, operative mortality rates range from 2%[184] to 13%,[188] with most series reporting mortality <10%.[176–179,183] Earlier reports with pulmonary artery banding suggested an in-hospital mortality associated with that procedure in the range of 13%.[188] The New England Regional Infant Cardiac Program found an overall mortality rate of 44% for infants undergoing primary VSD repair.[149] It is misleading to compare these figures because of differences in time frame, patients included in the study, and number of centers involved. It is clear, however, that at the present time, repair of uncomplicated VSD in the older child carries a low operative risk. The operative mortality in small infants is substantially higher, but remains less than 10%.[177] This mortality is apparently lower than the overall mortality associated with two-stage repair in the same group of infants.

Postoperative Management

The potential postoperative problems directly related to intracardiac repair of ventricular septal defect include residual left-to-right shunt, elevated pulmonary artery pressure, ventricular dysfunction, and surgical atrio-ventricular block. Distinguishing between the first three may occasionally be difficult in the post-surgical intensive care unit, but it is critical for the determination of appropriate therapy.

Residual left-to-right shunt after repair of VSD may occur in 14 to 30% of cases,[56,177,183,185] and may be hemodynamically significant in up to 10%.[183] Its clinical detection is confounded by a high prevalence of murmurs in the immediate postoperative period. In some centers, pulmonary artery catheters are routinely used for postoperative assessment,[199] and elevated pulmonary artery blood oxygen saturation can be used to detect significant left-to-right shunting.[199] Echocardiography with pulsed Doppler can also be adapted to the detection of residual defects. Patients with persistent cardiomegaly and evident low cardiac output in the early postoperative period should undergo noninvasive evaluation and, often, early postoperative cardiac catheterization. The presence of a residual left-to-right shunt with pulmonary-to-systemic flow ratio of >1.5:1 with evident compromise of cardiac output should be considered as a likely indication for reoperation.

Patients with preoperative pulmonary hypertension may have elevated pulmonary vascular resistance in the postoperative period and exhibit reduced cardiac output and right heart failure. Residual left-to-right shunt must be excluded. Noninvasive estimation of pulmonary artery pressure is difficult in the early postoperative period. Routine use of pulmonary artery catheters[199] or their use in patients known preoperatively to have elevated pulmonary vascular resistance may be helpful in identifying this condition, as well as assessing the response to therapy. Alleviation of the elevated resistance may be challenging. Maintenance of normal arterial P_{CO_2} and P_{O_2} by aggressive, and occasionally prolonged, mechanical ventilation may avert the pulmonary vasoconstriction associated with hypoventilation and hypoxemia. Hyperventilation is probably less effective, and hyperoxygenation (P_{O_2} >120 mm Hg) may be of no benefit. Pharmacologic agents that may be useful as pulmonary vasodilators include tolazoline, isoproterenol, nitroprusside,[200] and nitroglycerin. Each must be used carefully and with appropriate monitoring to assess efficacy. Extracorporeal membrane oxygenation has been used successfully for a patient with postoperative pulmonary hypertension unresponsive to conventional treatment.[201] An essential part of the management of postoperative pulmonary hypertension is patience, as the recovery period is often prolonged despite optimal therapy.

Patients may exhibit poor cardiac output in the postoperative period in the absence of residual shunt or elevated pulmonary vascular resistance. Certain subsets of patients may be particularly predisposed to myocardial dysfunction postoperatively. These include patients with very large preoperative shunts[202] and patients with long-standing left ventricular volume overload.[203,204] These patients are treated with inotropic agents and afterload reduction when necessary. Occasionally, longterm anti-congestive therapy is required.

Surgical complete atrio-ventricular block has been a relatively unusual complication of intracardiac repair of VSD since the early 1960's.[172,205,206] In most centers, the incidence is less than 2% with simple VSD.[180] Transient AV block may occasionally occur and is managed with temporary cardiac pacing. Insertion of a permanent pacemaker is generally deferred for 1 to 2 weeks to allow resolution of transient block.[207] Right bundle branch block is ex-

tremely common following VSD surgery and has not yet been associated with adverse effects.[97,208]

Longterm Results

Longterm outcome of patients following repair of ventricular septal defect is largely dependent on age and hemodynamic status at the time of repair. Follow-up catheterization studies have demonstrated normal pulmonary vascular resistance in most children repaired before 2 years of age.[56,158,172,191] Children undergoing surgery later may have a less predictable fall in pulmonary vascular resistance. Patients with normal resistance at the time of surgery do not experience a subsequent rise in resistance, but in certain of the patients with moderately elevated resistance who are repaired later, the pulmonary vascular resistance increases.[56,158,209,210] This increase in resistance is neither as uniform nor as marked, however, as with similar patients in whom surgery is not performed.[211] While the majority of patients surviving repair of VSD are asymptomatic,[56,212–214] Maron, et al., [214] found abnormal responses to exercise in nearly half of a group of patients studied 3 to 15 years postoperatively. Jarmakani, et al.,[215] found decreased left ventricular performance in a group of patients repaired at a mean age of 5 years. A subsequent study[203] disclosed better residual left ventricular performance in patients repaired before 1 year of age.

Late death, according to the National History Study in 1977, occurred in 10 of 126 infants and 7 of 259 older children who underwent surgical correction.[56] Others report similar incidence of late death.[211,216] The most common form of late death was "sudden death."[56] This may not necessarily imply sudden "unexpected" death, in that certain patients are at greater risk of sudden death by virtue of elevated pulmonary artery pressure,[213] or malignant arrhythmias.[216]

Patients with small defects who do not undergo surgical repair are generally asymptomatic.[56,217] While there may be subtle abnormalities of myocardial performance associated with chronic mild left ventricular volume overload,[218] these patients rarely manifest clinical deterioration,[217] and there is some evidence that they may benefit from dynamic exercise.[80] Late sudden deaths have not yet been reported in this group.[217,219]

Patients with large VSD and pulmonary vascular disease who are deemed "inoperable" generally undergo hemodynamic and clinical deterioration during the second and third decades of life, and most die before age 40,[10,19] although survival to age 63 has been reported.[220] Death is usually due to pneumonia, pulmonary hemorrhage, progression of right heart failure, or a sudden event (probably an arrhythmia).

ENDOCARDITIS, PREGNANCY, AND INSURABILITY

Infectious endocarditis is a well-known, and not uncommon, complication of ventricular septal defect.[221] Incidence estimates range from less than 1%[23] to 15%.[219,222] Surgical repair without residual defect reduces this risk substantially,[221] but residual defect after intracardiac repair appears to present the same or greater[222] risk for development of endocarditis as unoperated defects. At the present time, antibacterial prophylaxis for prevention of endocarditis is recommended for all children with ventricular septal defect, whether surgically repaired or not.

Small ventricular septal defect with good functional status does not increase maternal risk in pregnancy.[223] Patients with a large defect, or a postoperative defect with less-than-excellent clinical status, have a substantial likelihood of cardiac-related symptoms (angina or congestive heart failure) during pregnancy, although maternal death is rare. Mothers with ventricular septal defect have an increased incidence of spontaneous abortion,[223] and an apparent incidence of congenital heart disease in their offspring of approximately 21%.[223] This figure is substantially higher than earlier predictions based on the multifactorial inheritance model.[224]

Life insurance guidelines for patients with congenital heart disease have been outlined by the American Heart Association Council of Cardiovascular Disease in the Young.[225] Patients with small VSD are felt to have standard insurance risk. Moderate VSD, with cardiomegaly, increased pulmonary blood flow, and normal pulmonary vascular resistance, have minimum-to-moderate substandard insurance risk. Patients with large VSD are probably uninsurable. Patients who undergo repair of ventricular septal and have no residual defect or pulmonary hypertension have standard risk. Those with residual defects have moderate substandard risk. Those with pulmonary hypertension postoperatively are probably uninsurable.

GUIDELINES FOR MANAGEMENT

Based on the above considerations, we have established guidelines for the management of children with ventricular septal defect (Table 59–3). Their application to a particular patient is, of course, dependent upon the clinical circumstances and variation from center to center.

Infants with findings suggestive of ventricular septal defect must be carefully assessed for evidence of congestive heart failure and for the presence of associated lesions. The infant should be followed closely over the first 6 months of life, during which time falling pulmonary vascular resistance may cause an increase in left-to-right shunting. Many small defects will close spontaneously. Most pediatric cardiac centers do not continue to follow those patients. Children over 2 years of age whose defects have not closed spontaneously should undergo 2-D echocardiography to exclude left ventricular outflow tract obstruction and subarterial defect, which might predispose to aortic regurgitation. Patients with small defects generally then are followed periodically for overall assessment and re-emphasis of the need for bacterial endocarditis prophylaxis.

Infants with evidence of congestive heart failure should undergo invasive or noninvasive anatomic assessment. If congestive heart failure does not respond to medical therapy, complete repair is the preferred surgical treatment. If failure responds to medical therapy, including a satisfactory rate of growth, the infants await hemodynamic assessment (usually by cardiac catheterization) later in the first year of life. If pulmonary artery resistance is elevated, intracardiac repair is performed electively between 1 and 2 years of age. Children in whom pulmonary vascular resistance is not elevated, but in whom there is significant, persistent left-to-right shunting, usually undergo intracardiac repair prior to starting school, or earlier in many centers.

Following intracardiac repair, all children should have periodic evaluation by a cardiologist and continued endocarditis prophylaxis.

Table 59–3. Guidelines for Management

Age	*Echocardiography*	*Cardiac Catheterization*	*Surgery*
Under 6 months	1. Symptoms 2. Questionable findings 3. Associated conditions	1. Ambiguous echo findings 2. Preoperative	1. Uncontrolled congestive heart failure
6 to 24 months	1. Symptoms 2. Pulmonary hypertension 3. Associated conditions	1. Preoperative 2. Pulmonary hypertension	1. Pulmonary hypertension 2. Symptoms (or medications)
2 to 5 years	1. Associated conditions 2. Location of VSD	1. Preoperative	1. $Q_p/Q_s > 2/1$
Over 5 years	1. Location of VSD		

THE FUTURE

The trend for an improved outlook for these patients will doubtless continue over the next decade. A closer look at the "high-risk" patient group and further progress in the management of heart failure will hopefully permit even better patient selection and improved condition of patients referred to the operating room. Anatomic and hemodynamic data are becoming increasingly available without the need for catheterization. It is likely that diagnostic catheterization and angiocardiography, even for preoperative assessment, will become the exception. At the same time, interventional catheterization has become a reality for several other lesions and the catheter closure of ventricular septal defect is appealing. As yet, this procedure remains investigational, but may well become clinically useful for closure of muscular, and perhaps perimembranous, defects.[226]

Pulmonary vascular disease remains an area of unsolved problems. Early surgical correction of patients with elevated resistance has helped prevent the disease in many patients, but has not eliminated the condition entirely. Definitive therapy for patients with established pulmonary vascular disease does not seem likely in the near future, but improved medical palliative therapy may retard its progression, and heart-lung transplantation will become a more viable therapeutic option for some. Further investigation into the etiology of vascular disease itself, however, is most promising of all, as it can be applied to improved early identification of patients at risk for pulmonary vascular disease and possibly its early prevention.

CHAPTER 60

Defects of the Atrial Septum Including the Atrioventricular Canal

G Wesley Vick III
Jack L Titus

Congenital defects of the atrial septum are common. They may be located in different anatomic portions of the atrial septum; the location of the defect generally reflects the abnormality of embryogenesis that led to the anomaly.[1,2] Atrial septal defects may be only cardiac anomalies or they may be associated with other congenital cardiac abnormalities. The size may vary greatly. The functional consequences of defects of the atrial septum are related to the anatomic location of the defect, the size of the defect, and the presence or absence of other cardiac anomalies.[3–7]

Developmental abnormalities resulting from improper partitioning of the embryologic atrioventricular canal often lead to a communication between the right and left atria. Accordingly, the spectrum of defects comprising the group of atrioventricular canal anomalies is considered in this chapter, but as a separate section. Generally, all atrioventricular canal (endocardial cushion) defects that have an intra-atrial communication also have major abnormalities of the atrioventricular valves and the ventricular septum.

HISTORICAL ASPECTS

Galen knew that an interatrial communication existed in the normal fetus.[8] da Vinci described an atrial septal defect in a human autopsy specimen, illustrating his findings.[9] von Rokitansky gave complete pathological descriptions of atrial septal defects.[10] Roesler[11] described the findings at autopsy of 62 patients with atrial septal defects, one of which had had the diagnosis of atrial septal defect made during life. With increasing clinical awareness of the symptoms and signs accompanying atrial septal defects the clinical diagnosis was made more frequently. Bedford and coworkers[12] made the diagnosis of atrial septal defect in 53 patients, 10 of whom had the diagnosis confirmed by subsequent autopsy. The clinical application of cardiac catheterization beginning in the late 1940s made possible confirmation of the clinical impression of atrial septal defect by providing measurements of arterial saturations and pressures in cardiac chambers. Subsequently, the development of angiocardiography permitted direct visualization of abnormal communications between the atria and the anatomic features of such communications. In the late 1970s noninvasive visualization of atrial septal defects became possible with the development and application of two-dimensional echocardiography.

Surgical repair of atrial septal defects began in 1948. Initial techniques were dependent on suturing the defects using a rubber well sewn into an atrial opening. In this situation, the defect being repaired was not directly visualized.[13] Another early method used in repair of atrial septal defects was inflow occlusion, which was sometimes employed with hypothermia. Gibbon first employed cardiopulmonary bypass to close an atrial septal defect.[14] The technique of cardiopulmonary bypass greatly facilitated cardiac surgery, since it increased the time available for operative repair of defects and made it possible to operate with a bloodless field. Surgical procedures were soon developed for repair of all types of atrial septal and atrioventricular canal defects. In 1976, Mills and King[15] reported successful closure of an atrial septal defect by means of an occlusion device inserted by a catheter passed into the atrium. A modified catheter occlusion device for atrial septal defects designed by Rashkind and Cuaso is currently undergoing clinical trials.[16]

DEFINITIONS AND CLASSIFICATIONS

The anomalies considered in this chapter are all characterized by a direct opening between the left and right atria. Interatrial communications are considered in two groups: those resulting from abnormal development of the septa that normally partition the atrial portion of the heart into right and left atria and interatrial communications that result primarily from maldevelopment of partitioning of the atrioventricular canal and endocardial cushion defect anomalies (Fig. 60–1). The first group may be viewed as isolated atrial septal defects and the second group as atrioventricular canal defects.

Based on these considerations, the following classification scheme is used in this discussion:

Isolated atrial septal defects
- Probe-patent, valve-competent patent foramen ovale
- Atrial septal defect at the fossa ovalis (secundum atrial septal defect)
- Defect superior to fossa ovalis (sinus-venosus-type atrial septal defect, superior vena caval defect)
- Defect posterior and inferior to fossa ovalis (coronary sinus, inferior vena-caval-type atrial septal defect)
- Single atrium (common atrium)

Atrioventricular canal defects
- Complete forms
  - Divided anterior common leaflet
  - Divided anterior common leaflet without septal attachments
  - Undivided anterior common leaflet
- Incomplete forms
  - No interventricular communication
    - Partial forms
    - Intermediate forms
    - Transitional forms
    - With common atrium
    - Ostium primum atrial septal defect
    - Isolated cleft mitral valve
    - Isolated cleft tricuspid valve
  - With interventricular communication
    - Ventricular septal defect of atrioventricular canal type with normal atrioventricular valves
    - Ventricular septal defect of atrioventricular canal type with abnormal atrioventricular valves

The discussions that follow are separated into the two major subgroups of isolated atrial septal defects and atrioventricular canal defects.

ISOLATED ATRIAL SEPTAL DEFECTS

Embryologic Considerations

The atrial (receiving) partitioning of the primitive heart into the two atria of the fully developed heart results from the development of two septa known as septum primum and septum secundum. The names of these septa reflect the relative time of appearance of each in the embryo.[17,18] The septum primum develops during the fourth week of embryonic life as a more or less sickle-shaped sagittal fold in the middle of the primitive atrium that grows toward the endocardial cushions of the atrioventricular canal from the superior (cephalic) aspect of the primitive atrium. The concavity of the septum primum is directed inferiorly (apexward) toward the endocardial cushions of the atrioventricular canal. The opening at the inferior margin of the septum primum, which lies between it and the endocardial cushions of the atrioventricular canal, is the ostium primum. The ostium primum is most completely identified as the ostium primum of the septum primum. Prior to complete fusion of the septum primum with the endocardial cushions of the atrioventricular canal and closure of the ostium primum, a second opening appears in the septum primum. This second opening,

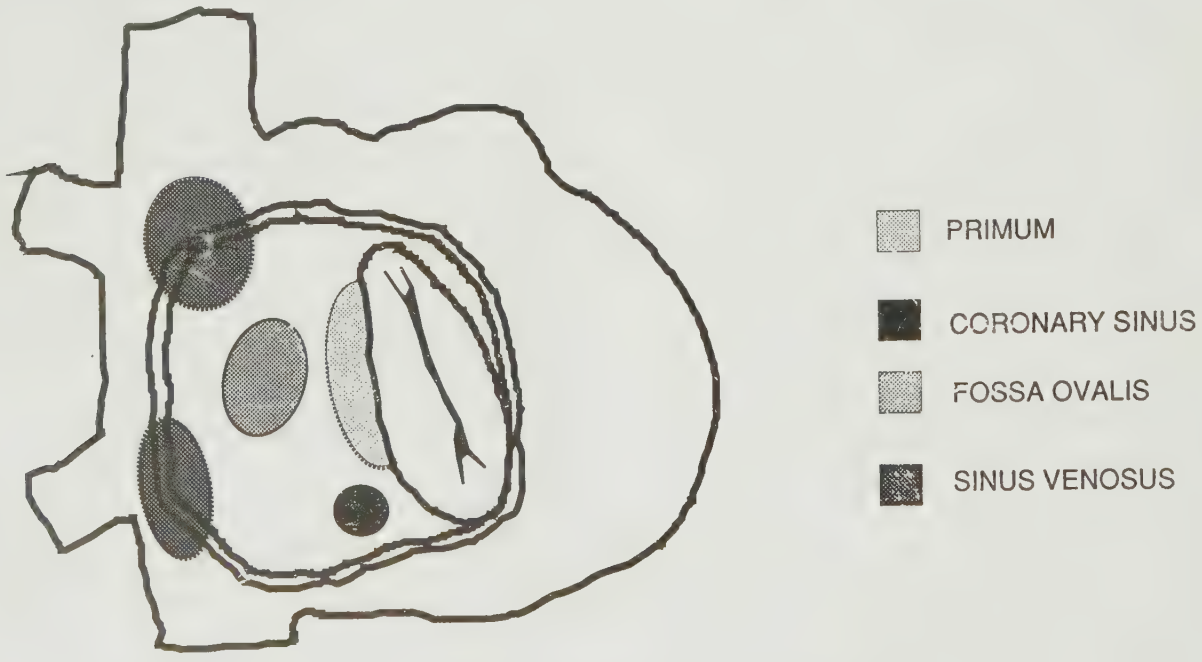

Fig. 60–1. Schematic diagram of the different types of atrial septal defect as viewed from the opened right atrium.

known as the ostium secundum, results from resorption of tissue in the superior part of the septum primum. The ostium secundum is more completely termed the ostium secundum of the septum primum.

The development of the ostium secundum of the septum primum occurs during the fifth and sixth weeks of embryologic life. At about the same time as the development of the ostium secundum, a second septum begins to develop. This septum is positioned to the right of the septum primum in the primitive heart and is known as the septum secundum. The septum secundum also is concave in shape, with the concavity directed more posteriorly toward the opening of the sinus venosus of the primitive heart. Its concave shape and its alignment permit the identification of two limbs of the septum secundum. One limb is located superiorly and the other is located inferiorly. The more inferior limb of the septum secundum fuses with the lowermost portion of the atrial septum, where it joins the endocardial cushion partitioning the atrioventricular canal.

The opening in the septum secundum resulting from its concave shape is termed the foramen ovale. The septum primum and septum secundum will fuse so that the foramen ovale of the septum secundum lies immediately to the right of the septum primum. As a result of the opening in the septum secundum (foramen ovale) and the opening in the septum primum (the ostium secundum), communication between the now separated right and left atria is possible, but only from right to left. Thus blood flow from the right atrium to the left atrium can and does occur through the foramen ovale of the septum secundum and the ostium secundum of the septum primum because the pulmonary vascular resistance of the developing lung exceeds the systemic vascular resistance and results in higher pressures in the right atrium of the fetus than in the left atrium. Atrial septal defects in this region may result from defective development of the septum secundum or from defective development (e.g., excessive resorption) of the septum primum. Accordingly, the true atrial septal defects in this region are best termed defects at the fossa ovalis, although by long-term usage, they are commonly referred to as secundum atrial septal defects. It should be noted that use of the term secundum to refer to these defects is correct only without any modifying adjectives such as ostium.

After birth, fusion of the two septa is completed in the region of the foramen ovale of the septum secundum and the septum primum, completely closing the ostium secundum of the septum primum and the foramen ovale. However, in approximately 25 to 30% of normal adult hearts, the flap of the septum primum does not completely fuse with the septum secundum. The septum primum then serves as a valve of the foramen ovale, which potentially could open and permit shunting when right atrial pressure exceeds left atrial pressure. Since in the normal postnatal state left atrial pressure exceeds right atrial pressure, the valve of the foramen ovale is usually closed.

Sinus venosus atrial defects lie outside the margins of the fossa ovalis. These defects are thought to be secondary to abnormal attachment of the right pulmonary veins to either the superior or inferior vena caval veins. An interatrial communication results when the wall between the vena caval and pulmonary veins is resorbed. Coronary sinus defects are thought to arise from failure of the wall between the coronary sinus and the left atrium to develop, so-called unroofing. Unroofing of the coronary sinus is frequently seen in the presence of a superior vena cava.

Epidemiologic Aspects

Fossa ovalis atrial septal defect is one of the most common congenital cardiac disorders. The study of Feldt et al.[19] in Olmsted County, Minnesota, showed that isolated secundum atrial septal defects accounted for approximately 7% of congenital cardiac defects. Most patients with isolated secundum atrial septal defects are females, by a factor of 2 to 1.

Genetic Aspects

Although fossa ovalis atrial septal defects usually occur sporadically, they may occur on a familial basis. The Holt–Oram syndrome is perhaps the best-known example of familial inheritance of atrial septal defects.[20] This disorder is characterized by congenital deformities of the upper limbs (most frequently absent or hypoplastic radii), electrocardiographic abnormalities such as right bundle block or first-degree atrioventricular block, and an autosomal dominant pattern of inheritance. There is a penetrance of nearly 100% with this disorder. Approximately 40% of the cases represent new mutations and the remainder are inherited from a parent. Although the Holt–Oram syndrome is apparently due to a single gene defect, the biochemical abnormality has not been defined at present.

Another example of familial inheritance of fossa ovalis atrial septal defects is the syndrome of familial atrial septal defect with prolonged atrioventricular conduction.[21] This mutant gene also has a high degree of penetrance but does not cause skeletal abnormalities. The identifying anomalies are prolonged atrioventricular conduction and the atrial septal defect in association with an autosomal dominant mode of inheritance.

In counseling patients and their parents, it is important to identify these syndromes, since 50% of first-degree relatives will be affected by them. By contrast, only 3% of first-degree relatives are affected with the usual sporadic type of atrial septal defect.

Anatomic Features

Valve-Competent Patent Foramen Ovale

Approximately 30% of otherwise normal adult hearts have a probe-patent, valve-competent foramen ovale, which is not usually considered an atrial septal defect.

Valve-Incompetent Patent Foramen Ovale

The smallest atrial septal defects are due to incompetent foramina ovale. They may be congenital or may be acquired by stretching of the right or left atria in conditions in which those chambers are enlarged.

Defects of the Fossa Ovalis

The typical fossa ovalis or secundum defect is contained within the area bordered by the limbus of the fossa ovalis. The size of these defects varies greatly. In addition, the atrial septum may be fenestrated, so that multiple defects are possible. Secundum defects may be confluent with other defects of the interatrial septum, such as a sinus venosus defect. The junction of the inferior vena cava and the right atrium is located slightly to the left of the limbus. Thus blood flowing in from the inferior vena cava has a tendency

to shunt from right to left across the septum. The eustachian valve has a tendency to overhang the atrial septum. This tendency can be important surgically, for it is possible to mistake the rim of the eustachian valve for the lower edge of an atrial septal defect.

Defect Posterior and Inferior to the Fossa Ovalis

Defects may exist posterior and inferior to the fossa ovalis. Hypoplasia or anterior displacement of the posterior limbus often coexists with these defects, as well as anomalous pulmonary venous connection of the right lung.

Sinus Venosus Defect

These defects are located in the part of the atrial septum subjacent to the superior vena caval orifice.[22] The right upper and middle-lobe pulmonary veins generally attach to the low superior vena cava or superior vena cava–right atrium junction in these patients, so that partial anomalous pulmonary venous return is present. Usually the superior vena cava overrides the atrium, so that some of the superior vena caval flow is directed into the left atrium, giving a right-to-left shunt. Occasionally, this override can be severe or even complete, with resultant marked cyanosis.

Coronary Sinus Defect

Coronary sinus atrial septal defects are characterized by absence of part or all of the common wall between the coronary sinus and the left atrium. A persistent left superior vena cava is also present in many cases.[23]

Associated Cardiovascular Defects

Atrial septal defects are often seen in conjunction with other congenital cardiac anomalies. In many of these anomalies, the associated defects are the lesions of primary importance. However, the atrial septal defect may still have a major role in the physiology of the lesion. A case in point is complete transposition of the great arteries, where an atrial septal defect allows the mixing between the pulmonary and systemic circulations necessary to sustain life. Another example is tricuspid atresia, in which the entire cardiac output must pass across the atrial septal defect.

Atrial septal defects are also frequently seen in conjunction with partial or total anomalous pulmonary venous connection. In total anomalous pulmonary venous connection the atrial septal defect is an essential feature, since the atrial septal defect is the only route whereby the pulmonary venous blood can return to the systemic circulation. Restriction of the atrial septal defect in affected individuals, which does occur, usually causes severe symptoms. Atrial septal defects are usually present with partial anomalous pulmonary venous return.

Acquired Cardiovascular Pathology Associated with Secundum Atrial Septal Defects

When the atrial septal defect is hemodynamically important, other cardiovascular structures are secondarily affected. The right atrial and the right ventricular size and thickness are increased. The pulmonary arteries are enlarged, and pulmonary vascular disease is sometimes present. Mitral valve prolapse may occur, a feature that is thought to result from the leftward shift of the ventricular septum caused by right ventricular enlargement.[24]

Patients with fossa ovalis atrial septal defects may contract rheumatic fever and develop mitral stenosis. This combination is termed Lutembacher's syndrome.[25] Mitral and/or tricuspid insufficiency may also develop in patients with atrial septal defects.

Physiology

Intrauterine and Postnatal

Because pulmonary blood flow is minimal before birth, nearly all blood reaching the left atrium must pass across the foramen ovale. When the lungs expand after birth, pulmonary venous return substantially increases and the systemic vascular resistance increases. The result in the normal infant is that left atrial pressure rises above the right atrial pressure, causing functional closure of the foramen ovale. When an atrial septal defect is present, the intrauterine physiology is essentially unchanged. However, the hemodynamic changes after birth do not close the atrial septum. Hence left-to-right shunting will tend to take place in these patients. Right-to-left shunting may also occur, and sometimes causes patients with atrial septal defect to exhibit mild cyanosis in the neonatal period.

Patent Foramen Ovale

If the flap valve of the foramen ovale is competent, shunting cannot occur as long as left atrial pressure remains higher than right atrial pressure. However, even in normal subjects, the right atrial pressure may transiently rise above the left atrial pressure. When this happens, right-to-left interatrial shunting may occur if the valve is functional. It is possible for blood clots and other emboli to pass across the atrial septum under these circumstances. In patients with pulmonary vascular disease or pulmonary stenosis, right-to-left shunting across a patent foramen ovale may occur.[26]

Defects of Small Size

We define small atrial septal defects as those that are associated with a Qp/Qs of less than 2:1 in the absence of significant associated cardiovascular anomalies. The presence of a small atrial septal defect does not cause major changes in cardiac hemodynamics. However, emboli can gain access to the left side of the circulatory system whenever the right atrial pressure rises above the left atrial pressure.

Defects of Moderate and Large Size

We define moderate and large atrial septal defects as being associated with a Qp/Qs of $\geq$2:1 in the absence of significant associated cardiovascular anomalies. In the presence of an atrial septal defect, the direction of the atrial shunting is determined by the relative pressures in the right and left atria. These atrial pressures are in turn principally determined by the resistances to filling of the respective ventricles. The amount of the resultant shunting is usually not dependent on the size of the interatrial communication, but rather on the relative compliance of the right and left ventricles.

During development, the atrial pressures in the cardiac cycle vary, as do the compliances of the right and left ventricles.[3] Immediately after birth the left and right ventricles are similar in compliance. Hence shunting tends to be minimal during the neonatal period, even with large defects. As the pulmonary vascular resistance drops and the right ventricle begins to assume its characteristic thin-walled configuration, the resistance to filling of the right ventricle drops also. For this reason, the left-to-right shunt

across atrial septal defects generally increases with time. Additionally, with increasing age the left ventricular compliance tends to increase, further increasing the tendency for left-to-right shunting.

When atrial defects are of large size, mean and phasic pressures will be equal when recorded by standard catheter measurements. Levin et al.[27] measured simultaneous right and left atrial pressures in patients with atrial septal defects using specially designed matched catheter systems to determine instantaneous pressure differences. All patients had a Qp/Qs of greater than 2:1. Shunt timing was determined by cineangiography, and the cine frames were related to the electrocardiogram with a photocell timing device. Though left atrial pressure was usually slightly higher than right atrial pressure during most of the cardiac cycle, the reverse was noted to occur transiently.[27] Thus a small right-to-left shunt of blood, predominantly from the inferior vena cava, occurred during early ventricular diastole or during the onset of ventricular contraction. Left-to-right pressure differences were most prominent during the second half of ventricular systole, with the peak differential occurring at the time of the left atrial *v* wave. The maximum left-to-right shunt was found to coincide in timing with this maximum pressure differential, after allowing for a 50- to 75-msec lag period.

The magnitude and duration of left-to-right and right-to-left atrial shunting varies with the respiratory cycle. Left-to-right shunting across the atrial septum is increased with the increased intrathoracic pressure of expiration and is decreased with the decreased intrathoracic pressure of inspiration. Right-to-left shunting across the atrial septum is decreased with the increased intrathoracic pressure of expiration and is increased with the decreased intrathoracic pressure of inspiration. Right ventricular hypertrophy and pulmonary disease increase the portion of the cardiac cycle during which right-to-left shunting takes place and increases the magnitude of the right-to-left shunt. Severe cyanosis can occur from right-to-left shunting when resistance to right ventricular inflow is high, as in critical pulmonic stenosis. When right-to-left shunting does occur across a secundum atrial septal defect, the shunted blood is derived primarily from the inferior vena cava, as blood from the superior vena cava tends to be directed across the tricuspid valve because of the orientation of the cardiac structures.

Physiology in Association with Additional Cardiovascular Pathologic Features

Right Ventricular Outflow Obstruction. As has been noted, patients with right ventricular outflow obstruction may develop sizable right-to-left shunts through an atrial septal defect or even a patent foramen ovale.[28,29] Severe obstruction will cause enlargement of the right atrium and may cause consequent stretching of the foramen ovale.

Pulmonary Vascular Disease. When pulmonary hypertension is present, the left-to-right shunt across the atrial septal defect is small and may be predominantly right to left. In some patients with pulmonary hypertension the presence of an atrial septal defect may be protective and prevent the development of acute right ventricular hypertension.

Left Ventricular Outflow Obstruction. Patients with left ventricular outflow obstruction will have increased resistance to filling of the left ventricle as opposed to the right ventricle. Hence they will tend to have a greater left-to-right shunt across the atrial septal defect than patients without left ventricular outflow obstruction.

Obstruction to Left Ventricular Inflow. Atrial septal defects are occasionally associated with congenital obstruction to left ventricular inflow, such as cor triatriatum and congenital mitral stenosis.[30–32] Patients with Lutembacher's syndrome develop acquired obstruction to left ventricular inflow. The atrial septal defect in these patients tends to ameliorate the left atrial (and consequent pulmonary venous) hypertension caused by the left ventricular inflow obstruction. However, the left-to-right shunting across the atrial septal defect (and hence the right ventricular volume overload) is increased.

Natural History

The natural history of small atrial septal defects seems to be excellent without specific therapy. Because these defects are difficult to detect, their incidence is probably clinically underestimated.

Isolated secundum atrial septal defects of moderate and large size do not cause major symptoms in most cases during infancy and childhood,[33–36] although occasionally even infants may develop severe congestive heart failure. In the absence of unrelated problems, over 99% of patients with isolated secundum defects will live past the first year of life. Children and infants with these defects tend to be smaller than normal, but failure to thrive on the basis of the atrial septal defect alone is rare. Exercise intolerance may develop in some patients as early as the second decade of life. Other may remain asymptomatic for several more decades.

As has also been noted, left-to-right shunting tends to increase with age in many patients. Thus the incidence of congestive heart failure with attendant fluid retention, hepatomegaly, and elevated jugular venous pressure rises with the age of these patients. The large shunts present in many older patients cause stretching of the atria, which presumably predisposes them to atrial arrhythmias, such as atrial flutter, fibrillation, and tachycardia. These arrhythmias increase in incidence with age and are a major cause of morbidity and mortality.

Sealy and colleagues[37] studied 108 preoperative patients with atrial septal defects ranging in age from 3 to 63 years and found an increased incidence of atrial arrhythmias in patients with large left-to-right shunts. Patients with a Qp/Qs of 2:1 or less had an 11% incidence of atrial arrhythmias, and patients with a Qp/Qs of 3:1 or greater had a 38% incidence of atrial arrhythmias. The incidence of arrhythmia was less than 25% in patients less than 30 years of age and greater than 50% in patients over 30 years of age. There was no evidence of a correlation between the incidence of arrhythmias and pulmonary artery pressure. Paroxysmal atrial arrhythmias, such as atrial flutter, atrial fibrillation, and supraventricular tachycardia, which are particularly likely to cause symptoms, were found by Brandenburg and colleagues[38] in 14% (27 of 188) of patients over 44 years of age with isolated secundum atrial septal defect. Atrial fibrillation or atrial flutter was present preoperatively in 38% (6 of 16) patients over 60 years of age treated surgically by Brandenburg and colleagues.[38] By contrast, only 2% of 204 patients with atrial septal defect less than 18 years old studied by Boelkens and colleagues had atrial arrhythmias of any kind.[39]

Pulmonary vascular disease may develop in patients with atrial septal defect. This complication is infrequent in childhood and

adolescence and uncommon even in older adults with large defects. Steele and colleagues reviewed the histories of 702 patients with isolated secundum or sinus venosus atrial septal defects and identified 40 patients (6%) with pulmonary vascular obstructive disease.[40] Most (34 of 40) of these patients were females and all were over 19 years of age. It is of note that the proportion of females with pulmonary hypertension in this series substantially exceeds the 2:1 predominance of atrial septal defect in females. A high mortality rate was associated with a total pulmonary resistance of greater than 15 units/m^2, regardless of whether treatment was medical or surgical. Surgical treatment improved outcome in patients with a total pulmonary resistance of less than 15 units/m^2. Seventeen of the 40 patients died during the followup period, which had a median length of 12 years. Two patients died within 24 hours after technically successful surgery and two patients died from noncardiac causes. Cardiac failure was cited as the cause of death in all other deaths.[40]

The childhood incidence of pulmonary vascular disease in association with atrial septal defect may be relatively high in certain regions, however. Cherian and colleagues reported an incidence of pulmonary vascular disease of 7% in the first decade of life and 8% in the second decade of life in a series of 709 patients with isolated secundum atrial septal defect from Vellore, India.[41] Dalen and associates[42] found that pulmonary hypertension was more common in patients less than 20 years of age with atrial septal defect who lived at an altitude in excess of 4000 ft than in such patients who lived at an altitude of 2000 ft or less. Pulmonary hypertension was present in 11 of 53 patients living at an altitude of 4000 ft or more as opposed to 3 of 49 who resided at an altitude of 2000 ft or less.

The incidence of elevated pulmonary vascular resistance in patients with atrial septal defect increases with increasing age, and serial studies in some patients have demonstrated progression of disease with time, presumably due to continued damage to the pulmonary vasculature by elevated pulmonary blood flow. However, the rate of this progression is highly variable. Furthermore, it has been well documented that patients with large atrial septal defects and high pulmonary blood flow may survive until the sixth or seventh decade of life without developing elevated pulmonary artery pressure or resistance. Conversely, advanced pulmonary vascular disease has been reported in patients with atrial septal defect as young as 2 years of age.[43] This information suggests that factors other than elevated pulmonary blood flow are important causes of pulmonary vascular disease in these patients. Rabinovich and colleagues have suggested that a biologically deficient form of von Willebrand factor may contribute to the development of pulmonary vascular disease in patients with congenital heart disease, including atrial septal defect.[44]

Bacterial endocarditis is rare in patients with atrial septal defect in the absence of associated anomalies, and antibiotic prophylaxis is not uniformly recommended.[45,46] Paradoxical emboli may occur, however, even with small defects. The presence of an atrial septal defect should be considered in any patient with a cerebral or other systemic embolus in which there is no demonstrable left-sided source, particularly if there is systemic venous thrombosis.[47] Patients in whom fibrillation develops often have atrial thrombi, which may embolize systemically.

It has become apparent that a substantial number of atrial septal defects detected during infancy will close spontaneously. Kavey and colleagues[48] identified patients with secundum atrial septal defects using two-dimensional echocardiography in conjunction with physical examination, electrocardiography, and chest roentgenograms. After a followup period of at least 2 years, 17 of the patients no longer had echocardiographic or other findings consistent with atrial septal defect by a mean age of 4 years. Spontaneous closure of atrial septal defect has also been documented by cardiac catheterization. Cockerham and colleagues[49] detected the presence of an isolated secundum atrial septal defect by cardiac catheterization and cineangiography in 54 patients less than 2 years of age. None of the patients had obstructive lesions of the left side of the heart. It was documented at a subsequent catheterization that the atrial septal defect in 14 of these patients had completely closed. Other investigators have also described complete closure of atrial septal defects in early childhood.[50]

Atrial Septal Defect and Pregnancy

Pregnancy is generally well tolerated in patients with atrial septal defect who do not have pulmonary vascular disease. Espino Vela and Alvarado-Toro described a series of 105 patients with isolated atrial septal defect in which there were no deaths.[51] Pregnancy does place additional demands on the cardiovascular system, and may cause patients with previously occult atrial septal defects to become symptomatic. In particular, exercise intolerance and congestive heart failure may become apparent during pregnancy. Venous thrombosis, common during pregnancy because of stasis, may lead to paradoxical embolism when an atrial septal defect is present.[52,53] Pulmonary vascular disease is rare below the age of 30 in patients with atrial septal defect in most ethnic groups and geographical regions, but when it is present, pregnancy carries a substantial health risk for the mother and often results in miscarriage.[54,55] In these patients, maternal mortality may approach 50%. Causes of maternal death include preeclampsia, hemorrhage, and thromboembolism.[56]

Physical Examination

Inspection and Palpation

The height and weight of patients with atrial septal defects is often below normal, though usually not by substantial margins. A precordial bulge may be present in those with a large left-to-right shunt, and Harrison's grooves (transverse depressions on both sides above the lower border of the thorax) may be apparent in some patients.[29] The presence of a hypoplastic thumb or radius, or phocomelia should cause suspicion that the patient has the Holt–Oram syndrome.[20] Cyanosis may be present in infants, particularly those with right ventricular outflow obstruction. Cyanosis may also be present in the relatively unusual patient with pulmonary vascular disease. On occasion a large eustachian valve may direct inferior vena caval flow across a secundum defect or a sinus venosus defect of the inferior vena caval type.

In patients with a thin body habitus, a hyperdynamic right ventricular impulse may be observed. Palpation along the left sternal border and in the subxiphoid area will demonstrate this impulse,[57] often termed a right ventricular heave. When pulmonary vascular disease is present, or when obstruction to right ventricular outflow is present, the right ventricular impulse will be less dynamic and will have more of a tapping or thrusting quality, concomitant with the change from pressure to volume overload. An enlarged and

pulsatile pulmonary trunk may also be palpated in many patients at the second left intercostal space. When pulmonary hypertension is present, the impulse created by the pulmonary artery is even more prominent. A palpable pulmonic component of the second heart sound may be present in such patients.

Arterial Pulse. The arterial pulse is normal at rest in these patients. It is possible to demonstrate abnormalities when the Valsalva maneuver is employed, however.[58] During the straining phase of the Valsalva maneuver, normal subjects show a decrease in systemic venous return. In patients with atrial septal defects and relatively large left-to-right shunts, the large volume of blood pooled in the lungs permits left ventricular output to be maintained.

Jugular Venous Pulse. Patients with isolated and nonrestrictive atrial septal defects have a jugular venous pulse of normal amplitude. However, since the two atria are connected by a nonrestrictive channel, the A and V waves have equal height.[59] When pulmonary vascular disease supervenes, the right atrium contracts more forcefully, causing large A waves to be formed.[29]

Auscultation

The first heart sound, best heard at the apex and lower left sternal edge, is often split with atrial septal defects, and the second component is increased in intensity. This increased intensity is thought to result because the high amount of diastolic flow presses the leaflets toward the right ventricle and because the forceful right ventricular contraction causes an abrupt cephalad excursion of the tricuspid leaflets.

Atrial septal defects with moderate to large left-to-right shunts are associated with a pulmonary systolic murmur which begins shortly after the first heart sound, peaks in early to midsystole, and ends before the second heart sound. This murmur is not usually associated with a thrill. When a thrill is present, either a very large shunt or a pulmonic stenosis is frequently present. Rapid flow through the peripheral pulmonary arteries may cause systolic crescendo–decrescendo murmurs, which are most prominent at locations in the chest other than the second intercostal space.

The characteristic auscultatory finding in atrial septal defect is wide, fixed splitting of the second sound.[60,61] This finding is present in patients with large left-to-right shunts and normal pulmonary artery pressure. Two principal theories have been developed to explain fixed splitting of the second sound in atrial septal defect.[61,62]

The first explanation relates splitting of the second sound to the variations in systemic and pulmonary venous return created by inspiration and expiration, and the consequent effect on flow across the atrial septal defect.[61] In normal subjects the decreased intrathoracic pressure of inspiration augments systemic venous return and thus increases right ventricular stroke volume and ejection time. Concomitantly, pulmonary venous return to the left side of the heart is decreased, and left ventricular stroke volume and ejection time are decreased. Thus splitting of the second sound increases with inspiration in normal subjects. Expiration is associated with reduced systemic venous return, decreased right ventricular stroke volume, and decreased right ventricular ejection time. There is also increased pulmonary venous return with expiration, resulting in an increase in left ventricular stroke volume and ejection time. Therefore splitting of the second sound decreases with expiration in normal subjects.

In patients with atrial septal defect, the flow across the defect is diminished by the reduced pulmonary venous return of inspiration and increased by the increased pulmonary venous return of expiration. Since inspiration increases and expiration decreases systemic venous return, it follows that flow across the defect and systemic venous return change in a reciprocal manner, so that ventricular stroke volumes and ejection times remain essentially constant. As a consequence, the time difference between aortic and pulmonary valve closure is unchanged with respiration.

The second theory is based on evidence suggesting that pulmonary capacitance is the major factor in determining splitting of the second sound.[62] According to this explanation, inspiratory splitting of the second sound in normal subjects results primarily because pulmonary capacitance increases during inspiration. This increase in capacitance causes an inspiratory increase in the "hangout" interval (the time between the descending portions of the right ventricular and pulmonary arterial pressure pulses) and a consequent delay in the pulmonic component of the second sound. In normal subjects the pulmonary capacitance decreases upon expiration, there is a decrease in the hangout interval, and the splitting of the second sound decreases.[63]

In patients with atrial septal defect the capacitance of the pulmonary bed is increased and its impedance is decreased.[62] The increased capacitance causes an increase in the hangout interval and a consequent wide splitting between the first and second sounds. There is little respiratory variation in the pulmonary capacitance and consequently little variation in the hangout interval and splitting of the second sound.

The duration of electromechanical systole is the same in the right and left ventricles of these patients, because even though the right ventricle ejects a relatively larger volume than the left ventricle, it ejects it in an accelerated manner. If the pulmonary arterial pressure rises, the hangout interval decreases, but the split still does not vary with the phase of the respiratory cycle.

When the left-to-right shunt is small or negligible, as it is in most neonates with atrial septal defects, fixed splitting of the second sound does not occur. Fixed splitting does not occur in patients with partial anomalous pulmonary venous return and intact atrial septum, presumably due to the lack of reciprocal changes in left-to-right shunt and systemic venous return with inspiration.[64] Since relatively wide (but not truly fixed) splitting of the second sound is common in the supine position, it is better to evaluate the second sound when the patient is sitting or standing.

The intensities of the pulmonic and aortic components of the second sound are equal in most patients with uncomplicated atrial septal defects, probably because the main pulmonary artery is dilated and close to the chest wall. By contrast, in normal subjects the aortic component of the second sound is louder than the pulmonic component.[65] Patients with pulmonary hypertension generally have an accentuated pulmonic component of the second sound. However, occasionally a patient with normal pulmonary arterial pressures will have an increased intensity of the pulmonic component of the second sound.

The diastolic murmur most commonly associated with atrial septal defect is a mid-diastolic murmur associated with the high flow across the tricuspid valve. This murmur becomes apparent when the left-to-right shunt across the atrial septal defect is greater than 2 to 1. The murmur is of low to medium frequency and does not increase with inspiration. Another diastolic murmur sometimes associated with atrial septal defect is a low-pitched murmur of

pulmonic regurgitation, which is thought to be a consequence of dilatation of the pulmonary artery.

Because the pressure gradient across the atrial septum is seldom large, audible murmurs from flow across the atrial septal defect itself are rare, though intracardiac phonocardiography can demonstrate them.

In the occasional patient with atrial septal defect and right-to-left shunting due to pulmonary hypertension, auscultatory findings differ greatly from those usually found in atrial septal defects.[66] A right ventricular fourth heart sound may be present. The midsystolic pulmonic murmur is softer and shorter since only a normal stroke volume is ejected. The tricuspid flow murmur is not present. The pulmonic component of the second sound is increased in intensity but the fixed splitting narrows. If a murmur of pulmonic insufficiency is present, it is high-pitched. A holosystolic murmur of tricuspid insufficiency may also be present.

The auscultatory findings in mild valvular pulmonic stenosis or infundibular stenosis and idiopathic dilatation of the pulmonary artery may mimic those of atrial septal defect. All these disorders are associated with a systolic murmur and a split second sound. They may be differentiated from atrial septal defects by movement of the second sound with respiration, by a pulmonary ejection click, or by the absence of a tricuspid flow murmur. As has been noted, in atrial septal defect, the second sound does not move with respiration, and a tricuspid flow murmur is frequent. Pulmonary ejection clicks are uncommon in atrial septal defects uncomplicated by pulmonary hypertension.

Electrocardiogram

Sinus rhythm is usual in young patients with uncomplicated secundum atrial septal defects. However, electrophysiologic studies have demonstrated a substantial age-related incidence of sinus-node dysfunction beginning in early childhood.[67–69] Ruschhaupt and colleagues[68] evaluated 34 patients with secundum atrial septal defects prior to surgical intervention and found that 13 (38%) had a delayed sinus-node recovery time as a result of right atrial pacing. Sinus-node recovery times were prolonged in 7 of 10 patients older than 5 years of age, in 6 of 11 patients between 2.5 and 5 years of age, and in none of the 13 patients less than 2.5 years old. Clark and Kugler[67] found electrophysiologic evidence of sinus-node dysfunction before operation in 10 of 15 patients with atrial septal defects. Their patients had a mean age of 8 years and 5 were younger than 5 years of age.

Atrioventricular node dysfunction is less common than sinus-node dysfunction in patients with secundum atrial septal defect, but is not unusual.[69] Prolongation of the P–R interval is frequent and sometimes has a familial association. Beyond the third decade of life, patients with atrial septal defect have a high incidence of atrial arrhythmias, particularly atrial fibrillation, but also including atrial flutter and supraventricular tachycardia.[70]

Patients with atrial septal defects usually have a normal P wave. Occasionally, a particularly broad P wave is present that is not notched or bifid. This effect is thought to be caused by an enlarged right atrium. P waves seen in patients with secundum atrial septal defect may be peaked, but they are seldom of high amplitude. In secundum atrial septal defects, the frontal-plane P-wave axis is normally directed to the left and downward.

Sinus venosus atrial septal defects are often associated with a leftward frontal plane P-wave axis, negative in III and aVF and positive in aVL. Davia and colleagues found a frontal-plane P-wave axis of 0° or less in 13 of 48 patients.[22] Similar findings were present in the preoperative electrocardiograms reviewed by Kyger and colleagues.[71] When a persistent left superior vena cava is also present, a leftward frontal axis seems to be particularly common. Two explanations have been offered to account for the abnormal P-wave axis in patients with sinus venosus atrial septal defect. First, it has been suggested that the sinoatrial node in patients with sinus venosus atrial septal defects is displaced to a relatively inferior location, causing a shift in the pattern of atrial activation.[22] The second explanation, applicable in those cases with persistent left superior vena cava, is that an ectopic atrial pacemaker is present, a persistent remnant of the embryonic pacemaker present at the junction of the left common cardinal vein with the sinus venosus.[72] The first explanation does not account for the presence of a normal P-wave axis in most cases of sinus venosus atrial septal defect, and the second explanation does not account for the relatively frequent presence of a leftward frontal-plane P-wave axis in patients with no persistent left superior vena cava.[22] Thus neither explanation is entirely satisfactory. Unfortunately, the available morphologic information regarding the sinus node in sinus venosus atrial septal defect is limited.[73]

The QRS complex in patients with secundum atrial septal defects often has a slightly prolonged duration and a characteristic rSr′ or rsR′ pattern[74] (Fig. 60–2). The terminal r′ or R′ is often moderately slurred. Thus the terminal forces of the QRS complex are directed to the right, superiorly and anteriorly. The reason for this orientation of the QRS complex is thought to be disproportionate thickening of the right ventricular outflow tract, which is the last portion of the ventricle to depolarize. The term ''incomplete right bundle branch block'' is often used to describe this QRS pattern, but is a misnomer, since it is a consequence of hypertrophy, and not a conduction disturbance.

With increasing degrees of pulmonary hypertension, patients with secundum atrial septal defects tend to lose the rSr′ pattern in lead V_1 and develop a tall monophasic R wave with a deeply inverted T wave.

A frontal-plane QRS axis ranging from +95° to +135° with a clockwise loop is often present. Left-axis deviation of the QRS axis with a counterclockwise frontal-plane loop suggests the presence of an atrioventricular canal defect, but can occur with uncomplicated secundum atrial septal defect.

Chest Roentgenogram

The chest roentgenogram in patients with secundum atrial septal defect and sizable left-to-right shunts generally shows cardiac enlargement and increased pulmonary vascularity[75] (Fig. 60–3). The increased pulmonary vascularity typically extends to the periphery of the lung fields, with a dilated pulmonary trunk and central branches. Although the ascending and transverse aortas have normal diameters in these patients, the enlargement of the pulmonary arteries causes the aorta not to form the border of the cardiac silhouette. The consequence is that a characteristic ''triangular'' cardiac shape is created. Right atrial and right ventricular enlargement are usually seen, but left atrial and left ventricular sizes are usually normal.

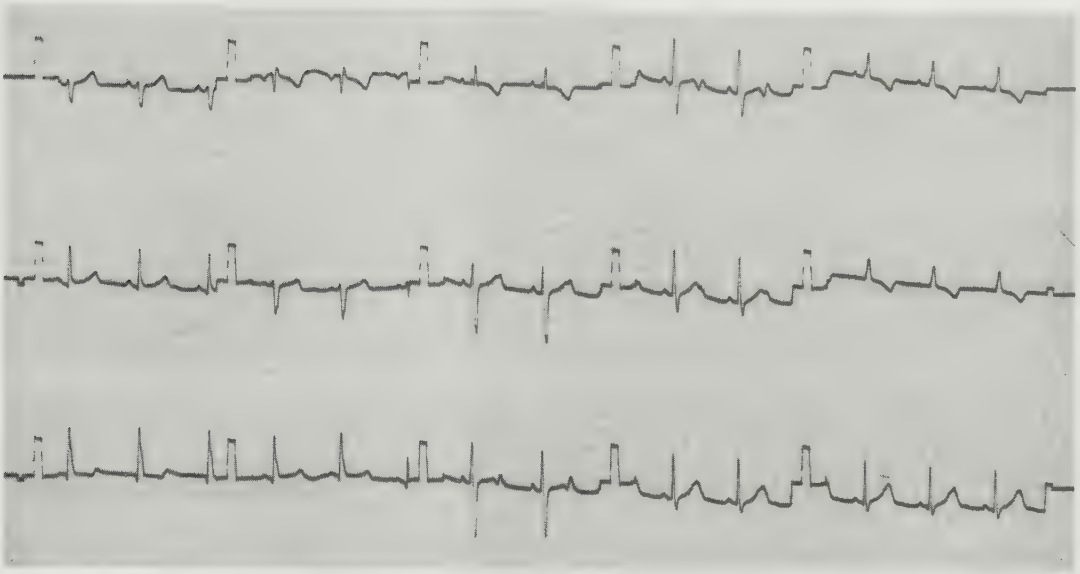

Fig. 60–2. Electrocardiogram from a 9-yr-old girl with a large secundum atrial septal defect. Note the rsR′ in lead V_1 and the rightward deviation of the frontal-plane QRS axis.

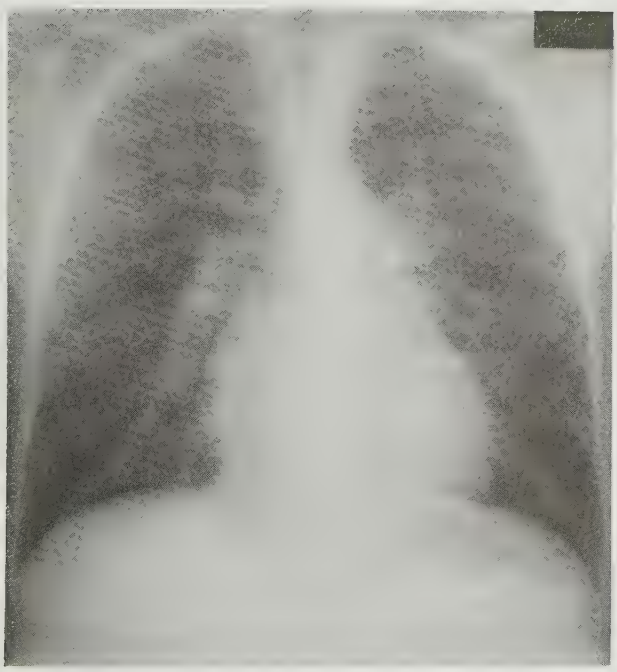

Fig. 60–3. Chest roentgenogram from a 9-yr-old girl with a secundum atrial septal defect and a large left-to-right shunt (electrocardiogram shown in Figure 60–2). The pulmonary artery vasculature is increased. The main pulmonary artery is enlarged. The ascending aorta is relatively inconspicuous.

Echocardiogram

M-Mode

The M-mode echocardiogram in patients with classic secundum atrial septal defect will usually show right ventricular enlargement, and paradoxical motion of the interventricular septum will be present in many cases.[76,77] Mitral valve motion appears normal in these patients, as opposed to those with atrioventricular canal defects, in whom the M-mode echocardiogram shows apparent diastolic motion of the mitral valve through the interventricular septum.

Two-Dimensional

Two-dimensional echocardiography can provide direct noninvasive visualization of all types of atrial septal defects[78–80] (Fig. 60–4). The reliability of the two-dimensional echocardiogram in demonstrating characteristic dropout in the atrial septum is best when the axis of the echo beam is perpendicular to the atrial septum. For most defects, a subcostal view provides such a perpendicular angle, though, depending on the location of the defect, there are other possible echocardiographic approaches, such as suprasternal or parasternal, that will yield an appropriate angle. Atrial septal defects can often be seen on the apical four-chamber view, but as a consequence of the parallel angle of the echo beam to the atrial septum and the thinness of the fossa ovalis, false echo dropout is often seen.

In addition to direct visualization of the atrial septal defect, two-dimensional echocardiography will also frequently demonstrate enlargement of the right atrium, right ventricle, and pulmonary arteries and will often show the paradoxical motion of the interventricular septum in a two-dimensional format. In many cases the pulmonary venous connections can be demonstrated.

Doppler

Abnormal flow across the atrial septum can be reliably detected by pulsed Doppler echocardiography.[81] The accuracy of Doppler

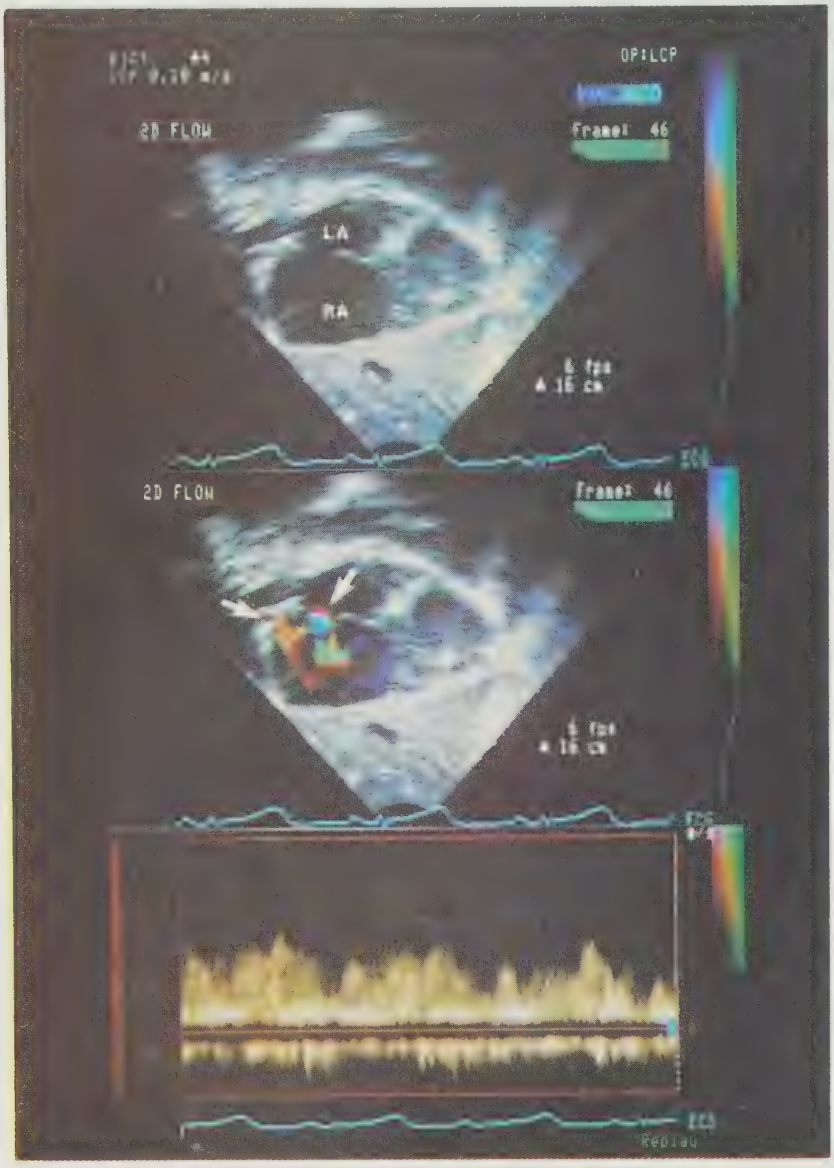

Fig. 60–4. Upper panel—Two-dimensional echocardiogram (subcostal view, anatomical orientation) demonstrating a secundum atrial septal defect between the left atrium (LA) and right atrium (RA). Middle panel—Color Doppler study of atrial flow in the same patient. Arrow on the patient's left indicates flow into the atrium from the superior vena cava. Arrow on the patient's right indicates left-to-right flow across the secundum atrial septal defect into the right atrium. Lower panel—Pulsed Doppler study with sample volume positioned over atrial septal defect demonstrates presence of flow toward the transducer, consistent with the presence of left-to-right shunting.

identification of flow across the atrial septum can be greatly improved by the use of two-dimensional echocardiographic direction of the Doppler sampling. Characteristically, a shunt across the atrial septal defect will show turbulent flow in the direction of the shunt and minimal flow in the opposite direction. With classic secundum atrial septal defects, the interatrial shunt occurs in late systole and early diastole. Since pressure gradients across the atrial septum are characteristically minimal when the defects are nonrestrictive, velocity is usually low.

Pulsed Doppler echocardiography can aid in the quantitation of pulmonary-to-systemic blood flow. By integrating the time-velocity Doppler tracings taken at either the tricuspid and mitral orifices or the pulmonic and aortic orifices and multiplying by the respective valve areas measured by two-dimensional echocardiography and by the heart rate, estimates of the right and left ventricular outputs and Qp/Qs can be obtained that agree relatively well with catheterization data.

Continuous-wave Doppler echocardiography can be of assistance in the assessment of patients with atrial septal defect. It is particularly useful in estimating the pressure gradient across the atrial septum in patients with left atrial hypertension and restrictive atrial septal defects, and in evaluating patients for obstruction to pulmonary venous return.[82]

Color Doppler also provides useful diagnostic information in these patients.[83,84] It allows for the direct visualization of the flow across the atrial defect and is particularly helpful in distinguishing normal right superior vena caval flow from abnormal left-to-right shunting across the atrial septum.

If additional confirmation of diagnosis is desired, contrast echocardiography using agitated saline or indocyanine green is effective in demonstrating the presence of atrial septal defects. A right-to-left shunt can be detected by direct visualization of microcavitation bubbles in the left atrium and left ventricle. A left-to-right shunt can be detected as a negative contrast washout effect in the right atrium provided good opacification of the atrium is achieved.[85] The presence of an unroofed coronary sinus in conjunction with

a persistent left superior vena cava can be demonstrated echocardiographically by injection of agitated saline or idocyanine green into a left arm vein. When the coronary sinus is unroofed, and a left-to-right shunt is present, echocontrast will be seen to opacify the left atrium prior to opacifying the right atrium.

Radionuclide Angiocardiography

After peripheral venous injection of radionuclide, the time–activity curve of radioactivity measured over the lungs will show a characteristic pattern due to recirculation in patients with intracardiac left-to-right shunts. Analysis of these curves with any of several methods will provide an estimate of the Qp/Qs ratio that under optimal conditions correlates well with catheterization results. This method has reduced accuracy in the presence of tricuspid or pulmonary regurgitation and is dependent on the injection of a rapid, discrete bolus of radionuclide. In selected patients, measurement of right and left ventricular ejection fraction with either the first-pass technique or gated blood pool studies may be clinically useful.[86]

Nuclear Magnetic Resonance Imaging

With appropriate techniques, the atrial septum can be demonstrated by magnetic resonance imaging.[87] Because cardiac motion tends to degrade the images, studies should be synchronized with the cardiac cycle, usually with use of the electrocardiogram. Most investigators have used the spin echo technique because this method provides good contrast between the cardiac chambers and blood vessels and flowing blood. However, recently developed flow-sensitive methods have the capability of demonstrating cardiac blood flow in cine format and may also prove useful. Magnetic resonance is particularly helpful in the evaluation of the pulmonary venous connections in atrial septal defect.

Cardiac Catheterization

Cardiac catheterization may not be essential for management when the result of noninvasive tests clearly demonstrate the presence of an atrial septal defect without associated anomalies.[88] When pulmonary vascular disease is suspected, however, determination of pulmonary vascular resistance by catheterization is indicated.[5] Patients with a pulmonary vascular resistance of greater than 12 to 14 units · m^2 are generally considered inoperable. Cardiac catheterization and appropriate cineangiography can be helpful in the evaluation of anomalies associated with atrial septal defect, such as partially anomalous pulmonary venous return or mitral valve disease.

Secundum atrial septal defect can sometimes be differentiated from sinus venosus and atrioventricular canal defects because characteristic high and low catheter courses across the atrial septum are seen with the latter two defects, whereas in atrial septal defect, the catheter passes across the middle portion of the atrial septum.

Left-to-right shunting across the atrial septum causes an increase or "step-up," in oxygen saturation in the right atrium. An increase of 10% over superior vena caval blood in one oxygen saturation series or an increase of 5% in two series is generally indicative of the presence of a left-to-right shunt at the atrial level. Exceptional situations that give similar results in oxygen saturation data without interatrial communications are ventricular septal defect with tricuspid insufficiency, left ventricular to atrial communication, and partial anomalous pulmonary venous return without atrial septal defect. When mixed venous and systemic arterial blood samples are obtained, the standard Fick equation can be used to calculate the ratio of pulmonary to systemic blood flow, Qp/Qs. Indicator dilution injections can be employed for obtaining both qualitative and quantitative information about shunt flow. Right-to-left shunting can be demonstrated with this technique, the presence of anomalous pulmonary venous return can be inferred when it is present, and Qp/Qs can be quantitated. The presence of an unroofed coronary sinus with left-to-right shunting can be identified by continuous oximetry employing a fiberoptic catheter pulled back in the coronary sinus.[89]

Intracardiac pressures and pressures in the great vessels can be directly measured at cardiac catheterization. Pressure gradient across the atrial septal defect is minimal in most patients with secundum atrial septal defect and often is obscured when fluid-filled catheter systems are used. Catheter-tip pressure transducers give more accurate pressure tracings, though they are technically more difficult to operate. Many patients with atrial septal defect and large left-to-right shunts will have a substantial pressure gradient across the pulmonary valve. This gradient is usually related to the high blood flow across the pulmonary outflow tract and resolves after surgical closure of the atrial septal defect. Such flow-related gradients may be as high as 40 mm Hg.

Cineangiography

The presence of an atrial septal defect with left-to-right shunting can be demonstrated in the anteroposterior and lateral projections by an injection of contrast medium into the main pulmonary artery. Contrast material can be seen to pass into the right atrium and ventricle and may reflux into the hepatic veins after such an injection in patients with atrial septal defects. A pulmonary artery injection is also a good method for evaluation of the pulmonary venous return and will usually demonstrate any abnormal connections. Although this technique is useful for demonstrating the presence of atrial septal defect, it does not provide good visualization of the size and location of atrial septal defects. For optimal direct visualization, an injection just outside the orifice of the right upper pulmonary vein in the cranially angulated left anterior oblique projection (often termed the "four-chamber" view) is the most appropriate examination.[90] With the four-chamber view, secundum atrial septal defects will be demonstrated in the middle of the atrial septum, sinus venosus defects of the superior vena caval type will be demonstrated at the top, and atrioventricular canal defects will be shown at the bottom (Figs. 60–5 and 60–6). Angiographic definition of coronary sinus atrial septal defect is made by selective injection into the left superior vena cava, pulmonary vein, or left atrium (Fig. 60–7). In the absence of elevated right atrial pressure, contrast material is seen to pass into the left atrium, inferiorly to the coronary sinus, and then into the right atrium.[91]

Treatment

It is generally agreed that secundum atrial septal defects associated with a large left-to-right shunt and either symptoms or

Fig. 60–5. Frame from a cineangiogram taken in the hepatoclavicular projection after injection at the orifice of the right upper pulmonary vein in a patient with a large secundum atrial septal defect. Note the location of the defect in the center of the atrial septum.

significant cardiomegaly should be electively closed in childhood. When the findings of a comprehensive noninvasive evaluation demonstrate a classical secundum atrial septal defect with no evidence of elevation of pulmonary artery pressure, many physicians believe that cardiac catheterization is not essential. When the atrial shunt is small or pulmonary hypertension is present, recommendations regarding closure are more controversial.[92] Small defects generally cause minimal difficulty and have a good prognosis. Therefore the gain from closing them may not be worth the risk of cardiopulmonary bypass. When advanced pulmonary vascular

disease is present, operative mortality and morbidity are high and closure of the atrial septal defect may actually worsen the prognosis.[93]

Surgical closure is almost invariably performed with the aid of cardiopulmonary bypass. Successful closure can be accomplished by direct suture or with either pericardial or Dacron patches.[94,95] Closure of large defects by direct suture can distort the atrium. Successful catheter closure of secundum atrial septal defects with occlusion devices has been performed and the method shows promise, particularly for the closure of small defects in the fossa ovalis area.

Repair of sinus venosus atrial septal defects requires a patch to redirect the right pulmonary venous return into the left atrium.[96] The patch must be placed in such a manner that pathways of adequate size are provided for the superior vena caval and pulmonary venous flow, since obstruction can result if these pathways are inadequate. The location of the sinus node, which is usually lateral to the superior cavoatrial junction but occasionally is located at the top of the right atrial appendage, is well away from the interatrial communication in patients with sinus venosus atrial septal defect. However, the blood supply of the sinus node is variable, and could potentially be compromised by surgery in the region of the superior vena caval–atrial junction. The sinus-node artery arises from either the right coronary artery (55% of cases) or the left coronary artery (45%). Anderson et al.[97] determined that the sinus-node artery approached the node from a posterior aspect in 11 of 25 hearts and from an anterior aspect in 10. Dual sinus-node arteries were present in four cases, approaching the node from both anterior and posterior aspects.

Repair of coronary sinus atrial septal defects is complicated by

the close proximity of the atrial septal defect to the atrioventricular node. Sutures must be placed very close to the superior rim of the defect in order to avoid heart block. Therefore a patch is recommended for defect closure in these cases. Coronary sinus atrial septal defects are frequently associated with a persistent left superior vena cava.[98] If the persistent left superior vena cava can be occluded without elevation in jugular venous pressure, it can be ligated. However, if jugular venous pressure is elevated after occlusion of the persistent left superior vena cava, a pericardial baffle repair has been recommended.[99] With this technique, the atrial septum is partially excised and replaced with a pericardial baffle, which redirects the flow of the persistent left superior vena cava into the right atrium and closes the interatrial communication.

Regardless of the type of atrial septal defect to be closed, care should be taken with venous cannulation. The technique of venous cannulation through the right atrial appendage has been successful in many patients. However, there is potential for damage to the sinoatrial node if a clamp is placed too proximal on the appendage at the beginning or end of the cannulation. Therefore some investigators have suggested use of cannulation at sites far removed from the sinoatrial node.[94,100,101]

Prognosis

Surgical results in uncomplicated secundum atrial septal defect are good. Mortality is less than 2% in many large series.[102–104] Whether or not life expectancy becomes completely normal after surgical closure of an uncomplicated secundum atrial septal defect in childhood remains to be determined. Most children undergoing atrial septal defect closure are asymptomatic before operation. Cardiac enlargement on chest roentgenogram may resolve in these children, and electrocardiographic evidence of right ventricular hypertrophy may disappear. Young[105] reported that heart size on chest roentgenogram was initially enlarged and returned to normal in 65% (46 of 71) of children with secundum atrial septal defect within 2 years after repair. In 86% of his patients, there was a shift of the QRS axis to the left and a decrease in the height of the R or R′ wave in lead V_1 after surgery.

However, in a substantial fraction of children undergoing repair of atrial septal defect (19 of 71, or 27%, in Young's series), regression of heart size to normal on chest roentgenogram does not occur. Electrocardiographic evidence of right ventricular hypertrophy may also persist in some patients (3 of 71, or 4%, in Young's series). Furthermore, right ventricular enlargement may persist for years after successful repair of atrial septal defect. Meyer and colleagues[106] performed serial M-mode echocardiograms in 51 children with isolated secundum atrial septal defect before and after surgery. They found there was an initial decrease in right ventricular size in the first three months after operation but that echocardiographic evidence of right ventricular dilation persisted in over 80% of these children for a period of up to 5 years. These results are corroborated by the data of Graham and colleagues, who performed preoperative and postoperative cardiac catheterization in three children with secundum atrial septal defects and found persistently elevated right ventricular volume 1 year after catheterization.[107]

Closure of atrial septal defects in childhood is often recommended to prevent supraventricular arrhythmias later in life. The incidence of chronic symptomatic postoperative arrhythmias is much lower in children after atrial septal defect repair than in untreated adults with large atrial septal defects. However, postoperative arrhythmias do occur in children who have undergone operative closure of secundum atrial septal defect. Bink-Boelkens and colleagues[108] reported a 23% incidence of postoperative arrhythmia in 204 children with secundum atrial septal defect. Sinus-node dysfunction was present in 39% and atrial flutter was present in 18% of the patients with arrhythmia. In 56% of the cases, dysrhythmia was first noted after discharge from the hospital. Atrial flutter developed in 9 of 15 of the children after the first postoperative year. Four patients (2%) required insertion of a pacemaker for treatment of bradycardia or a bradycardia–tachycardia syndrome postoperatively. Bricker and colleagues[109] have also noted that a small number (6 of 292, or 2%, in their series) of patients with atrial septal defect will require pacemakers for arrhythmias after surgery. In this regard, it is of note that Bharati and Lev have recently reported four cases of sudden death after atrial septal defect repair.[110] Surgical damage to the sinus node and fibrosis of conduction tissue were found.

Symptomatic arrhythmias are frequently present in adults after operation. These arrhythmias may persist after surgery or new arrhythmias may be caused by surgery. In some cases, surgical closure of atrial septal defect and relief of cardiac volume overload results in resolution of preoperative arrhythmias. Brandenburg and colleagues[111] found that atrial fibrillation was relieved by surgery in only 3 of 16 patients over 44 years of age. Results were better in patients who had paroxysmal supraventricular tachycardia. This arrhythmia did not recur postoperatively in 5 of 9 patients. Forfang and colleagues[112] found that 56 of 84 patients (67%) over 40 years of age with secundum atrial defect had arrhythmias. After surgical closure, 80% of their patients had arrhythmias at least once. However, only 21 of 55 patients (38%) followed into the late postoperative period had persistent arrhythmias that caused symptoms.

Bolens and Friedli[113] performed electrophysiologic studies in 18 children before and after surgical closure of a secundum atrial septal defect. They found that the preoperative A–H interval was prolonged, as was the corrected sinus-node recovery time and the atrioventricular nodal refractory period. Postoperatively, the A–H interval and the atrioventricular node refractory period decreased in length. The sinus-node recovery time decreased in 13 of 18 patients (72%). However, ectopic atrial rhythm developed postoperatively in 5 patients. The finding of shortening of the A–H interval correlates with the electrocardiographic finding of Bricker and colleagues that the P–R interval is shortened by surgical closure of an atrial septal defect.[109]

Patients with congestive heart failure due to left-to-right shunting and its consequent cardiac volume overload generally experience substantial relief of symptoms after closure of the defect. Weinberg and colleagues reported relief of symptoms in six of seven children with atrial septal defects who were in congestive heart failure.[114] Young noted relief of symptoms by surgical closure in three such children.[106] Relief can also be obtained by surgical closure in the occasional toddler or infant with atrial septal defect who experiences congestive heart failure,[115] though mortality may be increased in the presence of concomitant pulmonary hypertension.[116] Spangler et al. reported on a surgical series of 13 patients under 2 years of age with congestive heart failure secondary to an isolated secundum atrial septal defect.[115] Operative repair was performed in 12 patients without mortality and with relief of symp-

toms. However, no patient in this series had pulmonary artery hypertension.

Repair of atrial septal defect also relieves congestive heart failure in the adult patient. Rahimtoola et al. noted substantial improvement in congestive symptoms after surgical repair of 22 of 23 patients over 35 yr of age who had an atrial septal defect and a moderate to large left-to-right shunt.[103] Forfang et al. also noted resolution of symptoms of congestive failure after corrective surgery in patients over 40 yr of age.[112] Others have reported similar results.[117] Even patients 60 yr of age and older experience considerable relief of congestive symptoms after surgery, and operative repair can be performed with only a small increase in mortality in this age group.[118,119]

The mortality and morbidity of atrial septal defect repair are increased with pulmonary vascular disease. Rahimtoola and colleagues[103] reported a mortality of 24% (13 of 55) in patients with secundum or sinus venosus atrial septal defects with pulmonary artery pressure in excess of 60 mm Hg. Three of 35 patients with a pulmonary vascular resistance less than or equal to 8 units/m^2 died, and 10 of 20 patients with a pulmonary vascular resistance in excess of 8 units/m^2 died. More recently, Steele and colleagues[40] have described improved postoperative results in patients with isolated atrial septal defect and moderate degrees of pulmonary vascular obstructive disease. They found that 19 of 24 surgically treated patients with a pulmonary vascular resistance of between 7 and 15 units were alive at least 4 years after surgery. Eighteen of these patients had had substantial regression of symptoms. However, all four surgically treated patients with pulmonary vascular resistance in excess of 15 units/m^2 had suboptimal results. Two of these patients died in the immediate postoperative period and the two survivors had substantial progression of symptoms.

Several investigators have reported that repair of sinus venosus atrial septal defect is associated with an increased incidence of arrhythmias as compared with repair of secundum atrial septal defect. Clark and colleagues[120] found a preoperative incidence of sinus-node dysfunction of 18% in patients with sinus venosus atrial septal defect and 3% in patients with secundum atrial septal defect. Postoperatively, patients with sinus venosus atrial septal defect were found to have a 50% incidence of a sinus-node dysfunction, while patients with secundum atrial septal defect had a 31% incidence of sinus-node dysfunction. In Young's series,[105] 2 of 6 patients (33%) had chronic arrhythmias after repair of a sinus venosus atrial septal defect, whereas only 14% of his entire postoperative atrial septal defect group had chronic arrhythmias. Kyger and colleagues[121] noted an incidence of preoperative arrhythmia of 14% (15 of 109) in patients with sinus venosus atrial septal defect who underwent surgical closure. New postoperative arrhythmias were noted in 21% (23 of 109) of their patients. Most of these new arrhythmias (56%, or 13 of 23) resolved before discharge from the hospital. New tachyarrhythmias tended to resolve, whereas most bradyarrythmias persisted. However, Trusler and colleagues[122] found that only 3 of 29 children had symptoms related to arrhythmias after repair of sinus venosus atrial septal defect.

Obstruction to venous return at the superior vena caval–right atrial junction may occur after surgical repair of sinus venosus atrial septal defect.[123] Enlargement of this junction can be performed surgically, but should be performed carefully, because damage to the sinus node may be produced.

The risk of death from repair of coronary sinus atrial septal defect, either isolated or in association with a persistent left superior vena cava, is apparently low. Quaegebeur and colleagues reported on repair in eight such patients with no operative mortality or late deaths.[99] In many cases coronary sinus atrial septal defect is seen in conjunction with atrioventricular canal and other complex lesions. In these cases, the prognosis is principally determined by the associated anomaly. Because of the proximity of the atrioventricular node to the atrioventricular communication in coronary sinus atrial septal defect, atrioventricular block may be caused by surgical repair. Untreated coronary sinus atrial septal defect in association with persistent left superior vena cava is sometimes associated with cerebral embolization and abscess secondary to right-to-left shunting.

Patients with moderate and large secundum atrial septal defects who do not have surgical closure of the atrial septal defect generally do well without surgical treatment until the third decade of life, after which they tend to become progressively more symptomatic (see section on "Natural History"). However, because other disorders such as cancer and coronary artery disease supervene, only a fraction of patients born with an atrial septal defect of moderate or large size will actually die from the direct effects of the atrial septal defect. Thus in the absence of pulmonary hypertension, life expectancy in untreated isolated secundum atrial septal defects of moderate and large size may be as long as 50 to 60 years. Patients with small atrial septal defects have a good prognosis, and probably have nearly the same life expectancy as the general population.

PERSISTENT COMMON ATRIOVENTRICULAR CANAL DEFECTS

Atrioventricular canal defects include a range of malformations, a central feature of which is usually an atrial septal defect, and that involve, in addition to the atrial septum, the ventricular septum and one or both atrioventricular valves.[124,125] A number of terms have been applied to these malformations, including endocardial cushion defect, atrioventricular septal defects, canalis atrioventricularis communis, and persistent atrioventricular ostium.

Historical Aspects

Keith was aware of defects in the lower portion of the atrial septum and termed them foramen primum defects. He described them in his Hunterian lectures in 1909.[126] Abbott recognized both ostium primum atrial septal defects and common atrioventricular canal defects.[127] Rogers and Edwards concluded that these defects were similar morphologically.[128]

In 1956, Lillehei and colleagues reported the first successful repair of an atrioventricular canal defect, using cross-circulation.[129] In the same year Kirklin successfully repaired a partial atrioventricular canal defect through an atrial well.[130] The development of the pump oxygenator thereafter made repair of defects by open cardiotomy much more practical.

Further morphologic studies were stimulated by the rapid development of cardiac surgery. Wakai and Edwards performed an extensive review of pathological specimens with persistent common atrioventricular canal defect, noted the presence of associated defects, and also noted that the lesion was a serious one, as evidenced by the early age of demise of many of the patients that

they studied.[131] Lev described the location of the conduction system in relation to the atrioventricular canal defect in these patients.[132] In 1966 Rastelli and colleagues made a detailed description of the atrioventricular valve leaflets in patients with common atrioventricular canal defect.[133] Van Mierhop et al. performed extensive studies on cardiac embryogenesis that contributed greatly to understanding of the pathogenesis of these defects.[134] There have been many recent advances in the diagnosis and therapy of these defects. Rapid clinical identification and effective treatment are now possible in the great majority of patients.

Classification

There are a number of different types of atrioventricular canal defects and several methods for classification of these defects.[133,135,136] A distinction is usually made between partial and complete defects. Some authors use the term partial atrioventricular canal defect to indicate atrioventricular canal defects that have an interatrial communication but no interventricular communication and the term complete atrioventricular canal defect to describe atrioventricular canal defects that contain both an atrial and a ventricular septal defect. Others use the term partial atrioventricular canal defect to indicate the presence of separate mitral and tricuspid valve orifices and the term complete atrioventricular canal defect to indicate the presence of a common atrioventricular valve orifice. In this discussion we will use complete atrioventricular canal to indicate the presence of both atrial and ventricular septal defects and a common atrioventricular orifice. We will term all other cases of persistent common atrioventricular canal "partial" or "incomplete."

Embryologic Aspects

Atrioventricular canal defects appear to result primarily from abnormal development of the endocardial cushions.[17,18] In normal development the superior and inferior endocardial cushions grow together and fuse at approximately 5 weeks of age. Their fusion divides the common atrioventricular canal into two parts, the left and right atrioventricular canals. In patients with endocardial cushion defects, the superior and inferior cushions do not close completely. Because they do not close, they cannot fuse with the ostium primum, which normally grows inferiorly to meet them and close the atrial septum. Thus an interatrial communication is left at the lower portion of the atrial septum. This communication is often termed a persistent ostium primum defect, a description that may be something of a misnomer because the development of the ostium primum is not necessarily defective. In addition to causing an interatrial communication, the failure of fusion of the endocardial cushions results in an abnormally low position of the atrioventricular valves and an abnormally high position of the aortic valve, the basis for the characteristic "gooseneck" deformity. Though relatively small portions of the atrioventricular valves originate from the endocardial cushions, fusion of the left tubercles of the superior and inferior endocardial cushions must occur properly if the anterior leaflet of the mitral valve is to be formed normally. Since these cushions do not properly fuse in atrioventricular canal defects, most patients are left with an anterior and a posterior component to the anterior mitral valve leaflet.

Pathologic Aspects

General Features

Persistent common atrioventricular canal defects have a number of distinctive morphologic features, many of which are important physiologically and most of which must be considered in the surgical repair of the lesion.[133,135,136] Some of these features are seen in all atrioventricular canal defects. Others are a feature of only the complete defects. The following features are present to some degree in most atrioventricular canal defects[137–139]:

- The anterior or aortic leaflet of the mitral valve is abnormal in most hearts with atrioventricular canal defect. Anterior and posterior components of the leaflet are present, separated by a gap or "cleft."
- The septal leaflet of the tricuspid valve is abnormal in many cases of atrioventricular canal defect. As with the mitral valve, anterior and posterior components of the leaflet are present, separated by a gap or "cleft."
- The ventricular inlet septum is concave toward the atrium. Consequently, the ratio of the inlet distance (from the atrioventricular valve annulus to the ventricular apex) to the outlet distance (from the ventricular apex to the aortic valve) is substantially less than one in these patients. In normal subjects this ratio of distances is approximately one.
- The left ventricular outflow tract is not wedged between the two atrioventricular valves. Rather it is displaced anteriorly or "sprung." As a consequence, the left ventricular outflow tract is elongated and narrowed, giving the characteristic "gooseneck" appearance on anteroposterior cineangiograms.
- Because the left ventricular outflow tract is not wedged between the two atrioventricular valve orifices, the left and right atrioventricular valve attachments lie at the same level. In normal subjects, the atrioventricular valves are attached at different levels, with the insertion of the tricuspid valve displaced toward the apex of the heart. Hence there is a small area of septum, termed the atrioventricular septum, between the left ventricle and the left atrium. This septum is absent in persistent common atrioventricular canal defects, an absence that has led some authors to use the term "atrioventricular septal defect" instead of "persistent common atrioventricular canal defect."

The manner of attachment of the atrioventricular valve tissue determines whether or not a ventricular septal defect is present. In persistent common atrioventricular canal defects without a ventricular septal defect, the atrioventricular valves are attached to the crest of the ventricular septum, preventing interventricular communication. In patients who have a ventricular defect, the atrioventricular valves close above the deficient ventricular septum, leaving an interventricular communication.

Many cardiovascular structures are abnormal to variable degrees in patients with persistent common atrioventricular canal defects. Abnormalities in specific structures are described in more detail in the following paragraphs.

Atrial Septum

Most atrioventricular canal defects include an interatrial communication. These defects are often called ostium primum atrial septal defects. They lie at the lowest part of the atrial septum and are variable in size (but usually large in relation to cardiac size) depending on the amount of atrial septal tissue that is deficient in

addition to the atrioventricular septum. The lower edge of these defects is concave.

The remainder of the atrial septum may be formed normally, but often other abnormalities are present. The lower part of the limbus of the fossa ovalis may be absent. In addition to the ostium primum defect, other types of interatrial communications may be present in these patients. Associated secundum atrial defects are particularly common. It is possible for almost the entire atrial septum to be absent, in which case a "common atrium" exists, as discussed below.

Ventricular Septum

The basal portion of the ventricular septum is deficient in most hearts with persistent common atrioventricular canal. In hearts without a ventricular septal defect, the atrioventricular valve tissue attaches to the crest of the ventricular septum, preventing an interventricular communication. In hearts with a ventricular septal defect, this tissue does not attach along the entire length of the septum, creating a gap bounded superiorly by valve tissue and inferiorly by the crest of the septum.

From the right ventricular aspect, the ventricular septal defect seen in the atrioventricular canal defect lies in the uppermost part of the ventricular septum. It is bounded superiorly by the right aspect of the atrioventricular valve ring and is located posteriorly and inferiorly to the crista supraventricularis. From the left ventricular aspect, the defect is located in the outflow tract of the left ventricle and includes a substantial deficiency of the muscular septum adjacent to the anterior (aortic) leaflet of the mitral valve.

Separate ventricular septal defects of the muscular or perimembranous variety may exist in conjunction with the ventricular septal defect of the atrioventricular canal and may complicate diagnosis and therapy in these patients.

Isolated ventricular septal defects can exist in the inlet ventricular septum, located posteriorly and inferiorly to the crista supraventricularis and bounded superiorly by the ring of the tricuspid valve. Such defects are often referred to as ventricular septal defects of the atrioventricular canal type, though other features of persistent common atrioventricular canal may be absent.

Atrioventricular Valves

The hallmarks of the persistent atrioventricular canal defect are the abnormal atrioventricular valves. There are abnormalities in both the overall configuration and orientation of the valve apparatus and in the local structure of the atrioventricular valves. In both partial and complete forms of atrioventricular canal defect the atrioventricular valves lie in the same plane with respect to the base of the ventricular septum. By contrast, in the normal heart there is a small displacement of the plane of the tricuspid valve toward the apex. Additionally, whereas the annulus of the normal atrioventricular valves lie in one plane, the annulus of the atrioventricular valves in patients with persistent common atrioventricular canal defect is convex toward the cardiac apex.

In partial defects there are two separate atrioventricular valve annuli. In this situation the left and right atrioventricular valve leaflets are usually named according to the mitral and tricuspid valve components to which they correspond most closely. In complete atrioventricular canal defects there is a common atrioventricular valve. This common valve has a basic five-leaflet structure. There are two leaflets that straddle the interventricular septum and are tethered by chordae in both ventricles. These are called the anterior (or superior) and posterior (or inferior) bridging leaflets. Two leaflets are located in the right ventricle and roughly correspond to the anterior (or anterosuperior) and posterior (or mural) leaflets of the tricuspid valve. One leaflet is entirely contained within the left ventricle and is termed the left lateral (or mural) leaflet. The preceding valve-leaflet nomenclature is used here.

An alternative system of nomenclature has been developed by Kirklin and colleagues.[140] They note that the anterior bridging leaflet is usually divided into two portions by a commissure. They consider each of these portions to be a separate leaflet of the common valve. With their system, the valve leaflets in all persistent common atrioventricular canal defects, including partial defects, are named according to a six-leaflet concept. The posterior bridging leaflet in their system is termed the left inferior leaflet and the left lateral leaflet is given the same name as in the traditional system. The right anterior leaflet is designated as the right lateral leaflet and the right posterior leaflet is termed the right inferior leaflet. The left and right portions of the traditional anterior bridging leaflet are designated as the left and right superior leaflets, respectively.

In practice, there is wide variability in the atrioventricular valve morphology of this disorder. Some patients will have only four identifiable leaflets at autopsy, whereas others may have as many as seven. Furthermore, the leaflets are often deformed, with thickened midpoints and gnarled edges that coapt poorly. Additionally, the valve tensor apparatus (chordae and papillary muscles) is often severely abnormal, as will be discussed more fully below.

Incomplete Atrioventricular Canal Defects with No Interventricular Communication

Separate mitral and tricuspid valve annuli are usually present. The anterior (septal) leaflet of the mitral valve is composed of two components, which are usually of approximately equal size, separated by a gap or cleft. These two portions of the anterior leaflet attach to the crest of the ventricular septum by chordae tendineae and fuse with the septal leaflet of the tricuspid vale. This fusion prevents direct interventricular communication. The posterior (lateral, mural) leaflet of the mitral valve is usually normal.

The free edges of the components of the divided anterior leaflet attach to chordae tendineae that connect to the anterolateral or posteromedial papillary muscles of the left ventricle. The edges of the divided anterior leaflet that are facing each other do not usually attach to chordae tendineae. However, occasionally short chordae tendineae attach to the edges of the divided anterior leaflet, limiting its mobility and contributing to mitral valve insufficiency. The edges of the cleft anterior mitral valve are often thickened and irregular, causing poor coaptation with resultant mitral valvular insufficiency.

The tricuspid valve is usually abnormal also in partial forms of persistent common atrioventricular canal, with frequent absence of the anterior part of the septal leaflet and a widened anteroseptal commissure.

Transitional Forms of Atrioventricular Canal Defect

The terms "transitional" and "intermediate" were used by Wakai and Edwards to describe a group of malformations wherein a bridge of valvular tissue on the ventricular septal crest connected

the anterior leaflet with the septal extension of the posterior leaflet.[141]

Common Atrium

It is possible for almost the entire atrial septum to be absent. In these instance, at least one band of muscular tissue crosses the atrium as a vestigial atrial septum. These defects are nearly always associated with a cleft anterior leaflet of the mitral valve and a deficient summit of the ventricular septum.

Isolated Ostium Primum Atrial Septal Defect

Ostium primum atrial septal defects are characteristically associated with a cleft in the anterior leaflet of the mitral valve. A case of isolated ostium primum atrial septal defect with ostensibly normal atrioventricular valves has been described.[142] However, such defects must be extremely rare.

Complete Atrioventricular Canal Defect

In the complete form of atrioventricular canal defect there is a common atrioventricular orifice and a common atrioventricular valve. In most cases, both an ostium primum atrial septal defect and a ventricular septal defect of the atrioventricular canal type are present and are confluent. As has been noted, the common valve has an anterior leaflet that straddles or bridges the ventricular septum. Rastelli et al.[133] noted three major variations in the structure of this anterior bridging leaflet and classified complete atrioventricular canal defects accordingly. The technique of surgical repair differs for these three different forms of complete atrioventricular canal defect.

Divided, Septally Attached Anterior Common Leaflet

The anterior common leaflet is divided into two portions of approximately equal size in this type. One of these is located primarily in the right ventricle and one is located primarily in the left ventricle. The lateral part of each portion of the valve is attached to the anterior papillary muscle in the respective ventricle. Medially, the valve portions are attached to the crest of the ventricular septum by thin chordae tendineae that insert either on the crest of the ventricular septum or a few millimeters below it on the right ventricular side of the septum.

The interventricular communication in this type of defect is present above the crest of the ventricular septum, between the anterior and posterior bridging leaflets, at locations where the septum is bare of valvular tissue and through spaces that exist below these leaflets and between their chordae tendineae. At least part of the membranous septum is present in this form of complete atrioventricular canal defect, so that the ventricular septal defect does not extend to the aortic cusps.

As a consequence of the attachment of the left ventricular portion of the anterior common leaflet to the deficient ventricular septum, the apparent narrowing and elongation of the left ventricular outflow tract is accentuated.

Divided, Septally Unattached Anterior Common Leaflet

The anterior common leaflet is divided into two parts, neither of which is attached to the interventricular septum in the midline. Chordae tendineae from the midportions of the divided anterior leaflet are attached to a papillary muscle located in the right ventricle near the septum. Laterally, each portion of the valve is attached to the appropriate anterior papillary muscle.

An interventricular communication is present under the common leaflets. The ventricular septal defect extends to the aortic valve cusps. The left ventricular outflow tract is also narrowed and elongated with this type of defect.

Undivided, Septally Unattached Anterior Common Leaflet

The anterior common leaflet of this type is neither divided nor attached in its midportion to the septum or elsewhere. Rather, it "floats" above the ventricular septum. Laterally, the left and right portions of this common anterior leaflet are attached to the right and left anterior papillary muscles, respectively.

The interventricular communication lies below the common leaflets and extends to the aortic valve cusps. As with the other two types of complete atrioventricular canal defects, the left ventricular outflow tract is narrowed and elongated.

This third form of complete atrioventricular canal defect is most common in patients with major associated cardiac and/or extracardiac anomalies such as tetralogy of Fallot or Down's syndrome.

Titus and Rastelli[124] suggest that the three different forms of complete atrioventricular canal represent three different degrees of abnormal development of the anterior (superior) endocardial cushion with regard to its role in obliteration of interventricular communication in the embryonic heart and its role in formation of the anterior leaflet of the mitral valve and the septal leaflet of the tricuspid valve.

Piccoli and colleagues[135,136] accept the Rastelli classification groups, but do not agree with the concept of a common anterior leaflet that may be divided or undivided. Rather, they consider the traditionally termed common anterior leaflet to be composed of two leaflets. They call the left portion of the common anterior leaflet the superior bridging leaflet and they consider the right portion of this leaflet the anterosuperior leaflet of the tricuspid valve. The anatomy of the three Rastelli groups is explained in terms of differing degrees of bridging of the superior bridging leaflet with differing degrees of concomitant hypoplasia of the tricuspid anterosuperior leaflet. Kirklin and Barratt-Boyes also accept the Rastelli groups and provide a similar explanation of the anatomy based on their system of nomenclature.[143]

Posterior Common Leaflet

The posterior common leaflet, which is often rudimentary, is common to both ventricles. It is not usually divided into two distinct portions, and its edges are often thickened and curled. This leaflet is attached laterally by chordae tendineae to the posterior papillary muscles in the left and right ventricles. The posterior leaflet may attach in the midline to the muscular septum by short chordae tendineae.

Lateral Leaflets

The right and left lateral leaflets are analogous to the posterior leaflets of the tricuspid and mitral valves, respectively. They are usually well developed and attach to the anterior and posterior papillary muscles in the right and left ventricles in a normal manner.

Accessory Orifices

Accessory atrioventricular valve orifices are sometimes observed in association with atrioventricular canal defects.[144] Usu-

ally, all chordae tendineae that attach to such an accessory orifice converge and insert into a single papillary muscle. These accessory orifices generally do not cause hemodynamic abnormalities.

Papillary Muscles

The papillary muscles often have an abnormal configuration in persistent common atrioventricular canal defects.[145] In normal hearts the commissures and papillary muscles of the mitral valve are located at posteroseptal and anterolateral positions. In atrioventricular canal defects the papillary muscle groups are shifted laterally. On occasion there is only one papillary muscle group, in which case an ''iatrogenic parachute mitral valve'' will exist if the cleft in the anterior leaflet of the mitral vale is sutured closed.

Occasionally, two papillary muscles exist but the chordae tendineae from the anterior and posterior leaflets converge and insert almost entirely on the anterolateral muscle group. This abnormality is also potentially a parachute mitral valve.

Additionally, the right ventricular papillary muscles may be abnormal. In complete atrioventricular canal defects, the right medial papillary muscle may be located at an anomalous apical position or may be fused with the anterior papillary muscle to form an anomalous bifid anterior muscle.

Left Ventricular Outflow Tract

The left ventricular outflow tract in the persistent common atrioventricular canal defect is intrinsically narrow. However, physiologically important obstruction is unusual. When such obstruction occurs it may result from discrete membranes, from abnormally positioned papillary muscles, from atrioventricular valve tissue protruding into the left ventricular outflow tract, or from generalized severe hypoplasia of the left ventricular outflow tract.[146–148]

Left Ventricular Inflow Obstruction

Left ventricular inflow obstruction may occur with atrioventricular canal defects. Potential causes of obstruction are thickening of the valve leaflets, tethering of the ''cleft'' of the left atrioventricular valve to the septum, or narrowing of the entrance into the left ventricle, usually seen in conjunction with substantial right ventricular dominance.[146] Left ventricular inflow obstruction may also be caused by a supravalvular fibrous ring or cor triatriatum.[149]

Ventricular Dominance

Both left and right ventricular dominant forms of common atrioventricular canal occur.[137] Severe dominance of either ventricle substantially increases the risk of corrective surgery.[150]

The Conduction System

The defective atrioventricular septum in atrioventricular canal defect is associated with concomitant abnormalities in the atrioventricular conduction system, which have been demonstrated by pathological examination, and which have important surgical implications.[132,151,152] The atrioventricular node is displaced posteriorly from its usual relationship to the coronary sinus ostium. Frequently, these structures are directly adjacent. The undivided portion of the common bundle is shorter than normal. The course of the common bundle is closely related to the rim of the ventricular septum, especially at the posteroinferior rim. There is relatively early origin of the left bundle fibers and hypoplasia of the anteriorly directed left bundle fascicles. The posterior disposition of the conduction tissue is believed to account for the superior deviation of the mean QRS axis in the frontal plane with a counterclockwise QRS loop.

Acquired Cardiovascular Pathology Associated with Atrioventricular Canal Defect

Pulmonary Arteries

Patients with persistent common atrioventricular canal defects of the complete variety have a high risk of developing pulmonary vascular obstructive disease as they grow older.[153–156] Neufeld and colleagues demonstrated advanced pulmonary vascular disease (Heath–Edwards grades 3 and 4) in seven of eight patients with complete atrioventricular canal over age 1 year.[157] When pulmonary vascular disease is advanced, corrective surgery is contraindicated, since it is associated with substantially increased mortality and does not improve the prognosis of the patients. It is unlikely that pulmonary vascular disease will develop in childhood in patients with partial common atrioventricular canal defects though there is a small possibility that this will happen in later life.

Physiology

Intrauterine Physiology

Because of the proximity of the ostium primum atrial septal defect to the tricuspid valve it is possible that superior vena caval blood flow, which is usually directed through the tricuspid valve, will shunt across the atrial septal defect to the left ventricle, decreasing the oxygen saturation difference between the ascending and descending aorta in the fetus. If this were to happen, there would be a concomitant increase in the saturation of blood ejected by the right ventricle, increasing the P_{O_2} in the blood flowing to the pulmonary vessels and possibly affecting their development. If a large ventricular septal defect is present, shunting of additional right ventricular blood across the defect into the aorta could occur. This effect would further decrease the P_{O_2} in the ascending aorta and increase the P_{O_2} of blood perfusing the lungs.

Atrioventricular valve insufficiency could have an important effect on blood flow in the fetus. Since the blood is ejected directly from the left ventricle into the right atrium through the mitral cleft, the shunt is obligatory (i.e., not influenced by the pulmonary and systemic resistances). The shunt decreases the left ventricular stroke volume and increases the right atrial and right ventricular blood flow. Thus blood flow into the ascending aorta is diminished. The relative narrowing of the left ventricular outflow tract in the atrioventricular canal defect may further serve to diminish aortic blood flow.

Partial Atrioventricular Canal

In the absence of pulmonary stenosis or pulmonary vascular disease, there is predominant left-to-right shunting in patients with atrioventricular canal defects. When only an atrial septal defect is present without substantial left atrioventricular valvular insufficiency, the physiology is identical to that of an atrial septal defect with shunting primarily determined by the relationship of the pulmonary vascular resistances. When major left atrioventricular val-

vular insufficiency is present, there is an additional left-to-right shunt across the cleft mitral valve directly from left ventricle to left atrium, which has been termed "obligatory" because it is from a high- to a low-pressure chamber. This additional left-to-right shunt causes volume overload of both the left and right ventricles and is associated with heart failure in early life.

Complete Defects

When a large interventricular communication is present there is additional left-to-right shunting, usually associated with systemic pulmonary artery pressures in the absence of pulmonary stenosis. Left atrioventricular valve incompetence compounds the ventricular volume overload in these patients, who will often have symptoms caused by pulmonary congestion. When pulmonary vascular disease develops, as is likely in such patients, their symptoms may improve. When advanced vascular disease ensues in later life, the physiology is the same as in patients with Eisenmenger's syndrome with the additional volume overload imposed by left atrioventricular valve insufficiency.

Natural History

The natural history of atrioventricular canal defect depends primarily on the pathologic anatomy of the malformation.[158] In patients with only an ostium primum atrial septal defect and minimal insufficiency of the left atrioventricular valve, the clinical course is similar to that of patients with a large secundum atrial septal defect. Generally, these patients do well without treatment during infancy, childhood, and adolescence. During adulthood they have an increasing tendency to develop congestive heart failure, particularly as atrial arrhythmias develop.

Patients with ostium primum atrial septal defects and moderate to severe left atrioventricular valve insufficiency will develop congestive heart failure in early life with a consequently high morbidity and mortality if the atrioventricular valve insufficiency is pronounced. Otherwise they may survive until adulthood, when they experience increasingly severe symptoms.

Patients with complete atrioventricular canal defects generally develop severe symptoms of congestive heart failure in early infancy. They have frequent respiratory infections and poor weight gain.

Physical Examination

Appearance

Patients with partial atrioventricular canal defects and minimal mitral insufficiency usually appear normal in infancy and childhood. Patients with partial atrioventricular canal defects and substantial mitral insufficiency may manifest growth failure, and other signs of chronic congestive heart failure. Patients with complete common atrioventricular canal defects are usually symptomatic from early infancy, with such manifestations as poor physical development, hyperinflated thorax, bulging precordium, Harrison's grooves and mild or intermittent cyanosis. If there are no signs of chronic congestive heart failure in a patient with known complete common atrioventricular canal defect, pulmonary stenosis or pulmonary vascular obstructive disease should be suspected.

Down's syndrome, which is frequently associated with endocardial cushion defects, has a characteristic physical appearance.[159] Infants with this syndrome have flat facial profiles, oblique palpebral fissures, and a large protuberant tongue. The hands are generally short and broad, with a palmar simian crease, a short fourth finger, and a distal axial triradius. The skin is dry and distinctively pale. There are two distinctive ocular features. The most frequently seen is an inner epicanthic skin fold that inserts on the lower lid. Brushfield spots (speckled iris) are the second distinctive ocular feature. When Down's syndrome is seen in conjunction with the physical signs of chronic congestive heart failure, the coexistence of complete common atrioventricular canal should always be suspected.

Arterial and Jugular Venous Pulse

In partial endocardial cushion defect, mitral regurgitation is sometimes associated with a so-called water-hammer pulse, which is caused by the rapid ejection of a large left ventricular stroke volume. Patients with congestive heart failure may, however, have a small pulse volume. When mitral regurgitation is present the jugular venous pulse may have a dominant V wave, as the right atrium in these patients receives left ventricular systolic flow.[160]

Precordial Movement and Palpation

When mitral regurgitation is present in patients with partial endocardial cushion defect, a systolic thrill is often present. This thrill radiates toward the sternum. When a large left-to-right shunt is present, there is often a palpable impulse in the second and third left intercostal spaces, reflecting the presence of a dilated, pulsatile, pulmonary artery trunk. Sometimes the pulmonic component of the second heart sound is palpable as well. The right ventricular volume and pressure overload associated with complete atrioventricular canal defects is associated with a prominent systolic impulse or "heave" at the left sternal edge and in the subxiphoid area.

Auscultation

Complete atrioventricular canal defects may be associated with a variety of auscultatory manifestations, depending on the nature of the underlying pathologic physiology. Since one common atrioventricular valve is present, the first heart sound is usually single. When the atrioventricular conduction time is prolonged, as is often the case, the first heart sound will tend to be relatively soft. There is usually constant or fixed splitting of the second sound, though when severe pulmonary hypertension is present, this splitting will be narrow. Pulmonary hypertension is also generally associated with a loud pulmonic component of the second sound. A murmur of atrioventricular valve incompetence is frequently present.[161] This murmur is usually maximal at the left ventricular apex and often radiates toward the sternum rather than toward the left axilla, reflecting the predominance of left-ventricular-to-right-atrial shunting over left-ventricular-to-left-atrial shunting. When the ventricular septal defect is restrictive and there is substantial pressure gradient between the left and right ventricles, a separate murmur of ventricular septal defect may be present, most prominently heard at the lower left sternal border.

The auscultatory findings in ostium primum atrial septal defect are similar to those found in fossa ovalis defects with the addition of an apical holosystolic murmur, secondary to atrioventricular valve insufficiency, that radiates toward the sternum. A pulmonic

flow murmur is often present in the second left intercostal space. There is wide, fixed, splitting of the second heart sound.

Electrocardiogram

The most characteristic abnormality seen in atrioventricular canal defect is a superiorly oriented QRS frontal-plane axis with a counterclockwise depolarization pattern[162] (Fig. 60–8). Ongley and colleagues[163] analyzed the electrocardiograms of 30 patients with complete atrioventricular canal defects and 116 patients with partial atrioventricular canal defects whose diagnoses had been confirmed at surgery. The mean frontal-plane QRS axis was between 0° and −61° in 35 patients (30%) with partial atrioventricular canal defects and in 1 patient (3%) with complete atrioventricular canal defect. The axis was between −61° and −91° in 47 patients (40%) with partial atrioventricular canal defects and in 6 patients (30%) with complete atrioventricular canal defects. An axis between −91° and −151° was seen in 25 patients (22%) with partial atrioventricular canal defects and in 21 patients (70%) with complete atrioventricular canal defects. Three patients with partial atrioventricular canal defects (3%) and 1 patient with complete atrioventricular canal defect had a QRS axis between 90° and 180°. An indeterminate axis was present in one patient with complete atrioventricular canal defect and in six patients with partial atrioventricular canal defects. The mechanism of alteration of the frontal plane QRS axis in these patients is not due to ventricular hypertrophy, but rather is caused by abnormally positioned conduction tissue, which causes an abnormal cardiac activation sequence.[151] Body-surface and epicardial mapping techniques have demonstrated that activation of the left ventricular posterior wall takes place asynchronously.[164]

An additional electrocardiographic finding commonly associated with atrioventricular canal defects is a prolonged P–R interval.[163] Electrophysiologic studies have shown that this prolonged P–R interval is secondary to a delay in intra-atrial activation in many cases, rather than to a delay in atrioventricular nodal conduction.[69] The majority of patients show a normal P-wave axis, with an increase in either P-wave amplitude or width, suggesting left or right atrial enlargement. Patients with ostium primum atrial septal defects often have electrocardiographic signs of right ventricular hypertrophy, particularly an rsR′ pattern in the left precordial leads. Patients with complete atrioventricular canal defects also commonly exhibit electrocardiographic manifestations of right ventricular hypertrophy. Electrocardiographic suggestions of biventricular or left ventricular hypertrophy may also occur in these patients, particularly if mitral or atrioventricular valve insufficiency is severe.

Chest Roentgenogram

Cardiac enlargement is usually present on chest roentgenogram in patients with ostium primum or complete atrioventricular canal defects (Fig. 60–9). In particular, right atrial and right ventricular enlargement is often present. The enlarged right heart often displaces the left ventricle, making evaluation of left ventricular size difficult.

The main pulmonary artery is usually prominent, and if a large left-to-right shunt is present, there are usually increased pulmonary vascular markings. If severe pulmonary vascular disease is present, the distal pulmonary vessels may have a lucent, pruned appearance. Severe enlargement of the pulmonary trunk and left atrium may compress the left main-stem bronchus and cause atelectasis of parts of the left lung.

Echocardiogram

M-Mode

The M-mode echocardiogram in patients with atrioventricular canal defects will characteristically show apparent diastolic move-

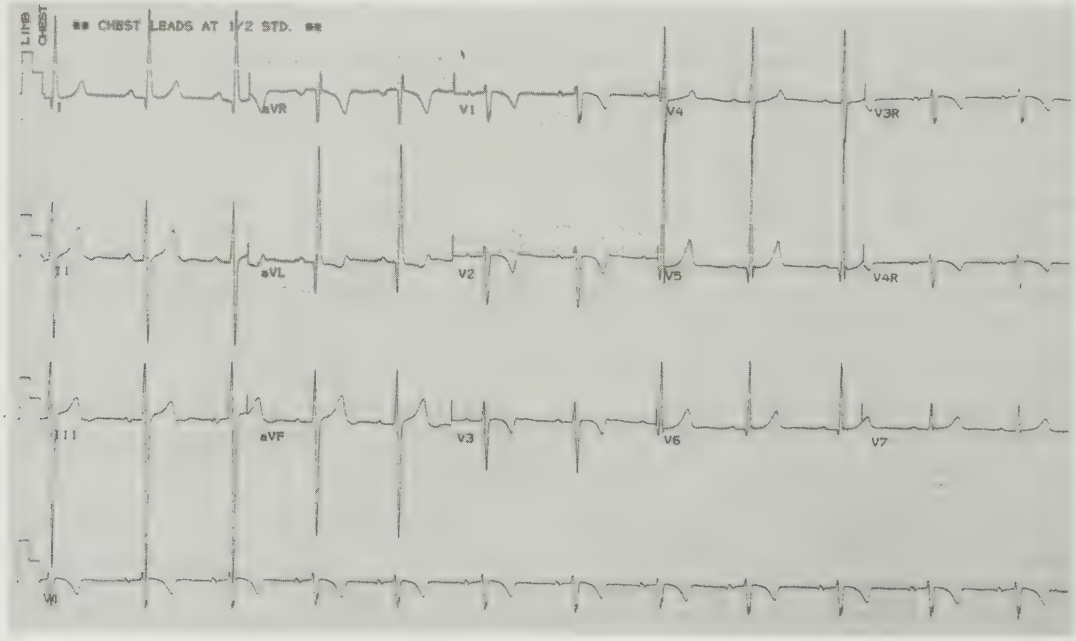

Fig. 60–8. Electrocardiogram from a 9-yr-old patient with a complete persistent atrioventricular canal defect and a pulmonary artery band. Note the position of the frontal-plane QRS axis.

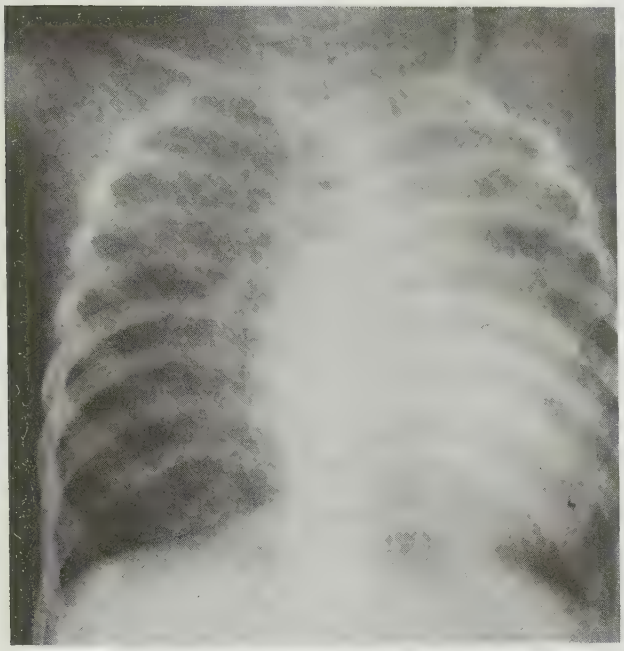

Fig. 60–9. Chest roentgenogram from an 8-mo-old patient with a complete persistent atrioventricular canal defect. Note the cardiomegaly and increased pulmonary vascularity.

ment of the mitral valve through the ventricular septum.[165,166] These findings are apparent in most atrioventricular canal deformities. M-mode echocardiography also reveals an enlarged right ventricle and paradoxical motion of the interventricular septum in many of these patients. Complete atrioventricular canal defects often exhibit gaps in ventricular septal echoes when scanning is performed from apex to base. Thus complete defects can sometimes be distinguished from partial defects. Although M-mode echocardiography is generally diagnostic in skilled hands, false-positive results can occur. In patients with right ventricular enlargement for other reasons, a medial transducer angulation may cause the mitral valve to appear to pass through the interventricular septum.

Two-Dimensional

The two-dimensional echocardiogram is highly reliable in identification of atrioventricular canal defects[167,168] (Fig. 60–10). The hallmark of the diagnosis is demonstration of an absent atrioventricular septum. In ostium primum atrial septal defects, the atrioventricular valve leaflets appear to originate from the crest of the ventricular septum. In complete atrioventricular canal defects, the bridging leaflets of the common atrioventricular valve are noted to cross the ventricular septum. If an atrioventricular septum is present, as evidenced by origin of the left- and right-sided atrioventricular valves at different levels, then the patient either has an isolated cleft mitral or tricuspid valve, or does not have an atrioventricular canal defect at all. The origin of both left and right atrioventricular valves at the same level does not necessarily imply that the patient has an atrioventricular canal defect.[169] Isolated inlet ventricular septal defects can exhibit this feature. However, in isolated inlet ventricular septal defect, the mitral valve is a normal mitral valve. In atrioventricular canal defects the left atrioventricular valve usually exhibits a cleft, which points toward the right atrium or right ventricle. Furthermore, as a consequence of the displacement of the left atrioventricular valve down the septum, the axis of the left atrioventricular valve opening is different in patients with atrioventricular canal defects and normal subjects. In atrioventricular canal defects, the left atrioventricular valve appears to open, on long-axis scans, at an angle pointing toward the lower portion of the ventricular septum and right ventricle. By contrast, in normal subjects, the axis of the left atrioventricular valve opening is toward the distal left ventricular free wall on long-axis scans.

Echocardiographers should use caution in making the diagnosis of atrioventricular canal defect in the presence of a large coronary sinus. In certain views, a large coronary sinus may appear to be an ostium primum atrial septal defect.

When the presence of an atrioventricular septal defect has been confirmed by two-dimensional echocardiography, it is necessary to complete the evaluation by assessing the detailed anatomy of the defect. When echocardiographic windows are adequate, skilled examination by experienced personnel should clearly define the following features of the defect.

Atrioventricular Valve Morphology. It is important to distinguish between defects with a common atrioventricular valve orifice and defects with two anatomically separate atrioventricular valves. This can be done best in the short-axis view. In complete atrioventricular canal defects, the anterior and posterior bridging leaflets are separate and not joined across the atrioventricular junction. In partial atrioventricular canal defects, these leaflets have fibrous continuity. Intermediate forms of atrioventricular canal defects can be identified echocardiographically in which this fibrous continuity is either a very thin strand or is not present across one of the bridging leaflets.

When separate atrioventricular orifices are present, both left and right atrioventricular valves are trileaflet structures. The left atrioventricular valve has a cleft or commissure that points toward the right atrium and right ventricle, as noted, and two commissures that point anterolaterally and posterolaterally. The right atrioventricular valve also has three commissures, pointing roughly anteriorly, posteriorly, and laterally. When a common atrioventricular orifice is present, common anterior and posterior atrioventricular valve leaflets are present that bridge the ventricular septum. These leaflets may either attach to the ventricular septum or float over the septum. As Rastelli[133] noted, three major groups of common atrioventricular canal defects can be identified based on the mode of attachment of the common anterior leaflet. The common anterior leaflet may be divided into two portions that attach to the crest of the ventricular septum, it may be divided into two portions that attach to a papillary muscle situated in the right ventricle near the septum, or it may be undivided and unattached to the septum. Careful echocardiographic investigation of the anterior bridging leaflet, particularly in short-axis cuts, can determine the attachments of the common anterior leaflet and thus enable noninvasive classification of the defect. The attachments of the posterior bridging leaflet should also be defined.

The two-dimensional echocardiogram can also demonstrate the presence of atrioventricular valve thickening. Thickened and gnarled atrioventricular valves are common in complete atrioventricular canal defects, and the presence of such deformities may complicate surgical repair. The total amount of usable atrioventricular valve tissue is also important surgically. As yet, no eval-

uation of this parameter has been made, but such an evaluation may be possible with two-dimensional echocardiography.

Occasionally, accessory atrioventricular valve orifices are present in conjunction with atrioventricular valve defects. These accessory orifices can be identified with two-dimensional echocardiography.

Presence of a Ventricular Component. The apical four-chamber view will demonstrate the presence or absence of a ventricular component to the atrioventricular canal defect. The ventricular component may be small and consist only of interstices between atrioventricular attachments to the crest or side of the ventricular septum. However, the ventricular septal defect can also be intermediate in size or quite large. It is important to define the size of the ventricular component of the atrioventricular canal as well as to rule out the presence of additional muscular ventricular septal defects.

Papillary Muscle Locations and Attachments. The papillary muscle attachments of the atrioventricular valve or valves should be defined in atrioventricular canal defects. It is particularly important to define atrioventricular valve attachments in the left ventricle.[170] The left ventricular papillary muscles are often closer together in patients with atrioventricular canal defects than in normal subjects. Sometimes only one left ventricular papillary muscle exists. Rarely, there are two distinct left ventricular papillary muscles but atrioventricular valve attachments to only one of these muscles. If the cleft of the left atrioventricular valve is closed surgically in either case, an iatrogenic parachute mitral valve will be created, with serious potential adverse consequences.

Atrial Septum. The size of the primum atrial septal defect should be determined. Scans from the subcostal view should facilitate this determination as well as the identification of additional atrial septal defects (secundum, sinus venosus) or common atrium.

Relative Chamber Sizes. The presence of left or right ventricular dominance is usually readily apparent on the echocardiogram, and is important from a prognostic standpoint.

Left Ventricular Outflow. The left ventricular outflow tract is narrowed in atrioventricular septal defects. Occasionally, it is obstructed by subaortic diaphragms, by anomalous left ventricular papillary muscles, or by fibrous "tissue tags." These obstructive lesions can usually be identified by careful echocardiographic examination. The aorta should be carefully examined in all patients with atrioventricular canal defects, as interrupted aortic arch and coarctation are frequent lesions. Doppler echocardiography can quantitate obstruction accurately when it is present.

Right Ventricular Outflow. Infundibular obstruction may be associated with atrioventricular canal defects, and usually has major surgical and prognostic implications. Thus careful echocardiographic evaluation of the right ventricular outflow tract is of major importance. As with the left ventricular outflow, Doppler studies are useful here to quantitate obstruction. The size of the distal pulmonary arteries should be determined echocardiographically when possible, as it usually is in infants and young children.

Ductus Arteriosus. The presence or absence of a patent ductus

arteriosus should be determined echocardiographically. A large patent ductus arteriosus may cause severe symptoms. It is important to know about the presence of even a small patent ductus arteriosus before considering cardiopulmonary bypass. Doppler echocardiography is often of great assistance in determining patency of the ductus arteriosus in these patients, particularly when pulmonary artery pressures are low. Then a continuous left-to-right shunt through the ductus is easily identified by two-dimensionally directed or color Doppler echocardiography. In patients with elevated pulmonary artery pressures, Doppler confirmation of ductal patency is more challenging because the left-to-right shunt is often phasic rather than continuous and may be detectable in only a small region of pulmonary artery.

Pulmonary Venous Connections. Total or partial anomalous pulmonary venous connection may occur in conjunction with atrioventricular canal defects. These lesions often have major prognostic importance and may greatly complicate surgical repair.

Systemic Venous Connections. Anomalies of systemic venous connections, such as persistent left superior vena cava and azygous continuation of the inferior vena cava are often important surgically and should be identified echocardiographically.

Visceral and Atrial Situs. Atrioventricular canal defects are frequently seen in conjunction with right and left isomerism. It is particularly important to identify right isomerism, since it is usually associated with asplenia, which requires antibiotic prophylaxis to prevent overwhelming infection.

Ventricular Function. Qualitative and quantitative estimates of ventricular function are readily made with echocardiography, and should be obtained.

Doppler

Doppler echocardiography can contribute substantially to the evaluation of atrioventricular canal defects. Pulsed Doppler is especially useful in the detection of left and right ventricular outflow obstruction and the presence of a ductus arteriosus. Pulsed Doppler examination also facilitates identification of atrioventricular valve regurgitation and has been employed to quantitate the degree of atrioventricular valve regurgitation.[171] As with other defects, pulsed Doppler echocardiography can provide relatively accurate estimates of pulmonary-to-systemic blood flow.

Continuous-wave Doppler is useful in quantitating pressure gradients. When a ventricular defect is present, the instantaneous pressure difference between the right and left ventricles can be determined using the modified Bernoulli formula. Similarly, pressure gradients across the left and right ventricular outflow tracts can be quantitated. Continuous-wave Doppler studies are particularly helpful in the followup of patients who have undergone pulmonary artery banding.[172] When pulmonary insufficiency is present, estimates of pulmonary artery diastolic pressure can be obtained. Similarly, estimates of pulmonary artery pressure can be made by quantitating the velocity of flow across the ductus arteriosus and measuring the systemic arterial blood pressure.

When tricuspid valve insufficiency is present, it is in principle possible to obtain estimates of right ventricular pressure. However, since a high-velocity left-ventricular-to-right-atrial flow of blood is often present in these patients, and since this flow may have a similar direction to the jet of tricuspid insufficiency, quantitation of the velocity of tricuspid valve insufficiency should be made with caution. Color Doppler identification of jet direction may be helpful in this regard.[173] Since multiple high-velocity jets of blood flow are frequently present in these patients, two-dimensional direction of continuous-wave Doppler beams should be used whenever possible, to avoid misidentification of the blood flow jets.

Color Doppler is also useful for determining the location and roughly quantitating the degree of atrioventricular valve insufficiency in these patients (Fig. 60–11). Additionally, color Doppler may also facilitate examination of patients for left and right ventricular outflow tract stenosis, for patent ductus arteriosus, and for multiple ventricular septal defects.

Radionuclide Angiography

Radionuclide angiography has been used to evaluate anomalous systemic venous connections. It may be useful in determining systemic-to-pulmonary venous flow ratios when atrioventricular valve insufficiency is absent or minimal.

Nuclear Magnetic Resonance

A major feature of atrioventricular canal defects, deficiency of the atrioventricular septum, is readily visualized with standard nuclear magnetic resonance imaging techniques.[174] In normal subjects as well as in patients with atrioventricular canal defects, the atrioventricular septum is best delineated by an imaging plane perpendicular to the axes of the lower atrial septum and the inlet ventricular septum. Such a plane demonstrates all four chambers of the heart, and is often termed the four-chamber view.

Because of the relatively thin structure and rapid motion of the atrioventricular valves, the atrioventricular valve anomalies associated with atrioventricular canal defects are difficult to characterize properly with current available nuclear magnetic resonance techniques. However, cine nuclear magnetic resonance methods show promise for detection and quantitation of the atrioventricular valve insufficiency often associated with the structural atrioventricular valve defects. Furthermore, nuclear magnetic resonance imaging can define many of the congenital cardiovascular abnormalities often associated with atrioventricular canal defects, such as coarctation of the aorta, pulmonary artery stenosis, pulmonary and systemic venous anomalies, and relative ventricular hypoplasia. Particularly in older patients, these associated anomalies may be difficult to define by other noninvasive techniques.

Cardiac Catheterization

Atrioventricular canal defects can be suspected at cardiac catheterization when the catheter course across the atrial septum is low. In many cases, because of the anatomy of these defects and the associated left-ventricular-to-right-atrial shunting, it is relatively difficult to maneuver the catheter into the right ventricle and out the pulmonary artery, as it tends either to pass into the left ventricle or flip back into the right atrium. Counterclockwise rotation with gradual movement of the catheter tip up the ventricular outlet septum will often succeed in such cases.[3] Balloon catheters can be used if other methods fail, but they are generally not recommended for angiography because of their relatively small lumens and tendency to recoil during injection. Oxygen saturation and hemodynamic findings in partial atrioventricular canal defect are generally similar to those obtained with catheterization of a secundum atrial septal defect.[175] Complete atrioventricular canal defects have these oxygen saturation and hemodynamic findings plus those of a ventricular septal defect.[176] It should be appreciated

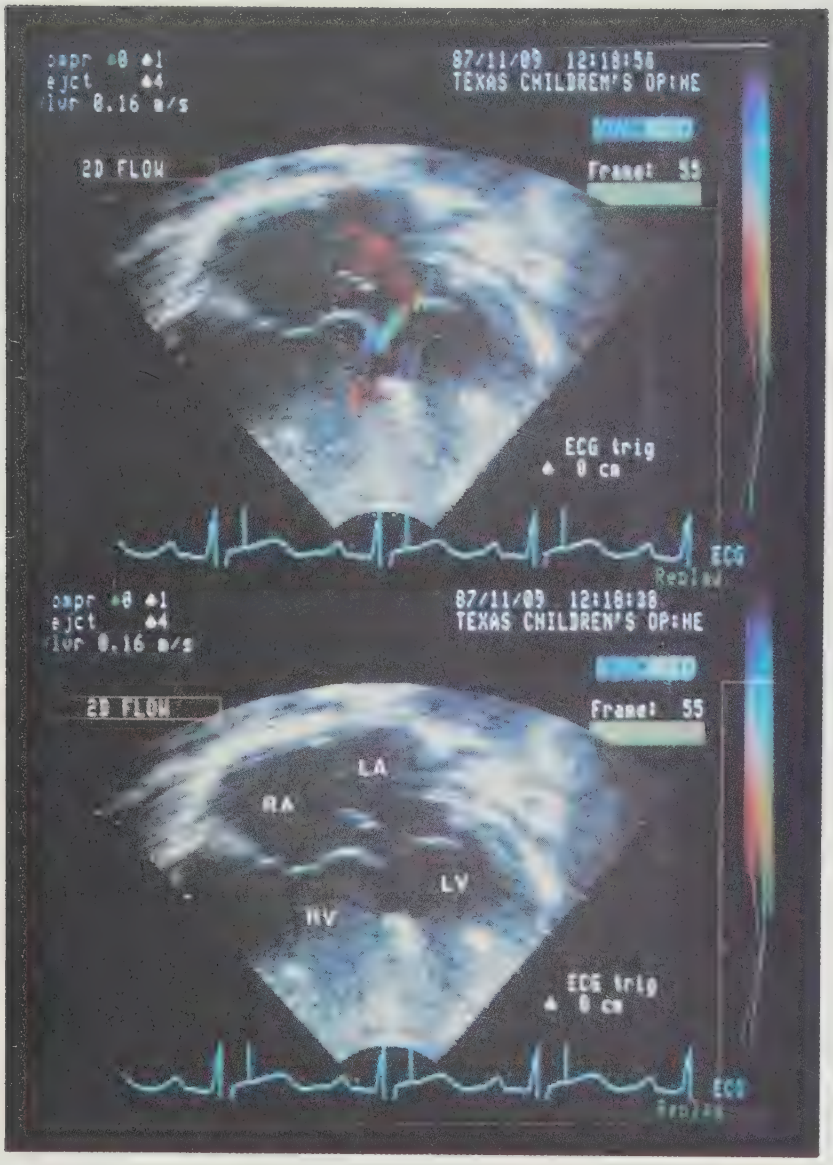

Fig. 60–11. Color Doppler study of a complete atrioventricular canal defect (apical four-chamber view, anatomical orientation). Top panel shows insufficiency from left portion of atrioventricular valve as greenish-yellow jet. RA = right atrium; LA = left atrium; RV = right ventricle; LV = left ventricle.

that calculation of pulmonary and systemic blood flow by the Fick method in these patients can be subject to errors and should be interpreted with caution. Estimation of systemic blood flow by this technique is dependent on obtaining a true mixed venous sample. When no intracardiac septal defects are present, pulmonary artery saturation provides an accurate estimate of the mixed venous oxygen saturation. In atrioventricular canal defects, oxygen saturation in the superior vena cava must be used, which may not represent the true mixed venous saturation. Similarly, estimation of pulmonary blood flow may be in error. A small pulmonary arteriovenous oxygen saturation difference may be present, in which case any variation in oxygen saturation among the pulmonary veins will lead to errors in the calculation. Errors will also be incurred if the patient is breathing an elevated concentration of oxygen and the effect of dissolved oxygen is not allowed for in the calculation. Estimates of systemic blood flow by indicator dilution curves will not be accurate in the presence of the usual left-ventricular-to-right-atrial shunt in these patients.

From the above considerations it follows that calculated pulmonary resistance values in these patients should be carefully evaluated. A number of authors suggest that evaluation of pulmonary vascular resistance while breathing 100% oxygen and after tolazoline injection should be performed if initial estimates indicate the presence of elevated pulmonary vascular resistance. Others suggest that patients should be intubated for evaluation if upper airway obstruction, with consequent carbon dioxide retention, is present at the time of cardiac catheterization. Patients with Down's syndrome often have some degree of upper airway obstruction from enlarged tonsils and adenoids. Calculated pulmonary vascular resistance values may improve markedly in these patients when the obstruction is relieved.[177]

Park and colleagues reported the results of cardiac catheterization in 53 patients with partial atrioventricular canal defects.[178] Patients with major associated cardiovascular anomalies such as coarctation were excluded from their series. Patient ages ranged from 2 months to 53 years, with a mean of 11 years. Systemic

arterial saturations while breathing room air were available in 41 patients. Arterial saturation was 95% or over in 25 of these patients and between 90 and 94% in 15. Only one patient had an arterial saturation between 80 and 89% while breathing room air. Mean arterial saturation for the group was 95%. Thus substantial systemic desaturation seems to be unusual in partial atrioventricular canal defect. Pulmonary resistances were less than 5 units in 40 of the patients. Two patients had mildly elevated resistances (6.2 and 7.5 units). Pulmonary-to-systemic blood-flow ratio was greater than 2:1 in 38 of the patients. Right-to-left shunting was demonstrable in 40 of the patients, but the average amount of the right-to-left shunt was only 9%. The maximum right-to-left shunt encountered was 28%.

Park and colleagues also reported the results of cardiac catheterization in 48 patients with complete atrioventricular canal defect.[178] Patient ages ranged from 2 days to 25 years. Systemic arterial saturations measured while breathing room air were available in 18 patients without pulmonary vascular disease. Thirteen of these patients had arterial saturation of less than 94% but greater than 89%. Two patients had arterial saturation of between 80 and 89%. Only three patients had an arterial saturation greater than or equal to 95%. Mean systemic arterial saturation for the group was 92%. Systemic arterial saturations measured while breathing room air were also available in 19 patients with pulmonary vascular disease. Six patients had saturations between 90 and 94%, but nine patients had saturations between 80 and 89% and four had saturations less than or equal to 79%. Mean arterial saturation for the group was 84%. Thus slight systemic arterial desaturation occurs in patients with complete atrioventricular canal defects in the absence of pulmonary vascular disease, but substantial systemic arterial desaturation is frequent in the presence of pulmonary vascular disease. In the patients without pulmonary vascular obstructive disease, the average pulmonary-to-systemic blood-flow ratio was greater than 2:1. Small right-to-left shunts were demonstrated by indicator dye dilution curves in 15 of 19 patients. In patients with complete atrioventricular canal defects and pulmonary vascular obstructive disease, right-to-left shunts were present in all patients, and the average amounts of left-to-right and right-to-left shunting was nearly equal at 38% and 39%, respectively.

Angiography

Selective left ventricular angiography in the anteroposterior projection demonstrates an elongated left ventricular outflow tract, with an abnormally low insertion of the anterior leaflet of the left atrioventricular valve, deficiency in the diaphragmatic wall of the left ventricle, and a disproportionately short inlet septum as compared with the outlet septum (Fig. 60–12). This combination of characteristics is diagnostic of an atrioventricular canal defect and is termed the ''gooseneck'' deformity.[179,180] The appearance of this deformity depends on left ventricular origin of the aorta. In the presence of double-outlet right ventricle the ''gooseneck'' may be difficult to recognize.

A thorough angiographic assessment of atrioventricular canal defects includes the following:

- Determination of the existence and size of ventricular components of the atrioventricular canal defect
- Determination of whether there is a common atrioventricular valve orifice or two separate atrioventricular valves
- Determination of the mode of connection of a common atrioventricular valve (balanced, left dominant, right dominant)

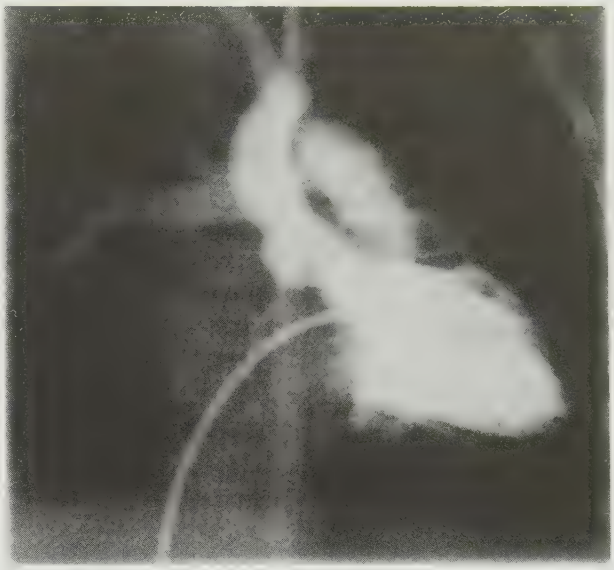

Fig. 60–12. Frame from a cineangiogram taken in the posteroanterior projection after injection into the left ventricle. Note the ''gooseneck'' deformity of the left ventricular outflow tract.

- Evaluation of the function of the atrioventricular valves
- Determination of the existence and size of atrial components of the atrioventricular canal defect
- Evaluation of the left ventricular outflow tract
- Evaluation of the right ventricular outflow tract and pulmonary arteries
- Detection of associated anomalies, such as anomalous pulmonary and systemic venous connections, patent ductus arteriosus, coarctation, and heterotaxia

Accomplishment of these objectives will usually require several contrast injections. Left ventricular injection into the hepatoclavicular or four-chamber view is the best method for evaluation of the inlet ventricular septum and for excluding apical muscular ventricular septal defects[90,181] (Fig. 60–13). Direct recognition of separate atrioventricular valve orifices or a common atrioventricular valve orifice is possible with this view. The mode of connection and the function of the left atrioventricular or common atrioventricular valve can also be evaluated from a left ventricular injection in the four-chamber view. The atrial septum is best assessed by an injection at the orifice of the right upper pulmonary vein in the hepatoclavicular position.[90,181] The size of the ostium primum atrial septal defect can be determined and the presence of additional secundum or sinus venosus atrial septal defects can be identified (Fig. 60–14). When there is a question about obstruction of the left ventricular outflow tract, left ventricular injection in the long-axis oblique projection will clearly demonstrate the left ventricular outflow tract along its axis. The right ventricular outflow tract and pulmonary arteries are best demonstrated by direct injection into the right ventricle or its outflow tract in the sitting-up or cranially angulated anteroposterior projection.[182] Patent ductus arteriosus, coarctation, and anomalous pulmonary venous connections are often associated with atrioventricular canal defects and can have deleterious effects if not identified before surgery. Additional contrast injections into the aorta and pulmonary arteries may be necessary to exclude these lesions.

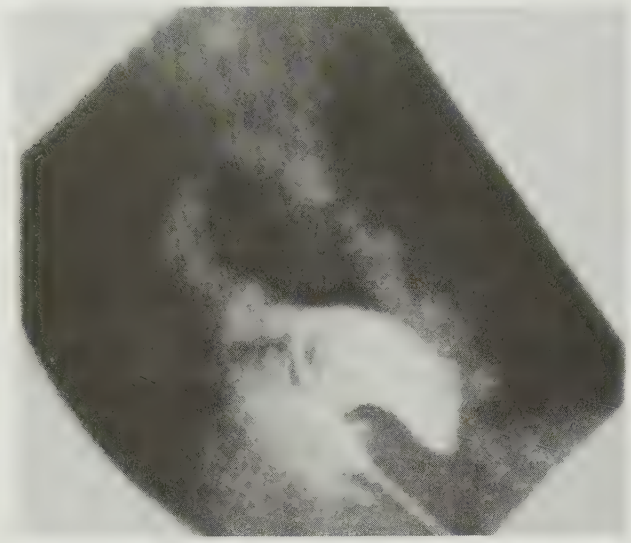

Fig. 60–13. Frame from a cineangiogram taken in the hepatoclavicular projection after injection into the left ventricle in a patient with complete atrioventricular canal defect. Note the large ventricular septal defect.

Angiographic definition is best when relatively large amounts of contrast are delivered rapidly through a large-bore catheter. This is particularly true in the presence of large left-to-right shunts, which rapidly dilute contrast delivered to the ventricles or pulmonary arteries. Since only a limited number of contrast injections are clinically feasible during a given study, noninvasive studies and prior angiographic examinations should be reviewed before catheterization so that optimal use of the available injections can be made. Digital angiography should prove to be of great assistance in this regard, because it requires substantially less contrast material. Nonionic contrast media should be useful in facilitating angiographic examinations in these patients.

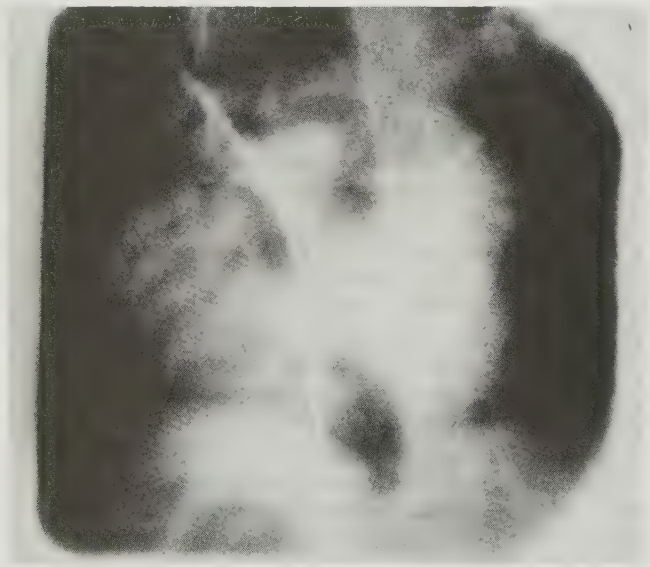

Fig. 60–14. Frame from a cineangiogram taken in the hepatoclavicular projection after injection at the orifice of the right upper pulmonary vein in a patient with a primum atrial septal defect. Note the low position of the defect in the atrial septum.

Electrophysiology

Electrophysiologic studies in preoperative patients with atrioventricular canal defects have demonstrated a prolonged intraatrial activation time with normal His–Purkinje conduction intervals. Twenty-one patients with atrioventricular canal, aged 3 months to 11 years, were evaluated preoperatively by Jacobsen and colleagues.[183] The high-right-atrial-to-low-right-atrial conduction time was prolonged in 15 of 18 patients (mean, 57 ± 20 msec) and the low-right-atrial-to-His-bundle conduction time was normal in 16 of 17 patients (mean, 82 ± 30 msec).

Nine patients with atrioventricular canal defects were studied by Jacobsen and colleagues after corrective surgery. High-right-atrial-to-low-right-atrial conduction time was prolonged in three of five patients. The low right-atrial-to-His-bundle conduction time was prolonged in two of seven patients, and one had acquired complete atrioventricular block in the His bundle. A prolonged His–Purkinje conduction time was found in two of eight patients. The site of prolongation of atrioventricular conduction could not be determined from the surface electrocardiogram in these patients. Fournier and colleagues[184] have obtained similar results preoperatively and postoperatively in patients with atrioventricular canal defects.

Treatment

Recommendations for treatment are dependent on the anatomic characteristics of the atrioventricular canal anomaly and on the state of the pulmonary vasculature. A central objective of treatment in these patients is to avoid development of pulmonary vascular obstructive disease.

When heart failure and associated pulmonary congestion are present, anticongestive measures such as diuretics and digoxin are indicated. Long periods of fluid restriction are generally counterproductive in small infants, since such restriction deprives them of calories needed for growth. Hydralazine has been shown to reduce the magnitude of left-to-right shunting in the short term in infants with atrioventricular canal defects,[185] but no long-term experience with the drug has been reported. Most cardiologists do not favor prolonged medical therapy in young patients without fixed pulmonary vascular obstructive disease if their symptoms are refractory, but rather refer them for surgical therapy when such therapy is feasible. Patients with an ostium primum atrial septal defect, separate atrioventricular valves, no ventricular defect, and minimal atrioventricular valve insufficiency generally are asymptomatic during infancy and childhood. Because repair of ostium primum atrial septal defect is associated with a greater potential morbidity than repair of a secundum atrial septal defect, many cardiologists do not recommend surgery at any age if cardiomegaly is absent, which usually is the case when atrioventricular valve insufficiency is mild and the pulmonary-to-systemic flow ratio is less than 2:1. Infants with partial atrioventricular canal defects that are symptomatic almost invariably have severe atrioventricular valve regurgitation. Pulmonary artery banding generally does not help these patients. Therefore corrective surgery with mitral valvuloplasty and atrial septal defect closure is usually recommended. Asymptomatic patients with ostium primum atrial septal defects

that do exhibit substantial cardiomegaly are usually referred for elective surgical repair when they near school age.

Patients with complete atrioventricular canal defects who do not have associated right ventricular outflow obstruction, generally have pulmonary pressures near systemic levels, and pulmonary vascular disease usually develops after the first year of life. Therefore either banding or corrective surgery during infancy is recommended in these patients.

Complete atrioventricular canal defects may be treated by pulmonary artery banding in infancy, followed by corrective surgery at an older age. Banding is most successful when high pulmonary blood flow from a large left-to-right shunt is present. In these cases, distal pulmonary artery pressure can be reduced to nearly normal levels and heart failure can be relieved.[186] However, banding may not result in substantially decreased distal pulmonary artery pressures if pulmonary vascular resistance is increased. Infants that do not have elevated pulmonary blood flow will not benefit from banding through a reduction in heart failure. Thus infants with atrioventricular canal defects and balanced or predominantly right-to-left shunting often do not improve symptomatically. When atrioventricular valve insufficiency, or an obligatory left-to-right shunt from left ventricle to right atrium, is the primary cause of cardiac volume overload, pulmonary artery banding will not relieve heart failure and may make it worse by increasing ventricular afterload. Pulmonary artery banding can distort the pulmonary arteries and thus complicate subsequent corrective surgery. Fisher and colleagues have obtained ventricular volume data suggesting that both right and left ventricular hypoplasia may be produced by pulmonary artery banding in patients with atrioventricular canal defects.[187]

Corrective surgery can now be performed even in early infancy.[188] There are several variants of the corrective surgical procedure.[140] Some surgeons use a single Dacron patch to close the atrial and ventricular components of the defect.[189] The right and left portions of the common atrioventricular valve are then resuspended from the patch. Other surgeons prefer to use a two-patch technique, and sandwich the leaflet tissue between the two patches.[190] The method of repair of the left atrioventricular valve also is controversial. Many agree with Carpentier that the left atrioventricular valve in these patients is best left as a trileaflet structure and that repair of the cleft should only be attempted as necessary to prevent postoperative regurgitation.[191] Others believe that it is best to attempt to reconstruct an approximation of a normal mitral valve.[192] Because of the highly variable anatomy of the defects, many aspects of each repair must be individualized. Particular attention should always be paid to ensuring a good left ventricular outflow.

Repair in the presence of right ventricular outflow obstruction (associated tetralogy of Fallot) is more complicated because it entails concomitant relief of infundibular and valvular pulmonic stenosis in addition to atrioventricular canal repair.[193] Additionally, the subaortic location of the ventricular septal defect in this combination of defects increases the technical difficulty of achieving appropriate division of the common atrioventricular valve, while maintaining a clear route from the left ventricle to the aorta. Fortunately, repair can usually be delayed until childhood in patients with obstruction to right ventricular outflow, since their pulmonary vasculature is protected by the obstruction. Patients symptomatic in infancy from low pulmonary blood flow can obtain effective relief from an aorticopulmonary shunting procedure.

The presence of left ventricular outflow obstruction also complicates repair of atrioventricular canal defects and increases risk, although successful corrective surgery can be accomplished with moderate degrees of obstruction.[194] Successful repair can also be accomplished when atrioventricular canal defects are found in association with double-outlet right ventricle[195] and with transposition of the great arteries,[143] although again, the added complexity of the repair increases the risk. Hypoplasia of the left or right ventricle is an important risk factor and may contraindicate repair when the hypoplasia is pronounced.

Severe pulmonary vascular disease is a contraindication to corrective surgery and pulmonary artery banding in patients with atrioventricular canal defect, since mortality is high, and since prognosis is not improved even if the surgery is technically successful and recovery takes place. However, in infants and young children, particularly those below the age of 2 years, the diagnosis of pulmonary vascular obstructive disease should be made with caution, because a generalized increase in muscularity of the pulmonary arterioles can lead to increased pulmonary resistance measurements at catheterization. This increased muscularity may regress subsequent to successful surgery. Culpepper and colleagues[196] reported two patients with complete atrioventricular canal defects, aged 4 and 12 months, who had elevated pulmonary vascular resistances (1472 and 710 dynes·sec·cm^{-5}/m^2) preoperatively and who had a decrease in pulmonary resistance to the normal range at a postoperative cardiac catheterization. Evaluation of pulmonary resistance and blood flow in the presence of pulmonary vasodilators such as tolazoline, pulmonary wedge arteriography, and open lung biopsy may all be of assistance in evaluation for pulmonary vascular disease.

Prognosis

The long-term results of surgical therapy for these patients depend greatly on the degree of preoperative pulmonary vascular disease and on the extent of residual left atrioventricular valve regurgitation. In many instances, the left atrioventricular valve regurgitation is substantially reduced and the left-to-right shunt abolished or reduced to minimal levels by corrective surgery. The distal pulmonary vasculature can be effectively protected by pulmonary artery banding in most patients. However, when severe pulmonary vascular disease is present preoperatively, morbidity and mortality are high, and improvement may not occur even in patients who survive operation. Postoperative arrhythmias can occur, including complete heart block, and may increase in incidence as patients grow older. With advancing age, patients may also require mitral valve replacement.

Partial Atrioventricular Canal Defect

Immediate and long-term results following repair of partial atrioventricular canal defect were described in 35 patients by Stewart and colleagues.[197] Mean age at the time of operation was 8 years. Two operative deaths occurred. One death, in a patient 1.5 years of age with systemic pulmonary artery pressure before surgery, was secondary to ventricular fibrillation 48 hours after operation. A second death, in a patient 60 years of age, was secondary to unexplained low cardiac output without substantial mitral valve incompetence. Two patients required reoperation. One had closure

of a recurrent atrial septal defect 4 years after the initial operation. In a second patient progressive mitral valve incompetence developed over several years; this patient underwent mitral valve replacement. At the time of their last followup examinations, all surviving patients were in New York Heart Association functional class I. Heart size was normal on chest roentgenogram, and all were in normal sinus rhythm. Before operation 17 of the patients had either moderate or severe mitral valvular incompetence. After initial operation, only one patient had moderate or severe mitral valve incompetence.

The clinical course of 52 adult patients with partial atrioventricular canal defects seen between 1955 and 1981 were reviewed by Hynes and colleagues.[198] The mean age of the patients was 37 years and all patients were 20 years of age or older. Forty of the patients (77%) had either no symptoms or mild symptoms at the time of operation. Ten patients (19%) were in New York Heart Association class III and two patients (4%) were in New York Heart Association class IV preoperatively. All 18 patients aged 45 or older were symptomatic to some extent with palpitations, exertional dyspnea, and/or chronic fatigue. Nine patients were in chronic atrial fibrillation preoperatively and one patient had intermittent complete heart block and a pacemaker. Forty-seven of the patients underwent surgical repair. There were three operative deaths, two of which were secondary to acute respiratory distress in the immediate postoperative period, and one of which was secondary to refractory ventricular fibrillation 24 hours postoperatively. There were two late deaths, one in a patient who had severe congestive heart failure due to mitral valve insufficiency preoperatively, and one in a patient with severe postoperative hemolysis probably secondary to a mechanical mitral valve prosthesis. Postoperative atrial arrhythmias requiring treatment were present in 15 of the patients (34%).

The study by Somerville,[199] which examined the clinical course of 122 patients with ostium primum atrial septal defect seen during a 6-year period from 1958 through 1964, documented a substantial incidence of disabling symptoms and cardiac-related deaths in untreated patients with partial atrioventricular canal defects. The number of deaths and severe symptoms increased markedly with increasing age. Deaths occurred at all ages. The youngest age at death was 2 weeks and the oldest 56 years. Eight of 96 patients (8%) less than 30 years of age were severely disabled and five deaths were recorded in patients less than 30. Seven of 27 patients (27%) over 30 years of age were severely disabled and deaths were recorded in 7 patients over 30 during the course of the study. Arrhythmias were the most common cause of deterioration. Arrhythmias were uncommon before age 30 but thereafter steadily increased in incidence so that absence of arrhythmias was unusual in the sixth and seventh decades of life. Atrial fibrillation was a major cause of symptoms. The commencement of atrial fibrillation was noted to coincide with the onset of severe dyspnea, raised jugular venous pressure, increasing heart size, and hepatomegaly. Spontaneous complete heart block developed in six of the patients and was tolerated poorly. Severe mitral insufficiency was the most common cause of symptoms in patients in sinus rhythm. Pulmonary vascular disease occurred in only 5 of 122 patients (4%), and 2 deaths were attributed to pulmonary vascular disease. It is of interest that no patient who had deteriorated as the result of an arrhythmia had evidence of pulmonary vascular disease.

Considered together, the above clinical studies of patients with partial atrioventricular canal defects support the conclusion that successful corrective surgery is associated with an improved prognosis in patients with partial atrioventricular canal defect. The studies also support the conclusion that prognosis is better in patients with large shunts that are repaired before adulthood. Relief of the volume overload secondary to left-to-right shunting through the atrial septal defect should reduce the stimulus for atrial enlargement and the consequent propensity to develop atrial arrhythmias.

However, because reoperation for mitral valve replacement is sometimes necessary, the indications for surgery should be carefully evaluated in infants and young children in whom small size would make valve replacement technically difficult. Indications for surgery should also be carefully evaluated in asymptomatic patients with this disorder who do not have large left-to-right shunts. Patients with small left-to-right shunts and low pulmonary artery pressures are probably at relatively low risk for complications secondary to the partial atrioventricular canal defect. Substantial evidence is not available to suggest that surgery improves prognosis in these patients.

Complete Atrioventricular Canal Defect

Early reports of pulmonary artery banding in patients with atrioventricular canal defect suggested that a high operative mortality was associated with the procedure. Somerville and colleagues[200] reported four operative deaths and one late death in 12 patients with atrioventricular canal defects who underwent banding. Eleven of the patients were under 1 year of age and one patient was 2 years old. Other investigators described similar results. However, recent data suggest that advances in surgical technique and postoperative care have substantially lowered the mortality of pulmonary artery banding in infants with atrioventricular canal defect.

Silverman and colleagues[186] noted a 4.7% in-hospital mortality for pulmonary artery banding in 21 consecutive infants. Repeat cardiac catheterization, performed at a mean of 19.6 months after banding demonstrated an average peak systolic band gradient of 41 mm Hg. In one patient the pulmonary artery band migrated distally to occlude the left pulmonary artery. Two late deaths occurred 6 to 12 months after pulmonary artery banding, one from respiratory infection and one from unknown causes. Four patients from this series later underwent successful corrective surgery with debanding of the pulmonary artery. The authors concluded that pulmonary artery banding was a rational alternative for initial treatment of symptomatic infants with complete atrioventricular canal defects, particularly in the presence of anatomic variants such as single left ventricular papillary muscle, relative hypoplasia of either the left or right ventricles, or left ventricular outflow tract obstruction. Williams and colleagues[165] have developed an individualized management plan, based on their experience in a five-year study of 46 children with complete atrioventricular canal defects. They suggest banding of the pulmonary artery in infants less than 4 to 5 kg in weight. Corrective surgery is advocated in larger infants and children when not contraindicated by unusual anatomic features or pulmonary vascular disease. With this approach, Williams and colleagues reported one death in the immediate postoperative period and three deaths from 8 months to 2½ years postoperatively for a late survival rate of 91%. Thirty-two children had undergone successful corrective surgery at the time of the report.

Other investigators have demonstrated that complete atrioventricular canal defects can be repaired primarily in early infancy with a low mortality rate. Bender and colleagues[201] performed corrective surgery on 24 consecutive infants with complete atrioventricular canal defects. Operative mortality was 8% (2 of 24). Both operative deaths occurred in infants with associated anomalies—coarctation of the aorta in one case and total anomalous pulmonary venous connection in the other. One late death occurred, and one patient required a pacemaker postoperatively. Postoperative cardiac catheterization in seven surviving patients demonstrated an average drop in peak systolic pulmonary artery pressure to 27 mm Hg. Preoperative pulmonary artery peak systolic pressure was 81 mm Hg in the 21 patients.

The functional and anatomic characteristics of 310 consecutive patients undergoing repair of atrioventricular septal defects from 1967 to 1982 were reviewed by Studer and colleagues.[150] Age was not found to correlate with risk after 1976. However, severity of atrioventricular valve incompetence, functional status preoperatively, presence of major associated cardiac anomalies, presence of interventricular communication, and hypoplasia of the left or right ventricle were found to be major risk factors. Actuarial risk for corrective surgery was determined to be 0.6 to 4% for patients in New York Heart Association functional class III without an interventricular communication, depending on the degree of atrioventricular valve insufficiency and 5 to 13% for such patients with an interventricular communication. In this series, surgically induced complete heart block developed in five patients, for an overall incidence of 1.6%. Four of these five cases of heart block occurred either in patients with major associated anomalies in addition to atrioventricular canal or after atrioventricular valve replacement. Thus heart block occurred in only 1 of 231 patients (0.4%) without major associated anomalies who underwent routine repair of atrioventricular canal. Actuarial survival at 12½ years after surgery was calculated to be 95% when mild atrioventricular valve insufficiency was present and 88% in the presence of moderate to severe atrioventricular valve insufficiency. Late followup information was available on 258 patients who survived surgery. Nineteen of these patients died before hospital discharge. Two deaths were of noncardiac origin. Two deaths occurred in patients with severely elevated pulmonary vascular resistance. Ten deaths occurred in patients known to have failure of the left atrioventricular valve repair.

Clapp and colleagues recently reviewed the course of 121 patients with complete atrioventricular canal defects who were seen over 10 years.[202] Of these patients, 70 underwent corrective surgery. Perioperative mortality was 30% overall (21 of 70). When six patients with hypoplastic right or left ventricles, five patients with a double-orifice mitral valve or deficiency of mitral tissue, and five patients with pulmonary vascular obstructive disease were excluded from the group, perioperative mortality was 13%. Three of the 49 survivors of corrective surgery died 17 to 42 months postoperatively. Two deaths were attributed to heart failure and severe pulmonary artery vascular disease. One unexpected death occurred 17 months after surgery. One patient required a pacemaker. No progressive rhythm disturbances were noted.

The study of Neufeld and colleagues[157] suggests that advanced pulmonary vascular disease develops in patients with complete atrioventricular canal between 6 months and 1 year of age. Lung specimens were examined from open biopsy or autopsy specimens in 44 patients with complete atrioventricular canal defects. After 1 year of age, Heath–Edwards grade 3 and 4 histologic changes were present in most patients who had not undergone surgery, suggesting that irreversible pulmonary vascular disease had developed by this age. Biopsy specimens from infants less than 6 months of age often exhibited medial hypertrophy but did not show changes suggestive of irreversible disease.

The above studies support the conclusion that prognosis is improved by surgical intervention in patients with complete atrioventricular canal defects. However, at least palliative pulmonary artery banding must be performed within the first year and in many cases within the first six months of life in order to prevent the onset of irreversible pulmonary vascular disease. Clearly, individual patients with complete atrioventricular canal defects can be successfully treated either with primary intracardiac repair or with a staged approach involving pulmonary artery banding and subsequent corrective surgery. There are experienced advocates of both approaches.

Primary repair is attractive for many reasons. The period during which the ventricles are subject to volume and pressure overload is reduced by early primary repair. Hopefully this will translate into improved ventricular function after correction and a reduced incidence of ventricular fibrosis and dysfunction in later life. Even when patients have successful results from banding, they still are at risk for developing complications such as embolic phenomena and brain abscess while they await corrective surgery. Additionally, patients who undergo banding must still face the risk of corrective surgery, which may be increased by the need to take down the band.

CHAPTER 61

Patent Ductus Arteriosus

Charles E Mullins

This chapter will cover the isolated persistent patent ductus arteriosus in the postneonatal infant, the child, and the adult, but will not deal with the patent ductus in the premature or early neonatal period. The ductus arteriosus is the only normal and essential structure in the fetus that becomes abnormal only by its persistent patency in the postfetal circulation.

EMBRYOLOGY

The ductus arteriosus embryologically originates from the distal portion of one of the sixth paired aortic arches[1] and provides a communication between the pulmonary artery and the descending aorta. The left, right, or both ductus can persist.[2,3] The persistence of either a left or right ductus and its course and connections from the aorta or its major branches to the pulmonary artery is closely associated with the development of the aortic arch. The ductus can connect from either the proximal right or left pulmonary artery to virtually any location on the aortic arch or proximal portions of any of the brachiocephalic vessels. The variations in the connections and the course of the ductus are related to where the lateralization ''breaks'' occur in the embryonic double aortic arch and the relation of the ''break position'' to the aortic end of the embryonic sixth arches (Fig. 61–1).

In the infant with a normal left aortic arch, the ductus originates from the distal left sixth arch and connects the main pulmonary artery to the left descending aorta distal to the origin of the left subclavian artery (position 4, Fig. 61–1). With a right aortic arch, a persistent ductus still usually will arise from the distal *left* sixth arch along with a remnant of left dorsal aorta (the Kommerell's diverticulum) either as an isolated structure off of the right descending aorta or in conjunction with an anomalous left subclavian artery (position 4, Fig. 61–1). In both situations the ductus or its ligamentum will pass behind the trachea and esophagus and create a vascular ring.[4] Rarely with a right aortic arch, the ductus will arise from the original distal right sixth arch and connect the proximal right pulmonary artery to the right descending aorta just distal to the origin of the right subclavian artery (position 1, Fig. 61–1). With ''breaks'' in the embryonic double arch at different locations the rare anterior ductus off of the base of a carotid or innominate artery or even the ductus arising from an isolated subclavian artery will occur. Bilateral ductus is created by the persistence of both distal sixth arches connecting the pulmonary arteries to various portions of the aortic arch or brachiocephalic vessels.

INCIDENCE

A persistent patent ductus arteriosus, as an isolated lesion, has been estimated to occur in between 1 in 2,500 and 1 in 5,000 live births.[5–7] As an isolated lesion, it represents between 9 and 12% of all presenting congenital heart lesions. In most series, there is a sex difference with a 2:1 female-to-male ratio.[8]

The ductus arteriosus may coexist with virtually all other congenital heart lesions and should be considered when the clinical features of left-to-right shunting seem out of proportion to the particular lesion being considered. The persistent ductus definitely should be ruled out when a patient with a more complex lesion is being considered for cardiopulmonary bypass. There are complex cardiac lesions where the persistence of the ductus is critical for

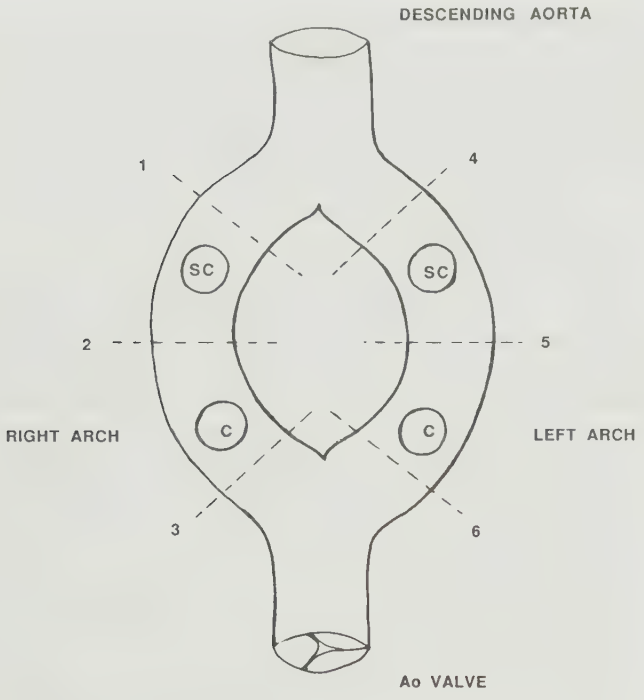

Fig. 61–1. Schematic diagram of the embryonic double aortic arch system. The potential positions or sites for "breaks" or divisions of a double arch in the eventual formation of a single right or left arch are numbered 1 through 6. The origin of the carotid and subclavian arteries on the embryonic double aortic arch are indicated by "C" and "SC" respectively. The usual left aortic arch with normal brachiocephalic vessels "break" at position 1 and the usual left ductus inserts near position 4.

the survival of the patient—the so-called ductus-dependent lesions. These lesions will be discussed later.

HISTOLOGY—MECHANISM OF NORMAL CLOSURE

The walls of the ductus arteriosus are similar in overall thickness to the adjacent pulmonary artery and aorta, and do contain an intima, media, and adventitia. However, in contrast to the true arterial structures where the media of the arteries is made up primarily of circumferential elastic fibers, the medial layer of the ductus arteriosus is composed of smooth muscle—longitudinally orientated in the inner layers and in a predominantly circular arrangement in the outer layers.[9–11] These layers of smooth muscle contain concentrically arranged loose laminae of elastic tissue and a network of very tiny, thin-walled vessels.[12,13] The intimal layer of the ductus wall is irregularly thickened into so-called "mounds" and contains considerable mucoid material.[14,15]

In the fetus, there is an environment of relatively low oxygen tension and a high level of circulating prostaglandins, both of which act to keep the ductus open.[16,17] The high levels of prostaglandins in the fetus are a result of minimal fetal circulation through the lungs where the prostaglandins are metabolized and of high levels of prostaglandin production in the placenta.[18] With birth, the placenta is removed from the circulation and the lungs are expanded, thus removing the major source of prostaglandins while at the same time, activating the organ where most of the prostaglandins are metabolized. Along with this, the normal respirations of the infant markedly increase the oxygen tension in the blood. The combined effect of the increased oxygen and decreased prostaglandins results in a contraction of both the longitudinal and circular smooth muscles within the ductal walls.[17,19] This, in turn, shortens the ductus and thickens the walls effectively obliterating the lumen.[17] The typical shape of the ductus has fostered the idea that the obliteration process begins at the pulmonary end, however, there is no evidence for this obliteration occurring preferentially at any location along the ductus. The aortic end of the ductus is probably held open by the combination of higher aortic pressure and, in turn, more rigid adjacent aortic wall. The functional obliteration of the ductus usually occurs within the first 15 hours after delivery. Later on, after this functional obliteration, there is enfolding of the endothelium with disruption of the intimal layers and subintimal necrosis.[20] This leads to later fibrosis and scarring with a permanent seal of the ductus.

ETIOLOGY—CAUSE OF PATENCY

All of the factors responsible for continued patency of the ductus are not known and even those shown to have an effect on ductus patency are not totally understood.

Prematurity and Hypoxemia

Certainly significant prematurity or immaturity of the infant at the time of delivery contributes to abnormal patency of the ductus.[21] Whether this is due to a paucity of the normal constricting muscles within the ductus or whether it is due to an absence of the metabolites in the immature lungs that normally clear the prostaglandins is not fully understood.[22] Causes of persistent low oxygen tension in the blood such as significant respiratory problems in the neonate[8,21,23–25] or an environment with lower oxygen tension such as very high altitudes[26–28] will contribute to persistent patency of the ductus.

Infectious, Genetic, and Environmental Factors

A rubella infection in the first trimester of pregnancy, particularly in the first 4 weeks of gestation, has a very high association with persistent patency of the ductus arteriosus.[29,30] The incidence of a persistent ductus in those rubella-affected infants, including those in association with other cardiac defects, has been as high as 85%. As an isolated cardiac lesion, it appears to occur in 50% of infants definitely affected with rubella.[31,32]

There also appears to be a genetic factor. Siblings of patients with a patent ductus have as high as a 2 to 4% incidence of recurrence of the same lesion.[33,34] The mechanism of genetic inheritance has not yet been determined and, in fact, may well be an additional environmental rather than genetic factor. In the ongoing Texas Children's Hospital study group of ductus arteriosus, it appears that there is a nonracially related, socioeconomic relationship to patency of the ductus with a higher incidence of patients with a patent ductus from a lower socioeconomic status than patients with any other lesion.

Even when an etiologic agent is implicated in causing patent ductus arteriosus, the mechanism of this etiology has not been worked out. Most cases of patent ductus arteriosus still seem to be random.

ANATOMY

In the usual heart with a normal left aortic arch, the persistent ductus forms a communication from the pulmonary artery just at the junction of the main and left pulmonary arteries, to the descending aorta just distal to the origin of the left subclavian artery. In doing so it takes a slight cephalad-to-caudal course as it passes from the more anterior pulmonary artery to the posterior descending aorta (Fig. 61–2). The ductus arteriosus may persist in an infinite variety of shapes and sizes. The "classic" or typical persistent ductus has a conical shape with a large aortic end tapering toward the pulmonary artery with the narrowest area of the ductus close to the junction with the pulmonary artery (Fig. 61–2). The "cone" may be short and broad or long and narrow, and it can be symmetrical or totally asymmetrical (Fig. 61–3). The ductus also can have a long tubular, or fingerlike, shape that can be straight or very tortuous in its course (Fig. 61–3). The total length of the persistent ductus, regardless of its shape or diameter, may vary from millimeters to centimeters. The base of the aortic end of the ductus can vary in size from several millimeters to several centimeters, again independent of the shape or the length of the ductus. The so-called "window ductus," seen externally as having no length, is a very short, large ductus with a large aortic base (Fig. 61–3). The ductus may occur with a right aortic arch (Fig. 61–4); rarely two ducti appear in the same patient (Fig. 61–5).

In congenital cardiac defects with very severe pulmonary stenosis or pulmonary atresia (the so-called ductus-dependent lesions where there is little or no prograde flow possible through the pulmonary valve during fetal or neonatal life), the ductus tends to be smaller and more tortuous. It usually arises more cephalad on the aortic arch with its aortic origin positioned more toward the concave apex of the arch (see Fig. 61–6), presumably due to the fetal blood flow in these ductus being from the aorta to the pulmonary artery. These ductus have the same histologic anatomy and tendency to close after delivery of the infant as the more typical or usual ductus.

The variations in anatomy of the persistent ductus account for many of the differences in physiology and presentation of patients with persistent ductus arteriosus.

PHYSIOLOGY

In the normal fetal circulation the nonaerated and unexpanded lung beds receive only 5 to 8% of the blood entering the pulmonary artery with the fetal ductus arteriosus serving as the predominate route of circulation for the blood passing through the fetal right ventricle and main pulmonary artery.[35] In this capacity 55 to 60% of the systemic circulation to the fetus passes right to left through the ductus. As a result, the fetal ductus normally is a large structure equal in diameter to the main pulmonary artery and descending aorta. Normally with the first few breaths by the neonate, the lungs expand, instantaneously expanding the pulmonary vascular bed and beginning the lowering of the pulmonary vascular resistance. Along with this the ductus begins to constrict and there is an immediate shift in the flow of the right ventricular/pulmonary artery blood away from the ductus arteriosus and into the lungs. Normally the constriction of the ductus continues rapidly and functionally is completed by 10 to 18 hours after birth. Until the functional closure is completed and as soon as the pulmonary resistance is lower than systemic, there will be some left-to-right flow from the aorta, through the ductus and into the pulmonary arteries. Structural closure is usually completed by the fifteenth to twenty-first day of life. Only when the ductus remains patent after 3 months is it considered abnormal.[36]

With patency of the ductus and once the pulmonary vascular resistance has dropped below the systemic vascular resistance, blood will flow from the aorta into the pulmonary artery resulting in a net left-to-right shunt. In the presence of normal pulmonary resistance, the left-to-right flow through the ductus continues throughout systole and diastole. In the normal postnatal circulation the fully saturated aortic blood passes from the descending aorta through the ductus and mixes with the systemic venous blood from the right ventricle in the pulmonary artery. This combination of blood passes through the lungs, into the left atrium, into the left ventricle, and back into the aorta. This results in an increased volume load on the left atrium and left ventricle. The resultant increase in left ventricle stroke volume is proportionate to the size of the left-to-right shunt. Unless the volume load is massive and results in significant elevation of pulmonary artery pressure, there

Fig. 61–2. Typical patent ductus arteriosus. Posteroanterior (left) and lateral (right) aortograms with injection into the descending aorta just distal to the ductus. Typical catheter passage from the femoral vein, through the right heart into the pulmonary artery and through the ductus into the descending aorta.

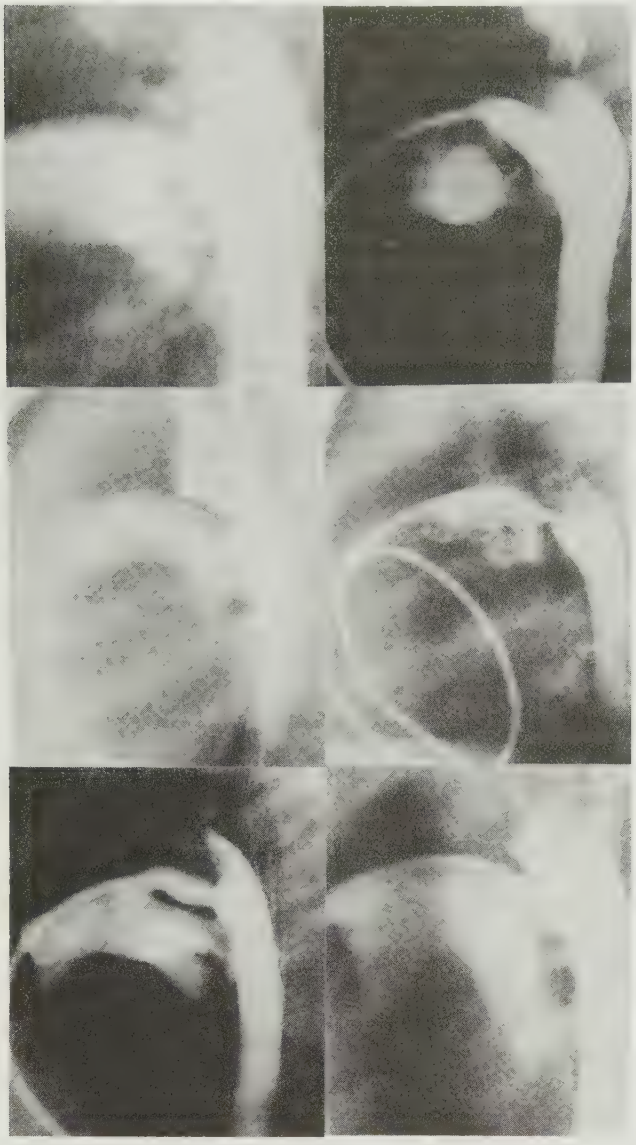

Fig. 61–3. Variations in the size and shape of the persistent ductus. Comparable lateral angiocardiograms with injection into the descending aorta. Short broad-based ductus (upper left); large, long conical ductus (upper right); small symmetrical conical ductus (middle left); small asymmetrical conical ductus (middle right); long tubular ductus (lower left); and a very short large "window" ductus.

is no added volume work and little or no pressure work on the right ventricle. As a result of the increased left-sided flow, there is distention and dilation of the left atrium and left ventricle. The left ventricle hypertrophies to adjust to the added work load.

With the increased left ventricle stroke volume and the central runoff from the aorta into the pulmonary artery, which continues throughout diastole, there is a resultant wide pulse pressure generated in the aorta. This increase in pulse pressure is proportionate to the volume of flow through the ductus.

Volume Changes

In the presence of a patent ductus arteriosus there is an absolute increase in the total circulating volume of the patient proportionate to the amount of left-to-right shunt. The net increase in volume is trapped or recirculating in the lungs while the circulating systemic volume remains normal or only slightly decreased. This results in pulmonary engorgement and decreased overall pulmonary compliance, again, proportionate to the amount of shunting. This pulmonary overcirculation causes most of the symptoms of a patent ductus. The reaction of the pulmonary vascular bed to the increased flow is totally unpredictable. Usually with a very large flow there will be some increase in the pulmonary vascular resistance, thus preventing massive overcirculation. However, there are individual patient variations in response to this increased pulmonary flow.

Nature of Left-to-Right Shunt

The amount of flow through the ductus varies with the size and shape of the ductus and with the differences between the systemic and pulmonary resistances.

Ductus Size

When the ductus remains widely patent, the only impediment to pulmonary flow from the aorta is the total pulmonary resistance. In the neonate with a large ductus arteriosus, the fetal pulmonary vascular resistance usually drops more slowly, allowing a more gradual but progressive increase in pulmonary flow. The increased pulmonary flow will continue to increase until the *total* pulmonary resistance increases and eventually reaches systemic levels as a result of both the reactivity of the pulmonary arterioles and the

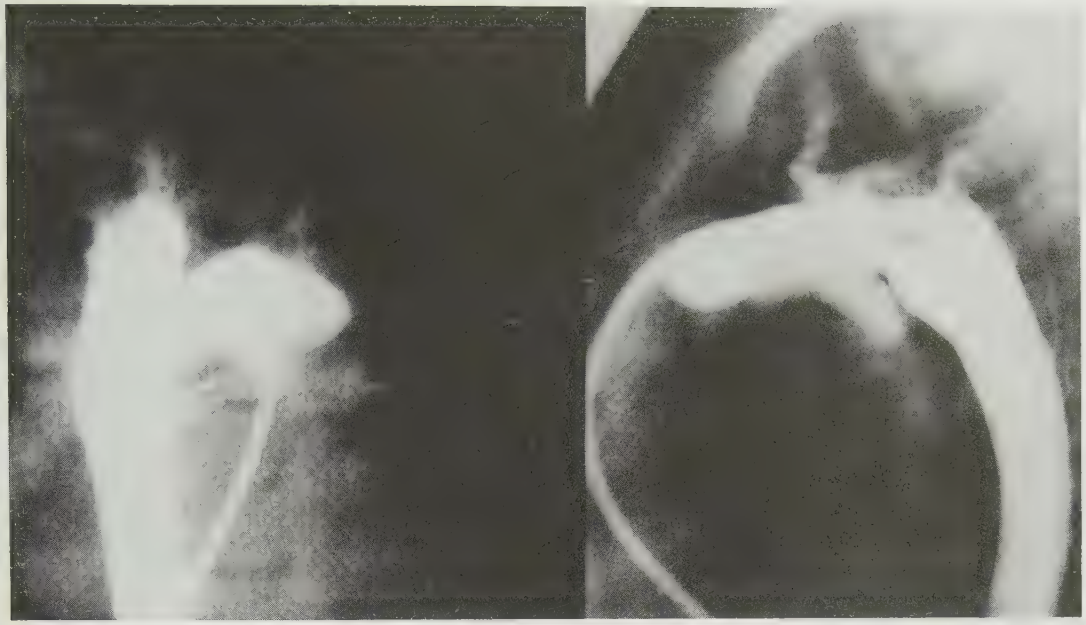

Fig. 61–4. Right ductus arteriosus. Posteroanterior (left) and lateral (right) descending aorta angiocardiogram shows ductus off right descending aorta. Catheter passage is from femoral vein through right heart, pulmonary artery, ductus into the descending aorta.

elevation of the left ventricular end-diastolic and left atrial pressures and/or the patient goes into florid pulmonary edema and heart failure.

The smaller the narrowest portion of the ductus, the less the flow through the ductus. In the absence of the other variables, the flow through the ductus and the net left-to-right shunt will be proportionate to the size of the narrowest area of the ductus.

Ductus Shape

The shape and, in turn, course of the ductus may vary the total flow and the velocity of flow through the ductus particularly in the case of the long and tortuous ductus. In this particular type of persistent ductus, the additional length of the ductus can add to the resistance to flow. Transient changes in shape and tortuosity of the ductus with slight changes in relative positions of adjacent mediastinal structures can instantaneously change flow through the ductus accounting for variations in clinical findings from minute to minute. This type of anatomy accounts for the "intermittent ductus." Marked alterations in the size and shape of the ductus can occur during cardiac catheter manipulations in the ductus even in patients well past the newborn period (Fig. 61–7).

Systemic Pressures

The higher the systemic pressure, the higher the driving pressure through the ductus and vice versa for lower systemic pressures. Thus abnormalities that increase systemic pressure will increase the ductal flow and increase any symptoms due to the ductus. This is particularly true of generalized systemic hypertension or localized upper extremity hypertension proximal to the aortic origin of the ductus as is the case in the usual coarctation of the aorta. On the other hand, other large intracardiac shunts or left ventricular outflow obstructive lesions that decrease systemic pressure, may decrease the magnitude of ductal shunting.

Pulmonary Resistance

The total pulmonary resistance is the major variable in the determination of the flow through the ductus. This is particularly so in the large, wide-open ductus that approaches the diameter of the

Fig. 61–5. Bilateral ductus arteriosus. Posteroanterior cineangiocardiogram of a catheter passage through a left ductus with injection into the left descending aorta (left frame). A large retroesophageal right subclavian artery fills from this injection. A lateral recirculation frame of the same injection (right frame) shows the catheter still through the left ductus with a right ductus filling an isolated right carotid artery and emptying into the stenotic right pulmonary artery.

Fig. 61–6. Large vertical ductus. A lateral aortogram in a patient with transposition of the great arteries and pulmonary atresia showing the origin of the ductus from the underside of the transverse arch.

adjacent aorta, but can be a significant variable in a ductus of any size. The total pulmonary resistance is a sum of the actual pulmonary vascular resistance plus the total outflow resistance from the pulmonary vascular bed. A high total pulmonary resistance, regardless of cause, can markedly decrease or even reverse flow through the ductus and will decrease the usual signs and symptoms of the persistent ductus. In the otherwise normal heart, the pulmonary resistance increase is usually in the pulmonary vasculature itself. Associated lesions such as mitral stenosis or various types of obstruction to pulmonary venous return can elevate the total pulmonary resistance to the point of stopping or even reversing ductal flow in the presence of normal pulmonary vascular resistance.

Reversed Ductus

A reversed ductus refers to the situation where there is right-to-left flow from the pulmonary artery to the aorta through the persistent ductus. This is a result of marked elevation of total pulmonary resistance plus or minus associated decreased resistance on the aortic side of the ductus. In the otherwise normal circulation, this will result in desaturated blood passing into the descending aorta from the pulmonary artery with resultant lower body (differential) cyanosis. This occurs most often with severe pulmonary vascular obstructive disease but also in the presence of left heart inflow obstructive lesions such as obstructed pulmonary venous connection, cor triatriatum, or mitral stenosis.

In the newborn with transposition of the great arteries and no other source of mixing, there will be bidirectional shunting of blood through the ductus. The unsaturated aortic blood will shunt from the aorta into the pulmonary circulation. However, with no other defect to allow mixing, or in this case, venting of the pulmonary bed, the lungs become "full" with resultant massive overcirculation and/or reactive increase in pulmonary resistance or both. The resultant total pulmonary resistance reaches systemic levels and a reversal of flow (pulmonary to aortic flow) results. Once the lungs are "full," this right-to-left and left-to-right flow occurs instantaneously and almost simultaneously within each cardiac cycle. In the rare combination of transposition of the great arteries, patent ductus, and coarctation of the aorta (pre- or juxtaductal), this will create the pathopneumonic situation of allowing desaturated blood to perfuse the upper body from the right ventricle and saturated blood from the left ventricle and pulmonary artery to perfuse the lower body. In these patients there will be bidirectional shunting at the ductus, however, the saturated blood of the right-to-left shunting will be directed predominately to the lower half of the body by the coarctation.

CLINICAL FEATURES OF THE PERSISTENT PATENT DUCTUS

Medical History

There is no characteristic clinical history for the patient with a persistent patent ductus. The presenting symptoms depend primarily on the anatomic and physiologic features of the ductus in each individual. The majority of patients will present with a heart murmur heard on routine physical examination and deny any symptoms related to the heart. A few patients will present with signs of decreased exercise tolerance or pulmonary congestion in conjunction with a murmur. These presentations can occur at any age. At the other extreme there is the infant with the large persistent ductus who presents at 3 to 6 weeks of age with tachypnea, diaphoresis, inability to feed, and either no weight gain or even weight loss.

Physical Examination

There are typical or "classical" physical findings of the persistent patent ductus arteriosus that are almost diagnostic of the ductus. The typical patient usually appears well with normal respirations and heart rate. The blood pressure usually shows a widened pulse pressure. On inspection there usually will be prominent or even visible suprasternal and carotid arterial pulsations.

The hallmark of the persistent patent ductus is the continuous or "machinery" murmur.[37] This murmur begins shortly after the first heart sound, crescendos to a maximum at about the second sound, and decrescendos throughout diastole. In intensity it is usually grade three, four, or five over six and maximum in the first and second left intercostal spaces at the left sternal border. It may be localized to that area or radiate widely to the suprasternal notch as well as down the left sternal border and out over both lung fields. As the examiner tracks down the sternum, the diastolic component becomes less apparent and the murmur sound only systolic. This is particularly true in the small infant.

The continuous murmur is usually associated with several other characteristic clinical signs. The grade four and louder murmurs

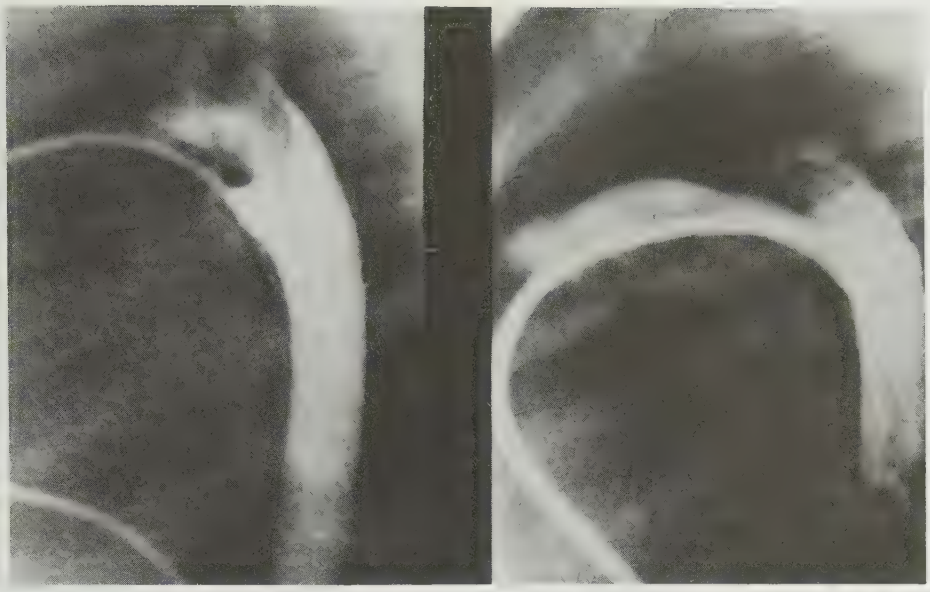

Fig. 61–7. Variable ductus. Lateral angiocardiograms obtained during the same catheterization in a 16-month-old infant. A 6 French catheter virtually occludes a "typical" small conical ductus (left frame). An 8 French sheath passing through the same ductus (right frame) allows free passage of contrast through a now large long tubular ductus approximately 10 minutes after the first angiocardiogram.

will be associated with a continuous thrill with the same localization as the murmur. There is often a left ventricular lift or heave to palpation. The second heart sound is increased in intensity, widely but variably split, and has a characteristic "slapping sail" sound. In the patients with a larger ductal flow there will be a diastolic flow rumble at the apex. The peripheral pulses will be prominent and bounding and with the larger ductus in the thinner patients, even visible in the axillary and femoral areas.

All of these clinical features may be altered in each individual patient according to the differences in the size, anatomy, and physiology of the ductus but usually the clinical findings are characteristic enough to make the diagnosis.

Variables

The variables in the ductus that alter the clinical findings are, of course, all interacting and usually cannot be separated; however, they do have some distinguishing features when they occur as isolated variations.

Ductus Size and Shape

The typical persistent ductus has a medium- to high-pitched, rough, continuous murmur that peaks at the second sound and extends throughout diastole. The smaller the ductus, usually the higher the pitch and the more localized is the continuous murmur. At the same time, the other clinical signs are less prominent with these very small ductus. The murmur in the small tortuous ductus actually may change its qualities from minute to minute with changes in body position, even to the point of disappearing completely. The larger ductus, on the other hand, usually has a louder, lower frequency, and rougher sounding murmur that ends before the end of diastole. Unless there is associated increased pulmonary vascular resistance, the larger the ductus is, the more prominent are the associated signs.

Pulmonary Pressures (Resistance)

The higher the pulmonary resistance, the less overall flow through the ductus. In particular, the diastolic run-off is initially decreased and, in turn, the clinical signs are diminished proportionately. The alterations in clinical findings due to changes in pulmonary resistance will usually overshadow the effect of all of the other variables on the clinical features of the ductus. Elevated pulmonary resistance will decrease or eliminate first the diastolic component of the murmur and if the pulmonary resistance is high enough, even the systolic component of the murmur. The pulse pressure will decrease and with the elevation of right ventricular pressure and prolongation of right ventricular ejection time, the second sound will become louder and single.

Elevation of the pulmonary resistance above systemic resistance produces right-to-left shunting at the ductus with resultant blueness of only, or predominantly, the lower half of the body. This classical differential cyanosis is pathognomonic of a persistent ductus with right-to-left shunting.

Patient Age

The age of the patient alone does not necessarily alter the clinical findings of the ductus; however, at the extremes there are some common exceptions.

Premature and Newborn. In the usual normal newborn there is a gradual enough drop in pulmonary resistance so that abnormal flow into the pulmonary arteries is usually not detectable by auscultation for several weeks or more. With an extremely large ductus, particularly in the small newborn, the abnormal flow may be present only in systole so the infant may have only a benign-sounding systolic murmur and even one localized more down the left sternal border. However, the infant will have very bounding and often even visible peripheral pulses.

Older Adult. As a result of changes in pulmonary compliance with the changes of aging, emphysema, and at least some degree of elevated pulmonary vascular resistance, the diastolic run-off into the pulmonary circulation is usually lessened and, as a result, the classical murmur of the ductus may be altered so that only the systolic component persists. On the other hand, as the systemic vasculature generally becomes more atherosclerotic, the blood pressure as well as the pulse pressure usually increases, giving the impression of an even greater run-off.

Roentgenography

The x-ray findings will vary with the size of the ductus and the amount of left-to-right shunting. With the very small, yet noisy patent ductus, often there is a perfectly normal roentgenogram. The earliest x-ray finding is usually a prominent main pulmonary artery segment blending with a prominent aortic knob along the upper left heart border. With a moderate-sized persistent ductus, the heart shadow will be slightly enlarged with a downward displacement of the apex (left ventricular configuration) and the pulmonary vascular markings will be increased. There may be a noticeable double density of an enlarged left atrium. The larger the shunting through the ductus, the more prominent these x-ray features become.

Electrocardiography

The ECG in the small persistent ductus is usually normal by strict criteria. The ductus with a moderate or larger left-to-right shunt will show left ventricular hypertrophy and occasionally left atrial enlargement.

Echo and Doppler Cardiography

The aortic end of the ductus can be reliably visualized and often traced to the pulmonary artery by meticulously performed two-dimensional echocardiography procedures performed with that goal in mind. On the other hand, the marked variation in the size, shape, and course of the persistent ductus make it difficult to consistently and reliably visualize it in its entirety and, in turn, to describe accurately its shape or measure the diameter of its narrowest segment.

By careful exploration of the entire area around the usual site of entry of a ductus into the pulmonary artery, the continuous-wave Doppler can pick up infinitesimally small jets of abnormal flow in the pulmonary artery even in the face of otherwise large volume pulmonary flow. By this technique even the smallest, nonaudible persistent ductus can be detected, but again, usually only with meticulous technique and when the persistent patency of the ductus is specifically being looked for. With color-flow Doppler, the actual jet of abnormal flow through the ductus can be visualized and more information obtained about the size and shape of the ductus (Fig. 61–8).

The greatest value of echocardiograms/Doppler cardiograms in the diagnosis of the persistent ductus is to exclude other significant intracardiac lesions when there are typical signs of the ductus or in the converse situation, to suggest or identify the presence of a ductus in the presence of other major known intracardiac defects or when there are complications of the ductus that alter the typical or presenting signs.

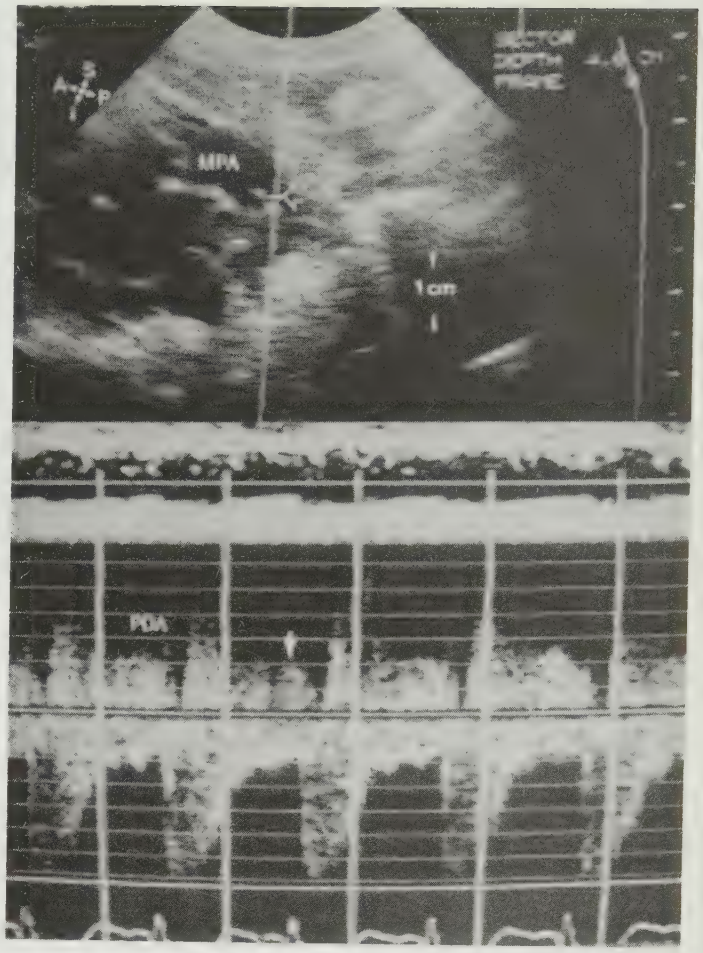

Fig. 61–8. Echocardiogram from a patient with patent ductus arteriosus, obtained from the suprasternal approach. Upper panel: the Doppler sample volume is in the ductus arteriosus (open arrow). A = anterior; S = superior; P = posterior; I = inferior. Lower panel: the Doppler tracing indicates the presence of continuous turbulent flow through the ductus into the pulmonary artery. MPA = main pulmonary artery, PDA = patent ductus arteriosus.

COMPLICATIONS OF PATENT DUCTUS

Patent ductus usually presents as an incidental finding with typical clinical findings unless there are complicating features. Most of the exceptions to this typical presentation occur in either the small infant or the older adult. The actual complications of the persistent ductus or the attempts to avoid these complications provide the major indications for surgical or other corrective procedures for the persistent ductus arteriosus.

Congestive Heart Failure

Congestive heart failure usually occurs in the very young infant with the large patent ductus or in the elderly with a large ductus after the effects of the chronic volume workload have taken their toll on the left atrium and left ventricle. In the elderly, the heart failure is often associated with atrial flutter or fibrillation. The failure is initially "left heart" with pulmonary congestion. Because of the large volume load and increased pressure in the pulmonary circulation, the right heart eventually must perform some of the extra work and, in the very large ductus, will also show signs of failure with hepatomegaly and even peripheral edema in the elderly or young infant. In the younger patients and many of the elderly, the congestive failure is reversible with the correction of the patent ductus.

Endocarditis

Bacterial endocarditis complicating a patent ductus is now an extremely rare occurrence.[38] Prior to the days of surgical repair and of routinely used antibiotics, endocarditis was one of the leading causes of death in adults with patent ductus arteriosus.[39,40] Both modalities of therapy became available at about the same time and with them a very marked decrease in this complication. Currently, even with antibiotic prophylaxis, an occasional case of

endocarditis will still be seen. This fact, plus the reported earlier high incidence and the ongoing need for prophylactic antibiotics, makes the prevention of endocarditis the major indication for correction of even the small ductus. The uncorrected patent ductus should be treated with the same vigorous antibiotic prophylaxis for the prevention of endocarditis as any other structural congenital heart lesion until it is corrected and for at least a year after the ductus has been completely corrected.

In the event that endocarditis should occur, most of the vegetations seem to accumulate at the pulmonary end of the ductus and shower emboli to the lungs, thus simulating a pneumonic or other pulmonary process. When endocarditis does occur on the patent ductus, it is recommended that it should be treated with a full course of the appropriate antibiotics determined from blood cultures before considering any surgical intervention. Surgical correction, in fact, should not be considered until several months after the completion of successful therapy and the tissues have had time to completely heal.

Aneurysm of Ductus

This extremely rare complication of the patent ductus usually occurs in the very young infant,[41] the very elderly patient,[42] or following surgery for the ductus[43,44] or endocarditis of the ductus. Spontaneously occurring aneurysms usually present as mediastinal masses with symptoms arising from the compression of adjacent nerves or pulmonary structures.[45] The diagnosis and exact details of aneurysms are best established by a quality angiocardiogram. When diagnosed, and when not due to an ongoing infection, the aneurysm should be removed surgically utilizing cardiopulmonary bypass and/or hypothermia with circulatory arrest. In the case of an infected aneurysm, the infection first should be treated completely unless there is unequivocal evidence for progression or expansion of the aneurysm in spite of the antibiotic therapy.

Pulmonary Vascular Disease

Most cases of pulmonary vascular disease associated with a patent ductus represent a concurrent condition present since birth and are usually not a result of the ductus. However, this is not always or at least not completely the case.[46,47] There are definitely documented cases of isolated patent ductus in adults with classical clinical signs of a ductus with a large left-to-right shunt and less than systemic pulmonary pressures and resistance that progresses on into unequivocal high pulmonary resistance and right-to-left shunting at the ductus. These cases are extremely rare; however, the difference between these patients and the majority that do not do this is not known, thus this potential complication represents another indication for the correction of all patent ductus.

DEFINITIVE DIAGNOSIS BY CARDIAC CATHETERIZATION

Catheter Passage

The usual patent ductus arteriosus can be diagnosed from the physical examination, x-ray and electrocardiogram studies, and when in doubt, usually confirmed with a carefully performed echo/Doppler evaluation. When there are atypical features, and particularly when precise echocardiographic studies by skilled echocardiographers are not available, then the definitive diagnosis must be by cardiac catheterization. With most cases of patent ductus arteriosus, in the performance of a right heart catheterization, as the catheter is manipulated from the right ventricle into the pulmonary artery, the catheter will selectively pass from the pulmonary through the ductus into the descending aorta. The catheter characteristically passes slightly laterally as the tip moves cephalad in the body and then courses slightly medially as the tip passes through the ductus and into the descending aorta and toward the patient's feet. This is not always the course of the catheter nor is it the only course that it may take through the ductus, so the catheter course alone should not be utilized to confirm or rule out the presence of a ductus. The passage of a catheter through a ventricular septal defect and around the arch or even through an aortic pulmonary window and subsequently around the arch, can be very similar. If the catheter passage through the ductus is accomplished, to confirm the presence of a ductus, it must be accompanied by an angiocardiogram.

Oxygen/Pressure Data

During the right heart catheterization there will be an increase in the measured oxygen saturation or content in the main pulmonary artery. Some increase in oxygen values continues out into both the right and left pulmonary arteries. In the usual ductus, the highest saturation is obtained in the main pulmonary artery adjacent to the orifice of the ductus with slightly decreased saturations in the branch pulmonary arteries. The amount of net increase in saturation will be dependent upon the size of the left-to right shunting and may be utilized to calculate the exact shunt. The average saturation from the distal pulmonary arteries should be used for the calculations rather than the saturation from the main pulmonary artery. Some pulmonary valve insufficiency is encountered with many ductus cases, particularly the large ones. This will result in an increase in oxygen saturation in the high right ventricular outflow tract as well as in the pulmonary arteries, and from the oxygen data alone, may cause confusion in the diagnoses with a ventricular septal defect. With the typical ductus, the pressures in the pulmonary artery are usually normal or very slightly elevated. With the large ductus, the pressures will be elevated in the right ventricle and pulmonary arteries, but rarely to, or near to, the systemic levels. When, with a patent ductus arteriosus, very high pressures at or near systemic levels do occur in the pulmonary artery, one must be suspicious of associated high total pulmonary resistance either on the basis of pulmonary vascular disease, pulmonary venous obstructive, or left heart inflow obstructive lesions.

Selective Angiography

The most definitive tool for the diagnosis and precise definition of the size and shape of a ductus is by means of a selective angiocardiogram. The preferred location for the injection of the contrast is into the descending aorta just distal to the aortic end of the suspected ductus. An injection of 1 ml of contrast per kilogram of patient body weight delivered within one or one and one-half heart beats in this location will clearly demonstrate the exact anatomy of the ductus (see Fig. 61–2). By injection in this location and with the predominate flow into the ductus occurring during diastole, the contrast will flow retrograde back into the mouth of the ductus and yet will not be diluted significantly by flow into the vessels of the head and neck, as is the case with

more proximal, particularly ascending aortal injections. The easiest and quickest technique for the performance of this angiocardiogram is to pass an angiocardiographic catheter prograde through the right heart and through the ductus into this position. The same location may be achieved be a retrograde catheterization. The best technique of filming is on cineangiocardiograms at a minimum of 30 and preferably 60 frames per second. The best view for the usual ductus is a straight lateral projection. Occasionally, a long tortuous ductus will take a peculiar course that will be better elongated by some angulation determined from the lateral view.

DIFFERENTIAL DIAGNOSIS

The classical persistent ductus arteriosus should be diagnosed by the skilled pediatric cardiologist from the typical physical examination, roentgenograms, and ECG. Many other lesions can produce a continuous murmur, however, when meticulous attention is given to the precise characteristics of the murmur plus the basic laboratory tests, the diagnosis of the ductus should be established. Or, on the other hand, some other lesion immediately should be suggested. Difficulty in the differential diagnoses of the persistent patent ductus arteriosus should only arise with the atypical or complicated patent ductus. Most of the lesions that can mimic or be confused with the patent ductus are included in the list of the differential diagnosis.

Ventricular Septal Defect in Infancy

The large persistent ductus in the young infant with congestive heart failure may sound more like a ventricular septal defect with only a long pansystolic murmur being easily audible. With the patent ductus, by very careful auscultation, some spillover of the murmur into diastole will be audible and the loud slapping second sound will be present. Unless the heart failure is profound, the peripheral pulses with the ductus will be bounding and should alert one to consider a patent ductus and pursue this with an echocardiogram and/or catheterization.

Aortic Pulmonary Window

The lesion that can mimic the patent ductus most closely and the one that is the most difficult to differentiate clinically is the rare aortic pulmonary window, also known as an aorticopulmonary fenestration. With this defect there is incomplete division of the embryonic common truncus resulting in a communication between the ascending aorta and the main pulmonary artery yet the development of two semilunar valves. The net physiologic effect can be exactly the same as the persistent ductus and, like the ductus, depends on the same variables of size of the defect and relative pulmonary and systemic resistances. The aortic pulmonary window usually is a very large defect and, as a consequence, results in a very large pulmonary flow. Since the communication with the pulmonary artery is proximal to all of the branches of the aorta and is so large, the net effect is that most of the left ventricular output is ejected almost directly into the pulmonary artery, with the "left over" flow continuing on to the systemic circulation. The result is that there actually is a decreased flow to the body so that the pulses may not feel full and the pulse pressure may not be increased. The murmur usually is localized more along the mid left sternal border. It is predominantly systolic with occasionally some slight spillover into diastole. The very rare small aortic pulmonary window does have a continuous murmur. The x-ray and ECG findings may be similar to the ductus. When considered and specifically looked for, the echocardiogram should visualize the window. The Doppler, however, will pick up abnormal continuous flow in the pulmonary artery similar to the ductus.

The confusion in diagnosis may persist during cardiac catheterization when an increase in oxygen saturation occurs in the main pulmonary artery. Although the right heart catheter, in an aortic pulmonary window, will pass from the main pulmonary artery into the *ascending* aorta and usually from there into a carotid vessel, it can pass from the ascending aorta around the arch and into the descending aorta giving a similar-appearing course to the ductus passage. Only a high-quality aortic angiocardiogram can absolutely separate the two lesions. Contrast injected in the aortic root often will spill so rapidly through the defect and into the pulmonary circuit that the details of the defect will be obscured. With an isolated aortic pulmonary window the descending aorta in the area of the ductus will appear intact with an injection into the descending aorta just distal to the usual entrance of the ductus. Contrast passing into the pulmonary artery first will pass retrograde around the arch with some filling of all of the brachiocephalic vessels. With the ductus, this same injection should directly and clearly visualize the patent ductus and fill the pulmonary arteries without significant visualization of the brachiocephalic vessels or the aortic root.

Because of its clinical similarities, but much different implications in terms of management, the aortic pulmonary window must always be considered and definitively ruled out when a patent ductus is suspected.

Venous Hum

The most often confused clinical entity with the patent ductus by the inexperienced observer is the innocent venous hum. This "continuous murmur" is generated by the normal high velocity venous flow in the superior vena cava of a child or patient with high cardiac output. The venous hum most frequently is localized in the first and second *right* intercostal spaces but can be heard on both sides. It has a more superficial sound, diastolic accentuation, marked change in quality with patient position, and can be obliterated by placing the patient supine and/or by gentle compression over the right or both jugular veins. All laboratory studies will be normal.

Truncus Arteriosus

The truncus arteriosus may occasionally be confused with a patent ductus because of the bounding or collapsing pulses and a murmur that may spill over from systole into diastole. The usual truncus arteriosus will present in early infancy before one month of age with profound heart failure. These infants will have a pansystolic or decrescendo systolic murmur that may spill into diastole and radiate over the lung fields. The patient will have collapsing pulses. Characteristically, they also have a very prominent ejection click and usually a single second heart sound on auscultation. The chest x-ray will show massive cardiomegaly and increased vascular markings. The electrocardiogram, more often, will show right or biventricular hypertrophy, but may show only left ventricular hypertrophy similar to the ductus. These infants will have varying degrees of desaturation that may or may not be clinically detectable, but should be demonstrated by ear oximetry

or cutaneous oximetry. The echocardiogram should clearly demonstrate the truncus arteriosus, which can be confirmed by catheterization and a quality ascending aorta (truncus) angiocardiogram. This will demonstrate the single semilunar valve and the aortopulmonary communication.

The rare infant with truncus arteriosus and some degree of right or left pulmonary stenosis may have a more characteristic continuous murmur. These infants are usually in less heart failure, but are more desaturated. The remainder of the differential is the same.

Absent Pulmonary Valve Syndrome

Infants with this combination of lesions usually present early in life with severe respiratory difficulty. On examination, they will have a characteristic to-and-fro separated systolic and diastolic murmur rather than the typical continuous or machinery murmur of the ductus arteriosus. This to-and-fro murmur is located along the left sternal border. They may or may not have an ejection click in association with this murmur. The electrocardiogram shows right axis deviation and right ventricular hypertrophy. The chest x-ray usually will show a small or only slightly enlarged heart and frequently severe hyperexpansion of the lungs. This hyperexpansion often is asymmetrical with one lung being markedly overexpanded with resultant compression or atelectasis of the opposite lung. The echocardiogram may be difficult in these patients because of the hyperexpansion of the lung. When obtainable, it should establish the diagnoses of at least ventricular septal defect and annular pulmonary stenosis and should find no evidence of a ductus.

A rare patient with this lesion will present at an older age with predominant to-and-fro heart murmur. The electrocardiogram, again, will show right axis deviation and right ventricular hypertrophy and the roentgenogram will show a slightly enlarged heart but with very prominent right and left hilar pulmonary vessels.

Cardiac catheterization will demonstrate hemodynamic findings similar to a "pink tetralogy" with less severe pulmonic stenosis. A right ventricular angiocardiogram will clearly show the annular stenosis, the ventricular septal defect, and the markedly dilated pulmonary arteries.

Ventricular Septal Defect with Aortic Regurgitation

Patients with ventricular septal defect and aortic regurgitation usually present with this combination of defects at a later age. If the patient has been previously known or evaluated, he or she may well have had a ventricular septal defect previously documented by echocardiogram and/or catheterization. Very often the ventricular septal defect is considered to be small. The patient returns with the new finding of a long diastolic murmur in addition to his earlier recognized pansystolic murmur. The examination at this time may reveal a systolic thrill along the sternal border and a pansystolic plateau-shaped murmur along the entire left sternal border, ending at the second sound. The second sound is increased and followed by a high-pitched, long decrescendo diastolic murmur that radiates down the left sternal border.[48] The frequency, length, and intensity of this diastolic murmur will depend on the degree of aortic regurgitation. As opposed to the persistent ductus arteriosus where the murmur crescendos up to the second sound and spills over into diastole, the murmur of ventricular septal defect with aortic regurgitation appears as two separate distinct murmurs with different frequencies and with almost a pause appearing between the systolic and diastolic components. There may be a diastolic rumble at the apex from either the increased flow of the ventricular septal defect and/or an Austin Flint type rumble from the aortic regurgitation. The peripheral pulses will be increased according to the severity of the aortic regurgitation as will the pulse pressure on blood pressure determination. On electrocardiogram, the patient may have biventricular hypertrophy or with long-standing aortic regurgitation, left ventricular hypertrophy. Roentgenography will show cardiomegaly proportionate to the earlier degree of shunting and to the degree of aortic regurgitation. The diagnosis should be documented by a high-quality echocardiogram specifically looking for the location of the ventricular defect and the degree of aortic regurgitation.

Ruptured Sinus of Valsalva and Fistula

The ruptured sinus of Valsalva is usually acquired later in life,[49] usually with no previous history of heart disease. It may occur spontaneously, following chest wall trauma or an episode of bacterial endocarditis. The onset is usually sudden or acute with the appearance of a loud, relatively superficial-sounding continuous murmur and often the associated appearance of significant congestive heart failure. On auscultation, the murmur is usually superficial sounding and more often localized over the lower sternum, particularly to the right of the midline.[49] The electrocardiogram may be normal or show early left ventricular strain. The chest x-ray, with a hemodynamically significant ruptured sinus and fistula, will show cardiomegaly and increased pulmonary flow. The echocardiogram may be able to document this lesion, but the definitive diagnosis should be by cardiac catheterization with an aortic root angiocardiogram.

Systemic Arteriovenous Fistula

Systemic arteriovenous fistula within the thorax can occur between any arterial and venous structures. Examples that may be confused with a patent ductus are communications between subclavian artery and innominate vein, between the internal mammary artery and vein, between bronchial arteries and branches of the systemic azygous system, or communications between other chest wall vessels. These communications do result in a continuous murmur; however, the murmur usually is localized to the area of the abnormal communication and appears more superficial and actually extracardiac in its location. The localization of the murmur depends on the point of communication between the vein and the artery. The systemic signs and symptoms depend on the size of the communication and the net shunt at that level. The differential from a patent ductus is usually obvious by the distant or separate location of the fistulous murmur. It will require a catheterization with an angiocardiogram to specifically localize the area of communication.

A variation in the usual systemic arteriovenous fistulae is the systemic to pulmonary artery fistula not associated with other significant congenital heart defects. The net hemodynamic effect is similar to a patent ductus. With the "venous end" of the fistulous vessel being the pulmonary artery or its branches, the clinical differentiation from a persistent ductus may be impossible prior to an angiocardiogram (Fig. 61–9).

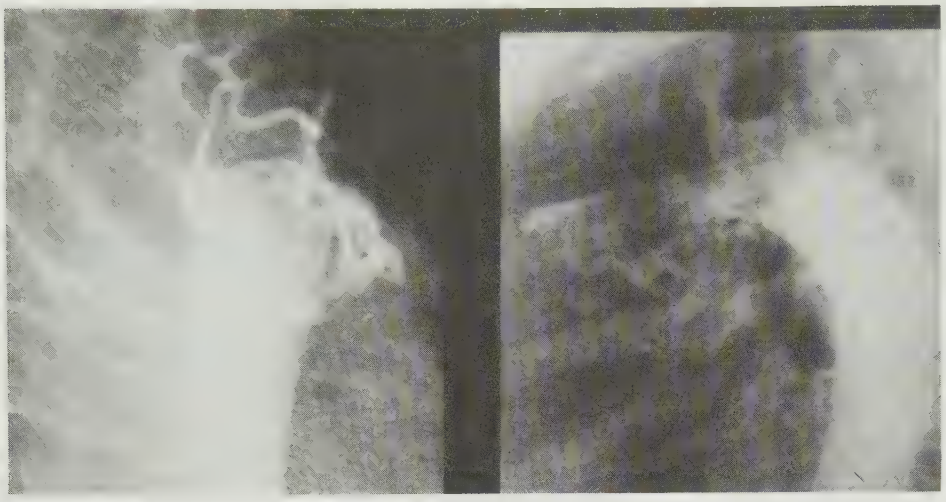

Fig. 61–9. Posteroanterior and lateral descending aorta aortograms showing a plexiform network of arteriopulmonary fistulous vessels actually encircling and eventually emptying into the main pulmonary artery. The clinical presentation in this patient was a high-pitched continuous murmur indistinguishable in location and quality from a small patent ductus.

Coronary Artery Fistula

Coronary artery fistulae produce a continuous murmur that is characteristically localized over the area of fistulous communication into the heart. In most cases, these are over the lower precordium and localized to the far right or left precordium away from the characteristic ductal area. The murmurs in these cases typically are continuous, but like the other systemic arteriovenous fistulae appear superficial on auscultation and usually are localized away from the site of the typical ductus murmur. The diagnosis usually is suspected from auscultation; however, it requires a cardiac catheterization and angiocardiograms to identify the area of fistulous communication specifically.

Pulmonary Arteriovenous Fistula

Pulmonary arteriovenous fistulae are usually multiple and often associated with multiple telangiectasia and at least mild cyanosis. The pulmonary atriovenous fistulae that do produce continuous murmurs over the lung field are usually larger and produce more marked cyanosis. The diagnosis is supported by the distribution of the murmurs, the cyanosis, and the right ventricular hypertrophy on electrocardiogram. The roentgenogram may show discrete densities throughout the lung fields. Confirmation of the diagnosis requires cardiac catheterization and pulmonary arteriograms.

Branch Pulmonary Artery Stenosis

Peripheral branch pulmonary artery stenosis may produce a continuous murmur. The murmur usually is later in onset continuing past the second sound into diastole. It is maximal over the peripheral lung fields, although it may be maximal over the left anterior chest in a similar location to the ductus arteriosus. Aside from the usual wide distribution of the murmur over the lung fields, these patients will have right ventricular hypertrophy on the electrocardiogram. The peripheral branch stenoses are usually difficult to visualize and quantitate by echocardiogram and will require cardiac catheterization with selective pulmonary angiography to delineate the defects exactly.

Systemic Collaterals with Pulmonary Atresia and Ventricular Septal Defect

The large systemic collaterals associated with pulmonary atresia type lesions do create loud continuous murmurs. These murmurs are usually localized in the vicinity of the lobes or lobules of the lungs supplied by the laterals, and thus, in general, are away from the area of the typical ductus murmur. Although most of these patients will be obviously cyanotic, those with large collaterals may present with congestive heart failure and nonclinically detectable cyanosis. Laboratory investigations, however, quickly separate these lesions. The majority of these patients have right ventricular hypertrophy, or at the least, biventricular hypertrophy on their electrocardiogram. They will have cardiomegaly, but characteristically with a concavity or deficiency in the area of the right ventricular outflow tract. These defects are thus easy to differentiate from a patent ductus on clinical grounds; however, the exact definition of the details of the collateral vessels will require an extensive and detailed catheterization with selective angiocardiograms.

DUCTUS ARTERIOSUS IN ASSOCIATION WITH ADDITIONAL, MORE COMPLEX LESIONS

The association of the persistent ductus with other defects has been alluded to earlier in this chapter. As a normally occurring structure in all infants and as a defect that is encouraged by the environmental circumstances found in association with many severe congenital heart defects, it is not surprising that it occurs in association with a high percentage of other congenital cardiac defects. The patent ductus may exist as a coincidental lesion possibly only complicating the other major lesion at the time of open heart surgery for the major lesion. More often, the shunting from the persistent ductus will aggravate the hemodynamics of the other lesion. At the other extreme, because of the complex anatomic variations and the abnormal hemodynamics of the major lesions, the survival of the patient may actually be dependent upon the ductus.

Aggravating Other Lesions

The major lesions aggravated by the persistent ductus are the other left-to-right shunt lesions where the ductus contributes more pulmonary flow to an already flooded pulmonary bed. The actual recognition of the combined defects is difficult enough, but often an even greater problem is the determination of which lesion is the most significant hemodynamically and then the choice of the

proper sequence of therapy. The primary example of this is the ductus coexisting with a ventricular septal defect. At catheterization, the systolic pressures in the right ventricle, pulmonary artery, left ventricle, and aorta are frequently equal and of no discriminatory value. Oxygen data will often reveal such a large increase in saturation at the ventricular level that even a large ductus will not show a significant further increase in saturation. For these combined shunt lesions, the best information comes from the visualization of the relative size of and flow through the defects by very high-quality cineangiocardiograms with injections immediately adjacent to the origin of each shunt lesion (i.e., in the left ventricle to visualize the ventricular septal defect or in the descending aorta to visualize the ductus). Other combined shunt lesions in this category include a ductus in combination with an atrial septal defect, an atrioventricular canal, or a combination of several of these.

Other lesions that a patent ductus will aggravate hemodynamically and symptomatically are the left heart inflow and/or left heart outflow obstructive lesions. The relative significance of the separate lesions can usually be determined from carefully acquired hemodynamics.

In the case of major intracardiac lesions significantly aggravated by the coexisting ductus, separate early correction of the more easily approached patent ductus usually is recommended. By this sequence, one can improve heart failure and gain time and growth before undertaking the repair of the major intracardiac lesion. In patients large enough for the use of the ductus occluding device, this approach is even more desirable.

Ductus-Dependent Lesions

At the other extreme of cardiac defects associated with a persistent ductus are those lesions where the infant's survival is dependent upon the continued patency of the ductus or a similar structure. These lesions must be accurately and expeditiously identified so that nothing is done to compromise the patency of the ductus. In the newborn period, efforts are made to keep the ductus open using pharmacologic agents such as prostaglandins until a surgical communication can be created to replace the function of the ductus.[50] There are opposite categories of patients that fall into the category of ductus-dependent lesions.

Cyanotic patients with severe or total ventricular to pulmonary artery outflow obstruction, with or without pulmonary artery hypoplasia, make up the first group. In these patients the total *pulmonary* flow is dependent upon the ductus.[51] These patients include those with any defects associated with pulmonary atresia (both with intact septum and with a ventricular septal defect) and many cases of tricuspid atresia where the interventricular communication is restrictive or there is additional right ventricular outflow obstruction. Patients with transposition of the great arteries or ventricular inversion who also have critical obstruction of the outflow to the pulmonary artery from the left ventricle, may fall into this category of ductus dependency.[51]

The second major category of totally ductus-dependent lesions are the patients with critical obstruction to *systemic* ventricular outflow or to part of systemic circulation and where the *systemic* flow or a significant part of the systemic flow is dependent upon the ductus. The most extreme degree of this type of lesion is the patient with aortic valve atresia and/or mitral valve atresia with a hypoplastic left ventricle where all systemic blood flow is from the right ventricle via the ductus arteriosus. With closure of the ductus, systemic flow is entirely stopped.

A second group of patients with systemic flow dependent on the ductus are those with only part of systemic flow obstructed and dependent upon the ductus—those patients with coarctation of the aorta or interruption of the aortic arch.[51,52] In most of these patients, when the ductus closes, there is decrease or cessation of blood flow to the lower half of the body. In the interrupted aortic arch and at least partially in the coarctation, this is due to the actual cessation of flow from the right ventricle to the descending aorta. In the coarctation of the aorta there is a second important role played by the ductus. The outpouching of the open aortic end of the ductus serves as a detour channel around the adjacent obstruction of the aorta caused by the posterior coarctation "shelf." This mechanism has been demonstrated both hemodynamically and angiographically and is the mechanism of the beneficial effect of prostaglandins in treating newborn patients with coarctation of the aorta and heart failure.

MANAGEMENT AND THERAPY OF DUCTUS

Medical Management

The usual patient with patent ductus is asymptomatic, presents with an incidental murmur, and requires no acute medical management. Those infants who do present with signs of congestive heart failure usually will respond to the usual decongestive regime including digoxin and diuretic therapy and on such a regime can be managed until they are several years old and good candidates for nonsurgical closure. When medical management fails in infancy, these patients are referred to surgery.

Surgical Management

In addition to these small infants, the policy at Texas Children's Hospital in the past was to refer any patient for surgical correction who had congestive heart failure that was refractory or poorly responsive to medical management regardless of the age or weight of the patient. Similarly in the past, most patients with asymptomatic patent ductus were referred for elective surgical ligation and division after they reached 4 or 5 years of age. By that age, the patients were beyond the age range where intubation created extra problems, they were slightly more understanding, and they reacted more favorably psychologically with primarily only "topical" fears. Some institutions recommend surgical repair of a patent ductus for any evidence of heart failure or electively at any time after 12 months of age, while others electively close the ductus whenever it is discovered, as it will need to be done sometime and is an easy operation.

Repair of the ductus does not require the use of cardiopulmonary bypass. The surgical approach to the typical persistent ductus ideally is through a left posterolateral thoracotomy incision in the third intercostal space in infancy or fourth left intercostal space in patients past infancy. Once the ductus is identified and dissected free from the surrounding tissues, it is ligated at both the aortic and pulmonary artery ends and divided between the sutures. The postoperative thoracotomy patients usually require a chest tube for 24 hours and a hospital convalescence of 6 to 7 days. Once discharged, these patients require an additional 6 to 8 weeks before they can return to full, unrestricted physical activity.

Fig. 61–10. Rashkind Ductal Occluding Device® of 12-mm diameter shown in the side and frontal view. The side view (left) shows the two opposing umbrellas opened against each other. The frontal view (right) shows the surface of the fabric and the three arms of the one umbrella.

The surgical repair of the ductus is considered "easy" and "safe" and does carry a low, but not absent, morbidity or mortality.[53,54] Cases of "recanalization," or more likely incomplete initial ligation,[55,56] have occurred with persistence of the ductus following only surgical ligation. With the more detailed and sophisticated techniques of evaluating these patients using color-flow Doppler, the incidence of this may prove to be higher. As with any thoracic surgical procedure, bleeding, which can be extensive, may occur. More specific to the surgery for the persistent ductus, injury to the recurrent laryngeal nerve or disruption of the thoracic duct with resultant chylothorax has been reported. The more serious complications of surgical repair of the ductus include ligation of the left pulmonary artery, the descending aorta, or even a carotid artery instead of the ductus, all with potentially catastrophic results.

Catheter Closure of Patent Ductus

The advent of a catheter technique for closure of the patent ductus[57] already has changed these policies at Texas Children's Hospital and undoubtedly will soon affect the policies of most progressive institutions in the world. The small infant weighing less than 7 or 8 kg with a large persistent ductus and in refractory heart failure is now the only unequivocal indication for surgical repair of a ductus.

Dr. Werner Porstmann first devised a catheter-delivered device for the nonsurgical closure of a patent ductus.[58,59] This device required a very large and complicated combined arterial and venous delivery system. Although still in use in a few locations for larger patients, it never gained much general popularity or use. Dr. William Rashkind developed a completely different and smaller device and system for transcatheter closure of the persistent ductus arteriosus.[60] After numerous modifications, his device was introduced into clinical trials in 1981. The details of the technique are discussed in Chapter 130 on Therapeutic Catheterizations.

The Rashkind Ductus Occlusion Device® is comprised of two small fabric umbrellas on stainless steel frames. The two umbrellas are connected together at the centers by a spring mechanism that holds the umbrellas in the open position in opposition to each other (Fig. 61–10). The occlusion device is delivered to the ductus through a special 8 French delivery catheter from either the atrial or venous route. The device is positioned in the ductus with one umbrella on the aortic end and the other umbrella on the pulmonary end of the ductus. When released in this location, the opposing umbrellas occlude flow through the ductus (Fig. 61–11).

As a part of the original collaborative clinical trials, the device has been used in 150 patients at Texas Children's Hospital with an overall success rate of over 80% total occlusion and with no complications from the device or the delivery procedure. The majority of the "failures" occurring now are hemodynamically insignificant, *inaudible* residual ductus only detectable by high-quality color-flow Doppler techniques. The nonsurgical closure of the ductus is now the recommended initial therapy for all patients with ductus who can be medically managed until they are at least 8 kg in weight. The patient undergoing transcatheter closure of the ductus spends the night following catheterization in the hospital and is discharged to full normal physical activity the following day. The only disadvantage to the nonsurgical approach is that if it cannot be accomplished, the patient will still require surgery to correct the ductus.

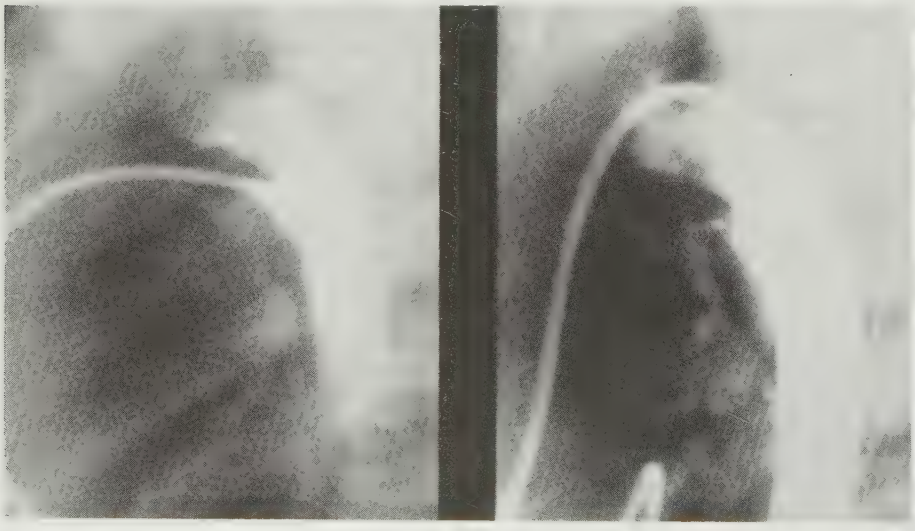

Fig. 61–11. Two comparable lateral descending aortograms showing (left) a catheter passing through a patent ductus, and (right) the same ductus totally occluded by the Rashkind Ductal Occluding Device.

CHAPTER 62

Clinical Physiology of Right-to-Left Shunts

J Timothy Bricker

Tetralogy of Fallot can be considered the archetype of right-to-left shunt physiology. In the patient with tetralogy of Fallot, a large interventricular communication is present with a restriction to pulmonary blood flow. The degree of hypoxemia ranges from slight to profound. The amount of obstruction of flow into the pulmonary arteries is the major factor determining the degree of hypoxemia. Other lesions, such as a single ventricle with pulmonary stenosis, can be thought of as "tetralogy physiology."

As stated in Chapter 58, it is relatively easy to reduce complex congenital cardiac defects into one of four physiologic types: left-to-right shunt physiology, right-to-left shunt physiology, transposition physiology, and the physiology of obstructive and regurgitant lesions without shunts. A great many malformations can be considered under the category of right-to-left shunt physiology.

In the patient with a right-to-left shunt, the blood flow to the pulmonary capillary bed is lower than the flow to the systemic capillary bed. The differences between these two flows equals the amount of deoxygenated blood that is shunted from the right-sided (systemic venous) return to the left-sided (systemic arterial) circulation and is, by definition, the right-to-left shunt (Table 62–1). Calculation of the right-to-left shunt flow at cardiac catheterization is done by subtracting the systemic blood flow from the effective pulmonary blood flow. Systemic and pulmonary flows are calculated from the Fick equation based on measured saturations, oxygen consumption, and hemoglobin as discussed in Chapter 54. It is also possible to calculate a systemic-to-pulmonary flow ratio without calculation of flow (Table 62–1). A right-to-left shunt may occur at the level of the atria, ventricles, great vessels, or pulmonary microcirculation. The clinical consequences of a right-to-left shunt depend upon both the magnitude and the location of the shunt. In addition, the chronicity of the physiologic state and the adequacy of compensation are important factors in the clinical manifestations of a right-to-left shunt. Consequences of severe hypoxemia are discussed in greater detail in Chapter 116.

DETERMINANTS OF THE DEGREE OF RIGHT-TO-LEFT SHUNT AND OF CYANOSIS

The amount of obstruction to pulmonary flow is the usual major determinant of the magnitude of a right-to-left shunt. This obstruction may be at any of a number of different levels. For example, the obstruction to pulmonary blood flow is at the level of the tricuspid valve for the patient with tricuspid stenosis and an atrial septal defect. Muscular subpulmonic obstruction in the patient with a ventricular septal defect is a common cause of a ventricular level right-to-left shunt. Mid-ventricular obstruction (e.g., from a right ventricular muscle bundle) may also cause a right-to-left shunt at the ventricular level if there is a muscular ventricular septal defect. Obstruction to pulmonary blood flow may be at the level of the pulmonary valve. Pulmonary stenosis with an intact atrial and ventricular septum does not result in right-to-left physiology. Pulmonary stenosis, if severe, will result in right-to-left physiology for the patient with a ventricular septal defect or single ventricle. If critical pulmonary stenosis causes right ventricular dysfunction, one may find right-to-left physiology from an atrial level shunt.

Descriptions of cyanotic lesions by Fallot included patients with severe pulmonary stenosis, right ventricular hypertrophy, and atrial septal defect (which is still called trilogy of Fallot by some).

Table 62–1. Calculation of Right-to-Left Shunt

1. Right-to-left shunt $= Q_s - Q_{ep}$
2. Q_s = systemic blood flow $= \dfrac{\text{Oxygen uptake}}{(\text{Aorta } O_2 \text{ content} - \text{Mixed venous } O_2 \text{ content})}$
3. Q_{ep} = effective pulmonary blood flow $= \dfrac{\text{Oxygen uptake}}{(\text{Pulmonary venous } O_2 \text{ content} - \text{Mixed venous } O_2 \text{ content})}$
4. Pulmonary to systemic flow ratio $= Q_p/Q_s = \dfrac{\text{Aorta saturation} - \text{Mixed venous saturation}}{\text{Pulmonary vein saturation} - \text{Pulmonary artery saturation}}$

Obstruction at the level of the pulmonary valve with an intact ventricular septum, right ventricular dysfunction, and a patent foramen ovale may result in an atrial level right-to-left shunt for the neonate with critical pulmonary stenosis or for the adult who had closed valvotomy (Brock procedure) in childhood. Obstruction to pulmonary blood flow resulting in right-to-left physiology can be within the pulmonary arterial bed. Supravalvular pulmonary stenosis, bifurcational stenosis, main pulmonary artery stenosis, distal pulmonary artery stenosis, or diffuse hypoplasia of the pulmonary arteries may be the reason pulmonary blood flow is limited. Primary pulmonary hypertension or pulmonary vascular obstructive disease may result in right-to-left physiology in patients with an intracardiac communication. Thus, the patient who develops Eisenmenger reaction from a large left-to-right shunt eventually acquires the physiology of a right-to-left shunt. Patients with primary pulmonary hypertension and a patent foramen ovale have been known to present with unexplained cyanosis. If the pulmonary blood flow is supplied from the aorta, obstruction to pulmonary blood flow can increase if the ductus arteriosus closes, if aorticopulmonary collaterals become stenotic, or if an aorticopulmonary anastomosis that the surgeon has created becomes narrowed.

Although the typical patient with a right-to-left shunt is hypoxemic, this is not always so. For example, the patient with "pink tetralogy" (the acyanotic form of tetralogy of Fallot) may have a well-matched left-to-right and right-to-left shunt resulting in minimal or no hypoxemia. With this situation, the pulmonary blood flow is normal or even increased. Even though there is an intracardiac right-to-left shunt in the patient with "pink tetralogy" the degree of obstruction to pulmonary blood flow is slight and the pulmonary-to-systemic flow ratio may be normal. More complicated cardiac lesions with both right-to-left and left-to-right shunts may also be well balanced like the acyanotic tetralogy patient. The newborn with single ventricle and mild to moderate pulmonary stenosis, for example, is often physiologically well balanced. This baby may eventually require a pulmonary artery banding after the pulmonary vascular resistance drops if the pulmonary obstruction remains slight, or might need an operation for creation of a systemic to pulmonary artery shunt if pulmonary obstruction increases, or the baby may do well with no surgical intervention in infancy if the pulmonary and systemic flows remain well balanced. Thus it can be seen that the amount of right-to-left shunt can change with time depending upon the severity of obstruction to pulmonary blood flow and that this progression of severity of right-to-left shunt cannot be precisely predicted for an individual patient.

There are factors other than obstruction to pulmonary blood flow that alter the amount of right-to-left shunting. An abrupt increase in right-to-left shunt may result in a severe hypoxemia associated with hyperpnea, irritability, and intense cyanosis. Various factors such as crying, hyperpnea, and hypoxemia itself serve to perpetuate an episode of increased cyanosis. These episodes have been referred to as "tetralogy spells" (or "tet spells" in the jargon of the ward). Other terms that have been used for these episodes have included hypercyanotic spells, anoxic spells, paroxysmal dyspnea, and hyperpneic spells. In spite of the name "tet spells," these episodes occur in settings with right-to-left physiology other than tetralogy of Fallot. Although it was once thought that "spasm" of the infundibulum was the cause of these spells in tetralogy of Fallot, it is clear that hypercyanotic spells can occur in patients who do not have infundibular stenosis (or even an infundibulum). Although hypercyanotic spells are discussed elsewhere in this text, it is instructive to review some of the factors that may initiate a hypercyanotic spell in the context of the physiologic determinants of the degree of right-to-left shunting.

One of the physiologic changes that usually increases hypoxemia in patients with right-to-left physiology (and may precipitate hypercyanotic spells in patients at risk) is vasodilation of the systemic vascular bed. A comment sometimes obtained in the history is that a baby is more blue after a warm bath. We often note an increase in hypoxemia if a drug with vasodilating properties is administered (such as Thorazine for sedation). Sometimes an increase in cyanosis is observed with the vasodilation from a fever or exanthem. The vasodilation that occurs during exercise is one of the factors that transiently increases hypoxemia for patients with right-to-left physiology. Preferential runoff into the distal systemic capillary bed rather than into the pulmonary artery increases hypoxemia in the patient whose pulmonary flow depends on small aorticopulmonary connections. Changes in peripheral vascular resistance can also alter shunting in patients with right-to-left physiology who do not have aorticopulmonary connections. The effect is probably by means of changes in ventricular volumes and by causing a relative hypovolemia. Efforts to treat or prevent hypercyanotic spells have employed the relationship between systemic resistance and the magnitude of the right-to-left shunt. Older children with right-to-left physiology and severe hypoxemia may learn to squat to improve symptoms while at play. The major benefit to them is probably due to the increase in aortic afterload from kinking the femoral arteries (although other explanations have been proposed). The equivalent of this maneuver for the infant is the use of the knee-chest position to improve arterial saturation during a hypercyanotic spell. Neo-synephrine will improve arterial oxygen saturation during a hypercyanotic spell by constriction of the systemic arteriolar bed. Ketamine is often used as an anesthetic during cardiac catheterization of children with a right-to-left shunt because of the peripheral vasoconstriction which occurs with the use of this drug.

Intrathoracic pressure can affect the degree of right-to-left shunt in some patients. If the limitation to pulmonary blood flow is extreme, the small trickle of blood into low-pressure pulmonary arteries could be further diminshed by a high pressure surrounding those vessels. Examples of an increase in intrathoracic pressure affecting a right-to-left shunt could include crying, hyperpnea, Valsalva maneuver, exercise, obstructive or restrictive lung disease, and mechanical ventilation.

Tachycardia can increase the right-to-left shunt. Plausible mechanisms include changes in the amount of obstruction, a decrease in intravascular volume, or changes in the systemic vascular resistance due to the tachycardia. Supraventricular tachycardia or sinus tachycardia potentially will precipitate hypercyanotic spells. Decreasing the heart rate (by soothing the infant, by sedation, by cardiac reflexes associated with volume increase or arterial blood pressure increase, or by propranolol) can be employed in efforts to prevent or treat hypercyanotic spells.

The patient's blood volume is also a factor in the amount of right-to-left shunt. Dehydration from diarrhea or diuresis increases the hypoxemia of the infant with a cyanotic cardiac defect. Volume infusion can be effective in the treatment and prevention of hypercyanotic spells. The blood volume can affect the anatomic degree of obstruction by means of changes in intracardiac volumes. In addition, hypovolemia is related to tachycardia and the systemic vascular resistance.

Hypoxemia and cyanosis result from a right-to-left shunt of any magnitude. Cyanosis depends on not only the arterial saturation but also the hemoglobin level. Five grams of desaturated hemoglobin per deciliter of blood are required for the child to appear cyanotic. For example, the infant with the physiology of a right-to-left shunt who has a hemoglobin of 10 g/dL would not appear cyanotic to the examiner until the arterial saturation is about 50%. This infant can have a significantly impaired oxygen delivery to the body without a blue appearance on examination. Thus hypoxemia out of proportion to the observed cyanosis can exist in the patient who has a low hematocrit. In the same respect, increasing the hemoglobin will, within limits, increase the arterial oxygen content at a given saturation. If the hemoglobin was increased to 20 g/dL by blood transfusion in this patient who remained at 50% arterial saturation, the blood oxygen content would double although the child would appear much more cyanotic. An additional factor is that increasing the blood volume may increase the cardiac output, which would be likely to improve the pulmonary blood flow and increase the total systemic blood flow that serves to increase the delivery of oxygen to the total body.

COMPLICATIONS AND SEQUELAE OF RIGHT-TO-LEFT SHUNTS

The patient with an intracardiac right-to-left shunt is vulnerable to paradoxical embolization. If small emboli (such as clots or air bubbles from an intravenous line) occur in the systemic venous circulation, the result is small pulmonary emboli for the normal individual. These small pulmonary emboli generally do no harm and are not noticed. However, in the patient with a right-to-left shunt, embolization is likely to occur to the systemic arterial circulation with profound effects upon the patient. Emboli to the cerebral, coronary, mesenteric, or renal arterial beds may have important consequences. Amniotic fluid emboli during childbirth, for instance, can result in a devastating stroke. Efforts to prevent venous thromboembolic disease is particularly important in the patient with a right-to-left shunt. The use of air filters on intravenous lines is important to prevent air embolus. However, this cannot replace diligence in the prevention of air in intravenous tubing in these patients. One should be reluctant to use an intravenous line in the patient with a right-to-left shunt unless absolutely necessary because of the risk of paradoxical embolization. The use of a heparin lock in a patient with right-to-left shunt physiology has been avoided in our practice because of the belief that intermittent flushing may dislodge clots with a greater potential for paradoxical embolization than a carefully watched continuous intravenous infusion that has an air filter in line.

The hemoglobin level that is acceptable for the pediatric or neonatal patient with normal hemodynamics reflects a relative anemia for the child who is chronically hypoxemic because of a right-to-left shunt. The additional oxygen-carrying capacity that increases the efficiency of oxygen transport is limited by the circulatory disadvantages of polycythemia. At hematocrit levels over about 65%, the circulatory inefficiency of capillary sludging of blood outweighs the advantage from increases in oxygen-carrying capacity or further increases in the red blood cell volume. Excessive polycythemia causes symptoms of lethargy, headaches, joint pains, and overt neurologic abnormalities on occasion.

The patient with a right-to-left shunt is at risk for a brain abscess. The source of intracerebral abscesses in patients with a right-to-left shunt is typically from hematogenous spread rather than direct extension. Although organisms similar to those that cause endocarditis may cause brain abscesses, intracerebral abscesses may be due to anaerobic organisms or grow mixed flora as discussed by Patrick and Kaplan in Chapter 148 of this text.

Renal abnormalities in chronic hypoxemia from a right-to-left shunt are reviewed by Berry in Chapter 146. The usual finding is glomerulomegaly, which is typically associated with minimal or no functional abnormalities although hematuria or proteinuria is occasionally found.

Hypertrophic osteoarthropathy is a result of severe hypoxemia as discussed in Chapter 147. Hypertrophic osteoarthropathy is of more cosmetic consequence than functional importance. But for some adolescents with a right-to-left shunt, the cosmetic aspects of clubbing and cyanosis can be a devastating aspect of their cardiovascular handicap.

Chronic hypoxemia has direct cardiac effects as well. Hypoxemia on a chronic basis can result in myocardial function abnormalities and myocardial fibrosis histologically. Chronic hypoxemia has been associated with electrophysiologic abnormalities. This abnormality in cyanotic individuals may contribute to the postoperative arrhythmias found in this population. Preliminary data suggest that chronic hypoxemia may be a risk factor for the development of atherosclerotic disease.

CHAPTER 63

Tetralogy of Fallot and Tetralogy of Fallot with Pulmonary Atresia

William H Neches
Sang C Park
Jose A Ettedgui

The term tetralogy of Fallot refers to a spectrum of anatomic abnormalities that have a large and unrestrictive ventricular septal defect and right ventricular outflow tract obstruction. The clinical presentation varies from the asymptomatic acyanotic child with a heart murmur to the severely hypoxic newborn infant and depends largely on the nature and degree of this outflow obstruction. Although the anatomic features and clinical manifestations of this anomaly had been previously described, it was Fallot in 1888[1] who carefully detailed the clinical and pathologic correlations of this group of congenital cardiac malformations that he termed "maladie bleue" and which now bears his name. Over the ensuing 5 or 6 decades much was written about the clinical features, pathology, embryology, and natural history of tetralogy of Fallot, but is was not until 1945, with the development of systemic to pulmonary artery anastomoses,[2,3] that it became possible to improve and lengthen the life of patients with this abnormality. Ten years later, in 1955, Lillehei et al.[4] described the first successful repair of tetralogy and thus began the modern era of the surgical management of this lesion. Since there are a wide variety of anatomic abnormalities that produce a similar clinical picture, it seems appropriate to review the anatomic particulars of tetralogy of Fallot prior to any discussion of the clinical features, diagnosis, or management of patients with this disorder.

ANATOMIC CONSIDERATIONS

The earliest description of the conditions we refer to as the tetralogy of Fallot dates to the seventeenth century.[5] The eponym originated from the clinicopathologic correlations by Fallot in the late nineteenth century of a condition consisting of a ventricular septal defect, aortic override, pulmonary stenosis, and right ventricular hypertrophy.[1] The anatomic hallmark of the tetralogy of Fallot is the anterocephalad deviation of the outlet septum. Apart from producing infundibular pulmonary stenosis, this deviation accounts for the ventricular septal defect and the aortic override (Fig. 63–1). These anatomic features warrant a more detailed description. Their variability accounts for the wide spectrum of clinical and hemodynamic findings. It is currently accepted that hypertrophy of the right ventricle is the result of the underlying anatomic and hemodynamic abnormalities.

Right Ventricular Ouflow Tract and Pulmonary Arteries

In the normal heart, the outlet septum is positioned between the limbs of the septomarginal trabeculation and is undistinguishable from the ventriculoinfundibular fold. As mentioned earlier, anterocephalad deviation of the outlet septum in relation to the septomarginal trabeculation is the basic anatomic feature in tetralogy of Fallot. This deviation significantly narrows the right ventricular outflow tract and is responsible for most of the infundibular pulmonary stenosis (Fig. 63–2). Hypertrophy of the outlet septum, hypertrophy of muscle bundles extending into the anterior right ventricular free wall, and hypertrophy of the anterior limb of the septomarginal trabeculation contribute to the infundibular narrowing. The severity of infundibular obstruction ranges from mild to severe pulmonary stenosis to pulmonary atresia (Fig. 63–3). On occasion there can be an added obstruction within the body of the right ventricle, proximal to the stenotic infundibulum. This is produced by "anomalous muscle bundles" represented by hyper-

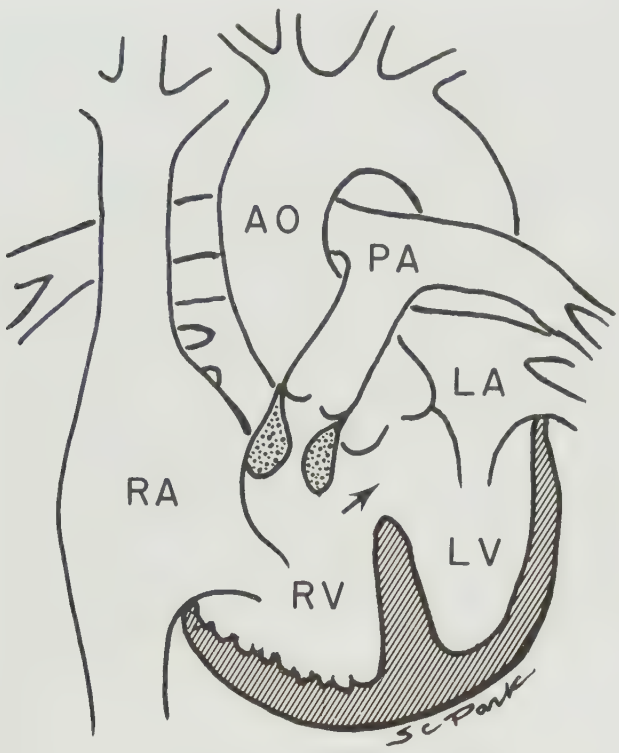

Fig. 63–1. Diagram illustrating the anatomic abnormalities in tetralogy of Fallot. Ao = Aorta; PA = Pulmonary artery; LA = Left atrium; RA = Right atrium; LV = Left ventricle; RV = Right ventricle. (These abbreviations are used in all illustrations.) Note the ventricular septal defect (arrow), infundibular pulmonary stenosis (stippled area), and the overriding aorta.

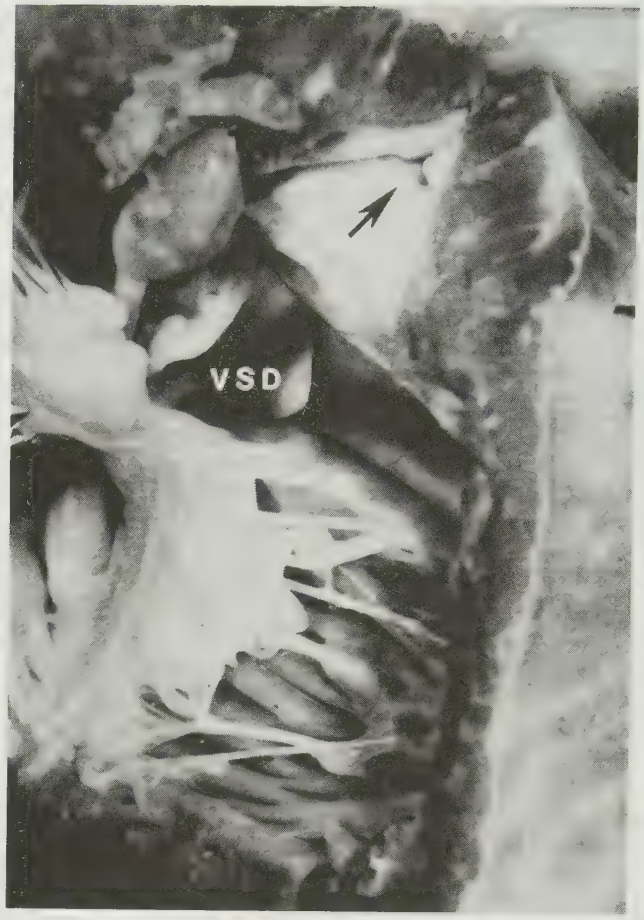

Fig. 63–2. Pathologic anatomy of tetralogy of Fallot (see text). Arrow = Infundibular pulmonary stenosis. VSD = Ventricular septal defect.

trophy of the apical component of the septomarginal trabeculation and other apical trabeculations.

Further obstruction to pulmonary blood flow often occurs at other levels (Fig. 63–4). Pulmonary valve stenosis is common[6,7] and can be due to a stenotic three leaflet, bicuspid, or unicuspid valve. Occasionally stenosis is the result of a small pulmonary valve "ring" or of supravalvar fibrous ridges. Stenoses at the origin of the right or left branch pulmonary arteries are common, and are usually amenable to surgical repair. Further narrowing in the distal branch pulmonary arteries may also occur but is more difficult to approach surgically.

One pulmonary artery may arise from the aortic arch instead of from the pulmonary trunk (Fig. 63–4). It is usually connected to the aorta through a patent ductus arteriosus or directly from the ascending aorta. The left pulmonary artery is more commonly affected than the right.[8–10] When the ductus closes, blood supply to the pulmonary artery becomes very limited and is usually through small collateral vessels. On the other hand, if the aortic communication remains widely patent, the pressure in the pulmonary artery may be at systemic level leading to the development of pulmonary vascular disease in the affected side.

Pulmonary Arteries and Collateral Circulation in Tetralogy of Fallot with Severe Pulmonary Stenosis or with Pulmonary Atresia

There is great variability in the anatomy of the pulmonary arteries and the source of pulmonary blood flow in tetralogy of Fallot with pulmonary atresia (Fig. 63–5). A fully developed, normal sized main pulmonary artery confluent with the right and left branches is not common. These central pulmonary arteries are usually small and hypoplastic. Angiographically they have a "seagull" appearance. More frequent possibilities include patent right and left pulmonary arteries that may be confluent with an absent main pulmonary artery, presence of one pulmonary artery with absence of the other, and finally, there may be complete absence of central pulmonary arteries. When present, the central pulmonary arteries are not necessarily connected to all of the intrapulmonary arterial segments. This creates the possibility of different lung segments having different sources of blood supply (i.e., collateral circulation). The intrapulmonary arteries, however, do not differ regardless of their connection to central pulmonary arteries or to collateral vessels.

Since there is no antegrade flow from the right ventricle to the pulmonary arteries, blood reaches the pulmonary vasculature through different routes. A patent ductus arteriosus is an important pathway that depends on the existence of central pulmonary arteries. In the presence of nonconfluent pulmonary arteries there may be bilateral ducti.

Another important source of pulmonary blood flow are major aortopulmonary collateral arteries. These vessels originate from

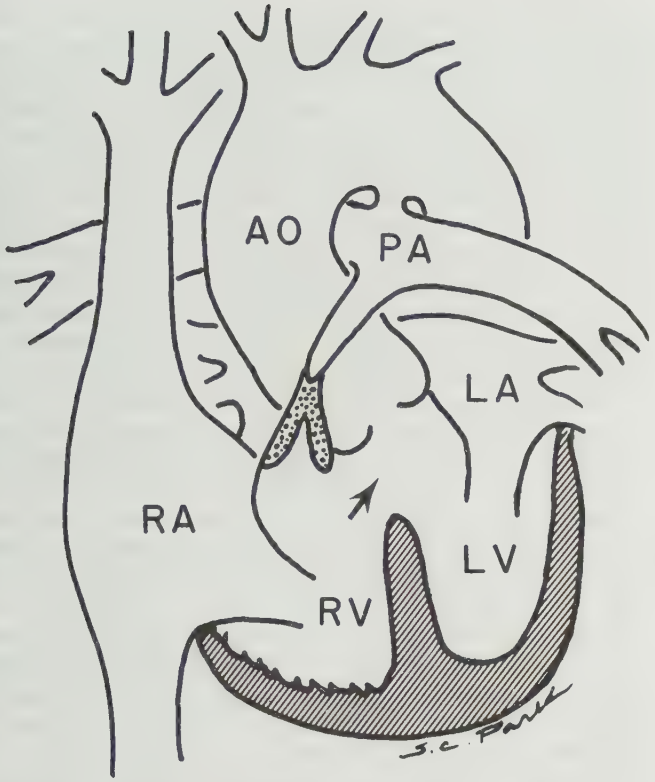

Fig. 63–3. Diagram illustrating the anatomic features of tetralogy of Fallot with pulmonary atresia. Ao = Aorta; PA = Pulmonary artery; LA = Left atrium; RA = Right atrium; LV = Left ventricle; RV = Right ventricle. Note the ventricular septal defect (arrow), infundibular and valvar atresia (stippled area), and hypoplastic main pulmonary segment. Pulmonary blood flow is via a patent ductus arteriosus.

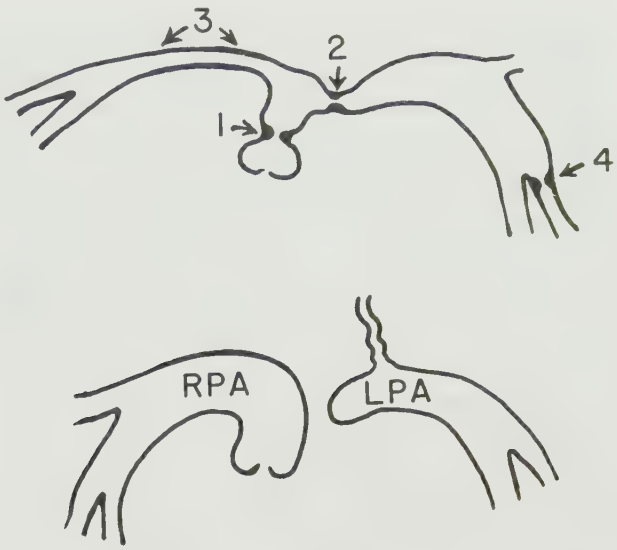

Fig. 63–4. Areas of pulmonary stenosis in tetralogy of Fallot. Top—Pulmonary artery stenosis: 1. Supravalvular stenosis; 2. Discrete pulmonary artery stenosis; 3. Tubular hypoplasia of a segment; 4. Distal arterial stenosis. Bottom—Discontinuity of the pulmonary arteries. The left pulmonary artery arises from a ductus arteriosus.

the intrathoracic portion of the descending aorta in the proximity of the left mainstem bronchus. Rarely, they may arise from the aortic arch or the subclavian artery. These vessels are embryologically and histologically different from bronchial arteries and ducti.[11–13] The number of collateral vessels is variable and they usually follow a tortuous course. They may anastomose to the central pulmonary arteries at the hilum or within the lung.[14] These aortopulmonary collaterals may directly supply blood to the intrapulmonary plexus in the absence of true pulmonary arteries. A collateral vessel may supply different segments of both lungs. Generally, the major aortopulmonary collateral arteries have stenoses in their course. The stenosis is usually located at the point of anastomosis to an intrapulmonary artery and histologically is produced by a mound of intimal tissue.[15] The severity of the stenosis is variable and occasionally some collateral arteries are unobstructed. The segments supplied by these vessels are at risk of developing pulmonary vascular disease.[12,14]

A third source of pulmonary blood flow is through acquired collateral arteries. These are multiple, small vessels that can originate from the bronchial arteries, intercostal arteries, and coronary arteries. Very rarely pulmonary blood flow is supplied through an aortopulmonary window.[16]

These multiple sources of pulmonary blood supply create the possibility of unifocal or multifocal pulmonary blood flow. Uni-

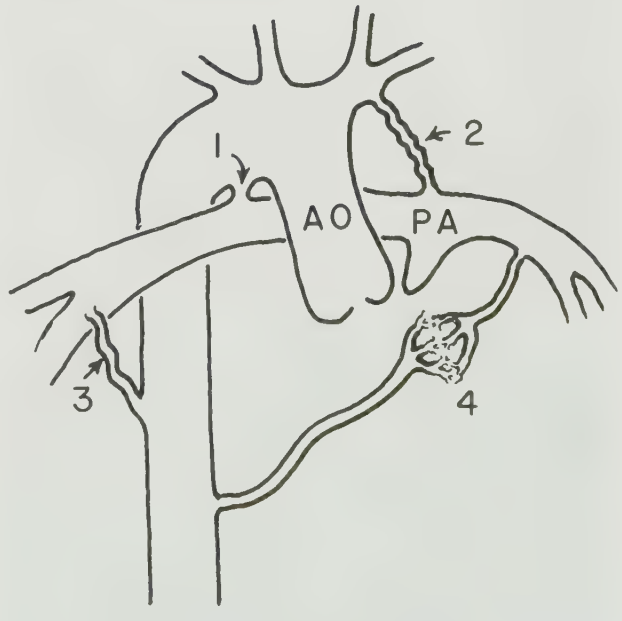

Fig. 63–5. Diagram of the pulmonary blood supply in tetralogy of Fallot with pulmonary atresia: 1. Ductus arteriosus from the descending aorta; 2. Ductus arteriosus from the innominate artery (left sided ductus is most common with a right aortic arch); 3. Aortopulmonary collateral vessel from the descending aorta; 4. Intercollateral anastomosis providing pulmonary blood flow.

focal pulmonary blood supply requires the presence of confluent pulmonary arteries, connected to all of the intrapulmonary arterial segments regardless of the origin of the flow to the true pulmonary arteries. Unifocal blood flow is very common in tetralogy of Fallot but is less frequent when there is associated pulmonary atresia.[17,18] In multifocal pulmonary blood supply the central pulmonary arteries, when present, are not connected to all of the intrapulmonary arterial segments of both lungs. There is a combination of lung segments supplied by central pulmonary arteries, segments supplied by major aortopulmonary collateral arteries and segments that have a dual supply[19] (see Fig. 63–3). This concept has relevance in the surgical management of patients with tetralogy of Fallot.

Ventricular Septal Defect

A large, unrestrictive malalignment ventricular septal defect is another of the consequences of the anterocephalad deviation of the outlet septum. The borders of the ventricular septal defect are the aortic valve leaflets and the ventriculoinfundibular fold superiorly, the fusion of the outlet septum to the anterior limb of the septomarginal trabeculation anteriorly, and the crest of the trabecular septum inferiorly[7] (Fig. 63–6). Of great surgical importance are the variations occurring along the posteroinferior margin of the defect. In 80% of patients this margin is the central fibrous body and the defect is therefore perimembranous. There will be fibrous continuity between the tricuspid valve and aortic valve through the ventricular septal defect. In 20% of patients there is a muscle bar along the posteroinferior rim of the defect separating the tricuspid valve from the aortic valve. In these cases the ventricular septal defect is muscular. The relevance of the distinction between a perimembranous and a muscular ventricular septal defect is related to the position of the penetrating bundle of His. In a perimembranous ventricular septal defect, the penetrating bundle runs along the posteroinferior margin of the defect and is at risk of being damaged at the time of surgical correction. In a muscular ventricular septal defect, the muscle bar along the posteroinferior rim of the defect provides a "cushion" or "safety margin" that allows the surgeon to suture the patch closing the ventricular septal defect with minimal risk of damaging the conduction tissues.

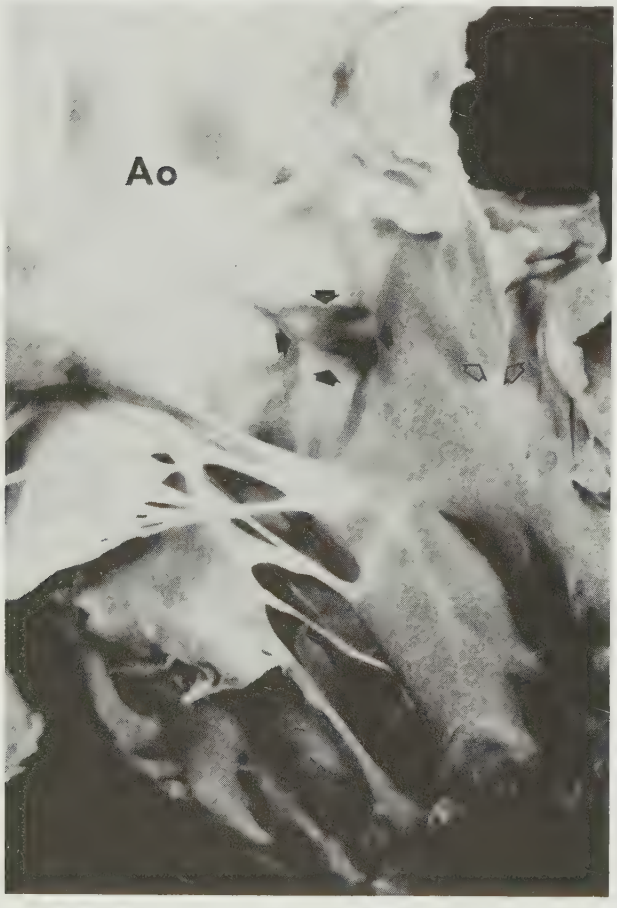

Fig. 63–6. Close up view of the ventricular septal defect in tetralogy of Fallot (see text). Closed arrows = Ventricular septal defect margins; Open arrows = Outlet septum.

In some patients the ventricular septal defect may extend into the inlet portion of the septum. In this situation, part of the tensor apparatus of the tricuspid valve extends into the left ventricle resulting in a straddling tricuspid valve.

An additional ventricular septal defect, or multiple defects, may be present in the trabecular portion of the intraventricular septum in from 3 to 15% of patients with tetralogy of Fallot.[20] Occasionally, a complete atrioventricular septal defect may coexist with the anterocephalad deviation of the outlet septum, therefore also falling in the category of the tetralogy of Fallot (i.e., tetralogy with AV canal).[21] These patients are a surgical challenge in view of the complexity of operative repair. A separate group of patients, often considered to have tetralogy of Fallot, are those that have a doubly committed subarterial ventricular septal defect.[22] In these hearts there is continuity between the aortic and pulmonary valves through the ventricular septal defect. For this type of defect to exist there has to be absence of the outlet septum. This obviously contradicts our definition of tetralogy of Fallot. Since in these patients pulmonary stenosis is the result of a small pulmonary valve "ring," we propose that these patients be considered separately from tetralogy of Fallot.

In a small number of patients with tetralogy of Fallot (less than 5%) the ventricular septal defect may be restrictive and produce suprasystemic right ventricular pressure. Since tetralogy is characterized by a large and unrestrictive defect, it would seem that these hearts do not meet this requirement. However, in almost all cases accessory or excessive tricuspid valve tissue has been found obstructing a large defect, often with anomalous attachments to the margins of the defect,[23,24] and the basic anatomy is otherwise similar to tetralogy.

Aortic Override

One way of avoiding the controversy over the existence of aortic override in the tetralogy of Fallot would be the term "biventricular aortic connection." This accurately describes the relation of the aorta to both right and left ventricles. However, the term aortic override continues to be valid.

In the normal heart, the right coronary sinus "overrides" the intact ventricular septum. The presence of a ventricular septal defect would create the impression of override. In tetralogy of Fallot, the aortic root may be dilated, further contributing to the impression of override.[25] This override has been demonstrated both

anatomically[26] and echocardiographically.[27] The degree of override ranges from 15 to 95%.[7] This extent of override raises the question of a double outlet right ventricle if more than 50% of the aorta is connected to the right ventricle. If a double outlet right ventricle is defined as an anatomic entity with a subaortic and subpulmonary infundibulum with discontinuity between the mitral and aortic valves, it obviously excludes the tetralogy of Fallot.[28,29]

Coronary Arteries

Abnormalities in the origin and distribution of the coronary arteries are common in the tetralogy of Fallot. A single right or left coronary artery was found by Dabizzi et al.[30] in 4% of their series. They also noted origin of the anterior descending artery arising from the right coronary in 4% and large conal branches from the right coronary in 19%. The importance of these anomalous vessels is dependent on their course across the infundibulum. They may seriously interfere with relief of the right ventricular outflow tract obstruction at the time of corrective surgery. Damage to these coronary artery branches can result in myocardial infarction and death.[21] Small fistulous connections to the pulmonary artery or right atrium (11.7%), and anastomoses with the bronchial arteries (26%) were a surprisingly frequent finding by Dabizzi et al.[30] Rare cases of origin of the anterior descending from the internal mammary artery have also been reported.[32]

Most anomalies of the coronary arteries are identifiable by the surgeon at the time of repair. However, these vessels may be buried in the myocardium[33] or in adhesions from previous operations,[34] hence the importance of preoperative diagnosis. In most centers coronary artery anatomy is assessed from aortic root angiography. There are authors that recommend selective coronary arteriography in every patient.[30,31,35]

Lungs and Intrapulmonary Arteries

Quantitative studies have demonstrated a decrease in lung volume in patients with tetralogy of Fallot and tetralogy with pulmonary atresia.[15,36] The branching patterns of the bronchi, pulmonary arteries, and veins were normal. However, the total number of alveoli was reduced. The number of preacinar and intraacinar pulmonary arteries are also normal, but their size is smaller than normal.[15,36,37] All these changes have been attributed to low pulmonary blood flow. However, surgically created shunts may lead to dilatation of the proximal arteries without affecting the size of the intra-acinar vessels.[15] Since most of the alveolar and pulmonary artery growth is completed by two years of age, it has been suggested that repair by this age may result in normal alveolar development and growth of the pulmonary vascular bed.[15,37]

Associated Anomalies

Tetralogy of Fallot is frequently associated with other anomalies. A patent foramen ovale and an atrial septal defect are common. The incidence of interatrial communications has been reported as high as 82%.[6] Drainage of the left superior vena cava to the coronary sinus was found in 11% of cases in an autopsy series.[6] Rarely, the left superior vena cava may drain directly into the left atrium. Abnormal pulmonary venous corrections are very rare.[38] Other rare anomalies associated with tetralogy of Fallot include supravalvular mitral stenosis[39] and discrete subaortic stenosis.

Congenital anomalies of the aortic valve are extremely rare.[40] Aortic insufficiency is more common in adults with tetralogy of Fallot.[41] It is usually the result of bacterial endocarditis of the aortic valve, long-standing aortic root dilatation, or operative damage.[42]

Approximately 25% of patients with tetralogy of Fallot have a right-sided aortic arch. This bears surgical importance at the time of deciding between a classic or a modified Blalock-Taussig shunt (see section on Systemic to Pulmonary Artery Anastomoses).

EMBRYOLOGY

A brief review of the development of the normal heart assists in understanding the currently accepted hypothesis of the morphogenesis of the tetralogy of Fallot. The distal bulbus and the truncus lie above the developing right ventricle. This region is separated into aortic and pulmonary outflow tracts by growth and fusion of the bulbotruncal ridges. During this process there is rotation of the distal bulbus, which brings the aortic component posteriorly. The semilunar valves are developing at the bulbotruncal junction and are separated from the atrioventricular valves by the inner curvature of the heart (ventriculoinfundibular fold). Attenuation of a portion of the inner curvature will result in fibrous continuity between the mitral and aortic valves. As a consequence of this whole process the posterior outlet of the bulbotruncal region is transferred to the left ventricle. The infundibular septum is aligned with the trabecular septum, only separated by the interventricular foramen. This area will be eventually closed by endocardial cushion and sulcus tissue to form the membranous portion of the ventricular septum. The anterior outlet component remains connected to the right ventricle.[43]

Faulty rotation of the bulbotruncal region will result in incomplete transfer of the posterior component to the left ventricle. The infundibular septum will not be aligned with the developing trabecular septum resulting in a malalignment ventricular septal defect with aortic override. Attenuation of the inner curvature of the heart will still lead to continuity between the mitral and aortic valves. The tricuspid valve can also be expected to be in continuity with the aortic valve across the ventricular septal defect. Up to now, this process accounts for several of the morphologic features of the tetralogy of Fallot but is incapable of explaining the infundibular pulmonary stenosis. An abnormality in the separation of the distal bulbus is the postulated mechanism for this stenosis. Anterior displacement of the bulbotruncal ridges will result in unequal separation of the developing outflow tracts and lead to infundibular stenosis. The combination of the abnormal rotation of the bulbotruncal region with unequal separation of its components would explain the basic anatomic features of the tetralogy of Fallot.[44,45] The amount of aortic override will depend on the extent of the faulty rotation. Similarly, a wide range of severity of infundibular stenosis can be expected as a result of the degree of malseptation. These variations would account for the wide anatomic and clinical spectrum of this condition. Hypertrophy of the right ventricle is the hemodynamic result of the underlying morphology.

An alternative theory was postulated by Van Praagh et al. in 1970[25] who suggested that tetralogy of Fallot was the result of underdevelopment of the subpulmonary infundibulum. It was proposed that the hallmark of the tetralogy was an abnormally small infundibulum. The degree of right ventricular outflow obstruction

would be directly proportional to the amount of infundibular hypoplasia. This underdevelopment would also fail to align the distal conal (outlet) septum with the rest of the ventricular septum, therefore explaining the ventricular septal defect. As of yet, there is no experimental embryologic evidence to support this theory. Further anatomic studies have shown that a short subpulmonary infundibulum is not a constant feature of the tetralogy of Fallot. A morphometric study revealed that the infundibulum was actually longer than normal.[26]

The different portions of the normal pulmonary circulation have different embryologic origins. The main pulmonary artery originates from septation of the truncus arteriosus; the right and left pulmonary arteries and their confluence are most likely derived from the sixth aortic arch, while the intrapulmonary arteries develop with the airways from the primitive lung buds. In early embryonic life the intrapulmonary arteries are connected simultaneously to sixth aortic arch structures and to the descending aorta through the intersegmental arteries.[46,47] In pulmonary atresia with a ventricular septal defect, these intersegmental arteries persist as aortopulmonary collaterals.[13] These vessels are embryologically different from the bronchial arteries.[11]

EPIDEMIOLOGY AND GENETICS

Tetralogy of Fallot occurs in about 6% of infants born with congenital heart disease. The prevalence reported in any study is dependent upon the nature of the series and what group of patients was included or excluded from the numerator. In 1973, Campbell[48] summarized seven series describing the prevalence of different cardiac malformations at birth. The overall prevalence of tetralogy of Fallot was 5.8% with a range in each series from 3.5 to 8%. Hoffman and Christianson[49] evaluated congenital heart disease in a cohort of 19,502 births and reported a 3.7% prevalence of tetralogy of Fallot. When their data were combined with the data from six other series, tetralogy was found in 5.1% of over 300 infants with congenital heart disease. The prevalence reported in these other studies ranged from a low of 3.9% to a high of 8.6%. In the largest prospective survey, Mitchell et al.[50] found the prevalence of tetralogy of Fallot to be 3.5% of live births with congenital heart disease in a cohort of over 56,000 total births. In contrast, the prevalence of tetralogy of Fallot is reported to be higher in series of patients referred for evaluation of congenital heart disease. Some of these series include studies by Rowe (9.7%) in Toronto,[51] Kramer (10.4%) in West Germany,[52] and the New England Regional Infant Cardiac Program (11%).[53] Since these series include patients referred to medical centers for the diagnosis and treatment of cardiovascular malformations, it is possible that the denominator may not include patients with less severe abnormalities that were not referred for evaluation. Thus, the actual prevalence of tetralogy is difficult to determine exactly but probably lies in the range of about 6%.

The etiology of tetralogy of Fallot remains obscure. Although tetralogy and most other forms of congenital heart disease generally occur as isolated abnormalities, children with tetralogy of Fallot are afflicted with additional major extra cardiac malformations significantly more often (15.7%) as compared to patients with other congenital heart defects (6.8%).[52] In addition, the extracardiac malformations may be more serious in patients with tetralogy and include cleft lip and palate, hypospadius, and skeletal malformations. Although tetralogy is not commonly part of specific hereditary malformation syndromes or chromosomal anomalies, it is commonly found in a number of malformation associations including cardiofacial, VACTERL, and CHARGE associations as well as the de Lange, Goldenhar, and Klippel-Feil syndromes.[52,54,55] In general, tetralogy of Fallot appears to occur sporadically and is not familial. However, it has been found to occur in greater frequency in siblings of patients with tetralogy than would be expected to occur on the basis of its frequency in the general population.[55,56] Nora and Nora[55] also found a recurrence risk of 4% in offspring when one parent had tetralogy of Fallot. This was slightly higher than the 3% recurrence risk in siblings. This suggests a multifactorial inheritance resulting from a genetic–environmental interaction. In view of the absence of a familial incidence or genetic inheritance pattern for tetralogy of Fallot, it may be that some unknown environmental factor plays a major role in the production of this abnormality. Although no specific etiologic agent has been identified, potential environmental teratogenic agents include viral infections and drugs such as trimethadione, sex hormones, and thalidomide.[55] Of note is the fact that tetralogy of Fallot was not reported to have occurred in the offspring of a large group of mothers with congenital cardiac anomalies.[57] On the other hand, since large numbers of patients with tetralogy who were repaired in the 1960s are only now reaching child-bearing age, the true incidence of congenital heart defects in their offspring is still unknown.

PHYSIOLOGY AND HEMODYNAMICS

The hemodynamic features produced by the anatomic abnormalities in tetralogy of Fallot are 1) equalization of right and left ventricular pressure, and 2) normal or reduced pulmonary artery pressure. Since the ventricular septal defect is large and unrestrictive and the right and left ventricles contract simultaneously, the end result is in effect a ''common'' ventricular chamber ejecting into the systemic and pulmonary circulations. The pulmonary and systemic blood flows are therefore dependent upon the relationship between the pulmonary and systemic outflow resistances. Normally the pulmonary resistance is about 10% of the systemic resistance and these resistances are determined by the respective distal arteriolar beds. However, in tetralogy of Fallot, the pulmonary vascular (arteriolar) resistance is usually normal or less than normal and the total outflow resistance to right ventricular ejection into the pulmonary vascular bed is instead related to relatively fixed anatomic obstruction. Potential areas for anatomic obstruction include the right ventricular outflow tract at the subvalvar, annular, or valvar levels and supravalvar or distal arterial stenoses as well. Thus, in patients with tetralogy of Fallot, the resistance to systemic outflow is still the arteriolar resistance of the distal vascular bed while the resistance to pulmonary outflow is the cumulative effect of the various levels of outflow obstruction.[58] In a small number of patients, less than 5%, the ventricular septal defect may be partially obstructed by excess or accessory tricuspid valve tissue, which can result in suprasystemic right ventricular pressure.[23,24]

The presenting symptoms and severity of clinical manifestations in patients with tetralogy of Fallot are dependent upon the relationship between the resistances to systemic and pulmonary outflow as defined above.[59] If the total right ventricular ouflow ob-

struction is such that pulmonary outflow resistance is less than the systemic resistance, there will be a net left-to-right shunt and the clinical manifestations will be similar to those of patients with a small to moderate sized ventricular septal defect. If the pulmonary and systemic outflow resistances are similar, there will be a balanced shunt with nearly equal pulmonary and systemic blood flows at rest. Lastly, when the resistance to pulmonary ouflow exceeds systemic resistance, there will be a net right-to-left shunt and systemic flow will be greater than pulmonary flow. In tetralogy of Fallot with pulmonary atresia the pulmonary outflow resistance is, of course, at its maximal level. In these patients, pulmonary blood flow occurs by way of a patent ductus arteriosus, or systemic to pulmonary collateral vessels. In most cases, resistance to pulmonary blood flow is determined by the cross-sectional area of the vessel or vessels feeding into the pulmonary circulation. This is usually a fixed resistance and does not vary with alterations of the patient's physiologic state such as exercise. In some situations, the pulmonary blood flow is determined by the pulmonary arteriolar resistance rather than an anatomic obstruction. This occurs in patients with tetralogy of Fallot, or tetralogy of Fallot with pulmonary atresia, who have large unrestrictive systemic to pulmonary collateral vessels or who have a large surgically created systemic to pulmonary artery anastomosis. These patients usually have increased pulmonary blood flow, are acyanotic or mildly cyanotic at rest and may manifest congestive heart failure. Pulmonary hypertension is often present and if the large shunt persists over an extended period of time then pulmonary vascular disease may develop. This high degree of pulmonary blood flow and increased pulmonary to systemic flow ratio is very unusual in the large majority of patients with tetralogy of Fallot. Thus, congestive heart failure is extremely rare except in the situations that have just been described.

Cyanosis may be mild or undetectable at rest in patients with tetralogy of Fallot, but usually becomes apparent, or increases, with physical activity. This increase in right-to-left shunting and the resultant decrease in systemic arterial oxygen saturation can be explained on the basis of a number of physiologic alterations that occur with exercise. Although there normally is a considerable increase in cardiac output associated with exercise, there is also a fall in systemic and pulmonary vascular resistances so that only a modest increase in arterial pressure occurs. In the patient with tetralogy of Fallot, the total pulmonary outflow resistance is either fixed or the degree of right ventricular outflow obstruction may even increase as a result of increased myocardial contractility. Unchanged or increased pulmonary resistance associated with an increased cardiac output and decreased systemic arterial resistance results in a considerable increase in the degree of right-to-left shunting, while effective cardiac output is maintained. The rapid decrease in systemic arterial oxygen saturation produces exertional dyspnea and decreased exercise tolerance. In contrast to episodes of paroxysmal hypoxemia or "tetralogy spells" that are described below, the systemic desaturation is limited by the duration of exercise and begins to improve as soon as the activity ceases.

Squatting

Squatting is a common posture in patients with tetralogy of Fallot, particularly in young children. These children are usually not taught to do this but seem to learn instinctively that they are more comfortable when assuming this knee-chest position. Squatting is often seen in children after exercise. However, children frequently are seen to assume a squatting position while playing quiet games with their peers who are all in a sitting position. It is generally recognized that patients with tetralogy of Fallot assume the squatting position because they feel better as a result of increased systemic arterial oxygen saturation.[60] The exact mechanism by which this occurs is still unclear. It has been suggested by some that squatting is associated with a sustained decrease in systemic venous return from the lower extremities which, after exercise, reduces the proportion of this more highly desaturated blood returning to the heart.[61,62] It is more likely, however, that squatting results in an increase in systemic arterial resistance due to kinking and compression of the major arterial circulation to the lower extremities. This increase in peripheral resistance in the presence of the fixed pulmonary outflow resistance, decreases the degree of right-to-left shunting and increases the pulmonary blood flow. The result is an immediate increase in the systemic arterial oxygen saturation.

Paroxysmal Hypoxemic Spells

Episodes of paroxysmal hypoxemia, also called "hypercyanotic spells," "tetralogy spells," "paroxysmal dyspnea" and other synonyms, are commonly seen in infants and young children with tetralogy of Fallot and in other cardiac malformations with similar physiology (i.e., in which pulmonary blood flow is dependent upon the ratio of pulmonary to systemic resistance). This physiology may be present, for example, in tricuspid atresia, transposition, or Eisenmenger's syndrome. Hypoxemic spells are usually self-limited and of less than 15 to 30 minutes duration. However, there is considerable variability, and in any patient at any time, a spell may last only a few minutes or may last an hour or longer. The spells more commonly occur in the morning but may occur during the day, especially following a nap when systemic resistance is low. They may be precipitated by activity, a sudden fright, or injury, or may occur spontaneously without any apparent cause.[63] When a spell begins in an infant or a child after exercise or a fright, it is characterized by increasing cyanosis and an increased rate and depth of respiration. The small infant may initially just appear to be fussy but cannot be quieted and then progresses to have increased cyanosis and the respiratory features of a spell. Further discussion of the clinical manifestations and treatment of hypoxemic spells is found in the section on Management.

The physiologic change that produces a hypoxemic spell is an increase in right-to-left shunting and the concomitant decrease in pulmonary blood flow. Although this is the same mechanism that produces the decrease in systemic arterial oxygen saturation during exercise, the spell tends to be progressive and rapidly results in metabolic acidosis as compared to the reversal of desaturation that occurs when exercise ceases. Wood suggested that hypoxemic spells were due to spasm of the infundibulum of the right ventricle, which precipitated a cycle of progressively increasing right-to-left shunting and metabolic acidosis.[64] Others have postulated that an increase in circulating catecholamines and the resulting increase in myocardial contractility produces an increase in the degree of infundibular stenosis.[65] Although this is the most widely accepted explanation for paroxysmal hypoxemic spells, it does not explain spells that occur in patients with tetralogy of Fallot and pulmonary atresia or other similar malformations where pulmonary blood flow does not cross the right ventricular outflow tract. Guntheroth et

al. have suggested that episodes of paroxysmal hyperpnea are the cause rather than the effect of the hypoxemic spell.[66] They suggested that the hyperpnea augments systemic venous return thus increasing right-to-left shunting as well as oxygen consumption through the increased work of breathing. This results in further hypoxemia, decreased systemic vascular resistance, and a further increase in right-to-left shunting. Others have demonstrated an increase in right-to-left shunting associated with episodes of paroxysmal atrial tachycardia and during rapid atrial pacing,[67] implying that tachycardia with a decreased right ventricular volume may contribute to increased right-to-left shunting. Regardless of whether any or all of these mechanisms is responsible for hypoxemic spells, the clinical manifestations and course of these episodes would be similar. An increase in right-to-left shunt and decrease in pulmonary blood flow would result in reduction of the systolic murmur across the right ventricular outflow tract, an increase in cyanosis and the other characteristic features of a spell regardless of which came first.

CLINICAL FEATURES

The presentation of patients with tetralogy of Fallot is quite variable and ranges from the small infant with severe hypoxemia to the asymptomatic child with so called "pink tetralogy."[59] The severity of symptoms is related to the degree of pulmonary stenosis while the constancy of these symptoms is determined by whether the stenosis is fixed or is a dynamic phenomenon with episodic increases in severity. Cyanosis is noted most often in the neonate with associated pulmonary atresia. Cyanosis may be the only indication of the underlying abnormality since these patients often have no murmur, and a single second heart sound on auscultation is a common finding in a neonate. Another relatively common presentation is the asymptomatic infant with a heart murmur. These patients may seem to have only a ventricular septal defect, since the murmur of the right ventricular outflow tract obstruction in the infant with tetralogy may be indistinguishable from that of an isolated ventricular septal defect. Since the radiographic examination may be normal, the only clues to the presence of tetralogy may be the absence or splitting of the second heart sound and the presence of right ventricular hypertrophy on the electrocardiogram. However, sometimes it is difficult to appreciate splitting of the second heart sound in the small infant, especially in the presence of tachycardia and a loud murmur of a ventricular septal defect. In addition, since a degree of right ventricular hypertrophy on the electrocardiogram may be normal in the newborn and small infant, the significance of this finding may not be apparent until after 6 months of age. Fortunately, the diagnosis is easily made by echocardiography, which would be performed to evaluate a patient presenting with these findings. Typically, in tetralogy of Fallot, cyanosis is first noted at 6 weeks to 6 months of age.

When cyanosis is present in the patient with tetralogy of Fallot, it is usually apparent in the mucous membranes of the mouth and in the nailbeds. Cyanosis may be present at birth or may appear later during infancy or childhood as a result of progression of the pulmonary stenosis. Other patients with tetralogy may be acyanotic at rest, with cyanosis appearing only with exercise or during hypoxemic episodes. In patients with persistent cyanosis, clubbing of the fingers and toes generally appears during infancy (rarely before 6 months) and will persist until after complete repair. Since tetralogy of Fallot and ventricular septal defect are the most common associations with other major extracardiac anomalies, it is important to evaluate for these cardiac defects carefully when a murmur is found in a patient with extracardiac malformations.

The physical findings in patients with tetralogy of Fallot are not specific for this lesion and are also present in patients with other cardiac malformations. No abnormalities are usually found on inspection other than the cyanosis and clubbing previously mentioned. A prominent parasternal impulse may be present on palpation of the precordium but this is not a consistent finding. Although significant right ventricular hypertrophy is always present, there is no right ventricular volume overload and thus an abnormal right ventricular impulse may not be apparent.

On auscultation, the first heart sound is normal and the second heart sound is usually single. In some patients with tetralogy who are acyanotic, the infundibular pulmonary stenosis may be less severe and the pulmonary artery pressure may be normal rather than low. In these patients it may be possible to appreciate the pulmonic component of a second heart sound.[68] An ejection sound may sometimes be present at the mid to upper left sternal border. This is rarely a pulmonary ejection sound in patients who have valvular stenosis and less severe infundibular stenosis. In most cases, especially when there is pulmonary atresia, the ejection sound appears to arise from the aortic root and would be termed an aortic root click.[68,69]

It has been well established that the murmur in patients with tetralogy of Fallot is caused by the flow across the right ventricular outflow tract.[70] In patients with other types of stenotic lesions such as isolated pulmonary stenosis or even with isolated ventricular septal defect, the intensity of the murmur is directly related to the pressure gradient across the stenotic area. Thus, more severe degrees of valvar pulmonary stenosis and smaller ventricular septal defects are associated with louder murmurs. In contrast, in patients with tetralogy of Fallot or in those with similar physiology, the intensity of the murmur varies inversely with the degree of pulmonary stenosis. In tetralogy, as the degree of pulmonary stenosis increases, there is increased right-to-left shunting and decreased flow across the right ventricular outflow tract. The murmur therefore decreases as the degree of pulmonary stenosis increases. The murmur in patients with tetralogy of Fallot is characteristically an ejection or crescendo–decrescendo murmur and is usually loudest at the upper left sternal border. Despite the fact that this murmur is due to the pulmonary stenosis it is not unusual in infants to find a plateau-shaped pansystolic murmur that may even be best heard at the mid to low left sternal border.[68] Diastolic murmurs are uncommon in the preoperative patient with tetralogy of Fallot. Although aortic regurgitation is of concern in the long-term evaluation of these patients, especially postoperatively, it is unusual during childhood. A to-and-fro murmur of pulmonary stenosis and pulmonary regurgitation is characteristic of the syndrome of tetralogy of Fallot with absent pulmonary valve and is discussed in Chapter 64. Continuous murmurs are also uncommon, but when found suggest the presence of severe tetralogy of Fallot or tetralogy of Fallot with pulmonary atresia and collateral circulation.[68] The presence of a continuous murmur heard only in the left infraclavicular area anteriorly would suggest a patent ductus arteriosus. If a similar murmur is heard to the right of the sternum, this should raise the possibility of an unusual right-sided patent ductus arteriosus or possibly even bilateral ducti. Although this situation is

more commonly seen in patients with complex forms of pulmonary atresia, the presence of this unusual clinical finding warrants careful investigation of systemic to pulmonary communications at the time of cardiac catheterization. The finding of continuous murmurs both anteriorly and posteriorly suggest the presence of systemic to pulmonary collaterals rather than a patent ductus arteriosus. This situation is more commonly encountered in patients with tetralogy of Fallot and pulmonary atresia who characteristically have no other murmur. If an additional ejection murmur is heard at the upper left sternal border, this suggests tetralogy of Fallot with at least some flow across the right ventricular outflow tract.

The physical findings in postoperative patients are dependent upon the presence of residual abnormalities. An ejection systolic murmur may be present at the upper left sternal border with its intensity in proportion to the degree of residual ouflow tract obstruction. When a pulmonary valvectomy or transannular right ventricular ouflow patch was required at the time of operation to relieve severe stenosis, the low-pitched decrescendo early diastolic murmur of pulmonary regurgitation may be found at the mid to low left sternal border. This must be differentiated from the high-pitched decrescendo diastolic murmur of aortic regurgitation that may be seen on longterm follow-up of patients with tetralogy of Fallot. A plateau pansystolic murmur at the low left sternal border is usually produced by a residual ventricular septal defect. This murmur needs to be differentiated from that of tricuspid regurgitation, which can occur as a result of injury to the tricuspid valve at the time of operation. Although these murmurs may be similar, the murmur of tricuspid regurgitation varies with respiration and if the degree of regurgitation is significant, there will be prominent "v waves" in the jugular venous pulses and possibly hepatic pulsations as well. Lastly, this must also be differentiated from mitral valve regurgitation, which is usually heard more laterally. Mitral regurgitation is uncommon but may occur in patients with severe left ventricular dysfunction especially if the dysfunction is due to myocardial infarction that occurred as a result of injury to a coronary artery at the time of operation.

NONINVASIVE STUDIES

Electrocardiogram

Right ventricular hypertrophy on the electrocardiogram is characteristic in patients with tetralogy of Fallot. In the neonate or small infant, right ventricular preponderance is present normally and it may not be until 3 to 4 months of age that one can be certain that the right ventricular hypertrophy on electrocardiogram is abnormal. After this age, right ventricular hypertrophy on the electrocardiogram in a patient with clinical findings suggestive of a ventricular septal defect should alert the physician that tetralogy of Fallot may be present and indicate the necessity for echocardiographic evaluation. In general, right axis deviation is also found and the degree of this axis deviation corresponds to the severity of the right ventricular hypertrophy. Left axis deviation is found in a small percentage of cases and may indicate the presence of an atrioventricular septal defect with tetralogy of Fallot or may be a normal variant.[71] Sometimes the axis may be indeterminate, but with Q waves in leads I and AVL and without Q waves in leads II, III, and AVF. This indicates an initially counterclockwise frontal plane vector loop even though the classic pattern of left axis deviation is not present. It is important to recognize this pattern preoperatively since the shift to postoperative left axis deviation suggests bifascicular block which may represent operative damage to the cardiac conduction system.[72,73] Clearly, the recognition of a disguised form of left axis deviation preoperatively would make it apparent that this postoperative finding represented no change and had little significance.

Arrhythmias are uncommon in patients with tetralogy of Fallot before surgery. Complete AV block has been reported in up to 5% of postoperative patients and usually is an indication for implantation of a permanent pacemaker.[74] It was originally thought that late onset of complete heart block was responsible for the sudden death that occurs on late followup of patients who have had repair of tetralogy of Fallot.[74,75] Over the last decade, it has become increasingly recognized that this sudden death may be caused more commonly by ventricular arrhythmias rather than the late onset of complete heart block.[76,77] Thus, the presence of ventricular ectopy on a routine electrocardiogram indicates the need for further evaluation by stress exercise testing and 24-hour ambulatory electrocardiographic monitoring. The problem of ventricular arrhythmias is discussed further in the section on Late Results.

Radiography

The chest radiograph in older children with tetralogy of Fallot exhibits the classically described "boot shaped" heart or "coeur en sabot" (Fig. 63–7). This is caused by mild enlargement of the right ventricle and concavity of the upper left heart border caused by absence of the main pulmonary artery segment. This is accompanied by decreased pulmonary vascular markings resulting from the reduced pulmonary blood flow. Occasionally, patients with tetralogy of Fallot or, in particular, those with pulmonary atresia may have normal or increased pulmonary vascular markings. This is associated with the presence of systemic to pulmonary collat-

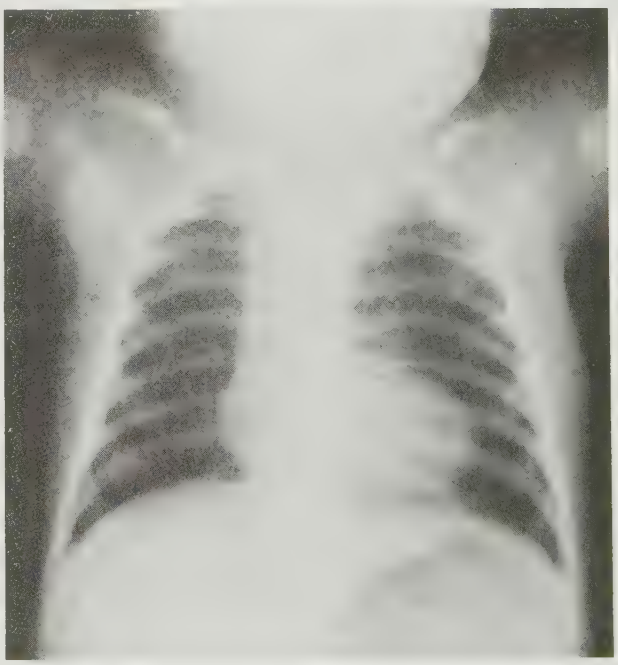

Fig. 63–7. Chest roentgenogram in tetralogy of Fallot.

erals. The combination of normal or increased pulmonary vascular markings and cardiomegaly suggests large collaterals with high pulmonary blood flow and should raise concern about the possibility of pulmonary hypertension in these vessels.

A right aortic arch is found in about one-fourth of patients with tetralogy of Fallot. Although this abnormality has little functional significance, it is extremely important when a systemic to pulmonary artery anastomosis is contemplated. A standard Blalock-Taussig anastomosis is performed on the side opposite the aortic arch, while a modified shunt is performed on the same side as the aortic arch. In addition, although a descending aorta to left pulmonary artery (Potts) anastomosis is rarely performed today, this procedure would be contraindicated if the aortic arch is to the right, since the bronchus will be interposed between the aorta and pulmonary artery.

In patients who have undergone a systemic to pulmonary artery anastomosis, the chest roentgenogram may reflect the hemodynamic effect of this procedure. If the anastomosis is large, increased pulmonary vascular markings are often seen on the side of the anastomosis, the ascending aorta is enlarged and cardiomegaly may be present. In patients who have undergone complete repair, the radiographic appearance is dependent upon the type and degree of residual abnormalities. A normal chest roentgenogram may be found in patients who have not required a transannular outflow patch and who have little or no volume overload from pulmonary insufficiency or a residual ventricular septal defect. Patients with only a mild to moderate degree of residual pulmonary stenosis may usually also have a normal chest roentgenogram. Increased pulmonary vascular markings and cardiomegaly may be found in patients with a residual ventricular septal defect and greater than twice normal pulmonary blood flow. If a transannular right ventricular outflow patch was necessary, pulmonary regurgitation is always present postoperatively. Right ventricular dilatation is usually found and there may be some aneurysmal dilatation of the right ventricular outflow region giving rise to the "box shaped" heart seen on chest roentgenogram in most of these patients. This problem will be discussed further in the section on Surgical Management.

Echocardiography

The anatomic features of the tetralogy of Fallot are generally identifiable echocardiographically. Prior to the availability of two-dimensional echocardiography, M-mode echocardiography revealed several features that were consistent with the diagnosis of the tetralogy of Fallot. On M-mode, a cranial "sweep" from the left ventricular cavity demonstrated discontinuity between the interventricular septum and the anterior wall of the aorta. This is due to the malalignment ventricular septal defect and overriding of the aortic root. Continuity between the anterior leaflet of the mitral valve and the posterior wall of the aorta is also demonstrated[78,79] (Fig. 63–8). These features are not exclusive of the tetralogy of Fallot and can be seen in other conditions with a malalignment ventricular septal defect. It can be very difficult to visualize the pulmonary valve using M-mode echocardiography alone.
